Materials and Methods: C57BL/6J male mice were treated with ENU and upon regaining fertility were mated to C3H/HeH females to produce an F1 population of males that were assayed as part of the dominant phenotype screen. A proportion of these F1 males were backcrossed to C3H/HeH females and then intercrossed with their daughters to produce G3 recessive pedigrees. At 12wks of age mice were tested using an intra-peritoneal glucose tolerance test (IPGTT) to ascertain their ability to respond to a glucose challenge. At 16wks of age, the same cohort of mice were put into metabolic cages for a period of 24hrs to facilitate collection of a 24hr urine sample and a fasted blood sample was also subsequently taken. Biochemical analysis of plasma and urine samples was performed using an Olympus AU400 clinical chemistry analyser. Outliers were identified as individuals with values for a parameter greater than 2 SD from the population mean.

Results: A total of 821 F1 males from the dominant screen and 548 G3 males from 34 recessive pedigrees have been screened using IPGTT and plasma biochemistry at 12 and 16wks of age, respectively; as well as urine biochemistry from 598 F1 males at 16wks of age. Outliers were re-tested to confirm an abnormal test result and a selection of the confirmed outliers were put into inheritance testing. In the dominant screen we have identified 24 outliers with abnormal IPGTT. Nine of these outliers were put into inheritance testing and seven were found to be inherited. Two of these lines (SweetP and Dipdab) are currently being investigated to refine the phenotype data and produce progeny for mapping studies. SweetP mice tested at 12wks of age show fasting hyperglycaemia and elevated glucose levels 2hrs after a glucose challenge. At 16wks of age SweetP mice exhibit fasting hyperinsulinaemia, glycosuria and are significantly heavier than unaffected littermates. Dipdab mice tested at 12wks of age exhibit elevated glucose levels 2hrs after a glucose challenge. At 16wks of age Dipdab mice exhibit fasting hyperinsulinaemia and are significantly heavier than unaffected littermates. In both SweetP and Dipdab lines, females are affected but to a lesser extent than the males. In the recessive screen we have identified 10 pedigrees with abnormal IPGTT phenotypes. Three of these pedigrees (Sugarlump, Bombon and Jazzie) are currently undergoing further investigation to confirm inheritance and refine phenotype data. Initial studies on Suagrlump mice have shown this to be a dominantly inherited phenotype with impaired glucose tolerance, hyperinsulinaemia and glycosuria.

Conclusion: We have identified a number of potentially interesting mouse models with impaired glucose tolerance and possible renal dysfunction using a phenotype driven approach. SweetP, Dipdab and Sugarlump are currently undergoing genome scans to facilitate the mapping and cloning of these mouse models.

Effects of pioglitazone on fuel homeostasis, plasma adiponectin, and p70S6 kinase activity at different stages of the diabetes-like syndrome of the Zucker Diabetic Fatty (ZDF) rat

Z. Szöcs¹, B. Brunmair¹, K. Stadlbauer¹, P. Nowotny¹, L. Bauer², A. Luger¹, C. Fürsinn¹;

¹Department of Medicine III, Division of Endocrinology & Metabolism, Medical University of Vienna, Austria,

²55pharma Drug Discovery & Development AG, Vienna, Austria.

Background and Aims: Clinical studies suggest that the glucose lowering potential of glitazones fades in the course of the progressive development of type 2 diabetes. To analyse the interdependence of disease development and glitazone action, we examined the effects of pioglitazone treatment in ZDF rats being at different stages of their type 2 diabetes-like syndrome.

Materials and Methods: Male obese ZDF rats were subjected to daily oral treatment with 12 mg*kg⁻¹*d⁻¹ pioglitazone at an age of 7, 11, or 16 weeks (referred to as age groups I, II, and III). Blood glucose and body weight were documented weekly, other parameters were measured at the end of the respective treatment period and included blood glucose, fat pad weight, plasma adiponectin, plasma lipids, glycogen stores, and the activity of p70S6 kinase, which is known to impair insulin signalling.

Results: Early intervention with pioglitazone (age group I) completely prevented deterioration of glycaemia as seen in untreated ZDF rats (increase in blood glucose between 7 and 12.5 weeks of age, mmol/l: vehicle, from 6.2±0.4 to 18.7±1.5, p<0.001; pioglitazone, from 6.0±0.3 to 6.5±0.4, ns). The same intervention at an age of 11 weeks (age group II) transiently ameliorated the prevailing hyperglycaemia (after 10 days of treatment: vehicle, 22.1±0.8, vs pioglitazone, 17.8±1.1 mmol/l, p<0.001), but this benefit faded during prolonged treatment (after 31 days: vehicle, 25.1±0.9, vs pioglitazone, 23.5±0.7 mmol/l, ns). In older animals (age group III), pioglitazone lacked any effect on blood glucose (after 10 days of treatment: 22.6±0.6 vs 22.2±1.5 mmol/l, ns). Pioglitazone-induced glucose lowering in age group I was accompanied by reduced plasma triglycerides (715±94 vs 126±5 mg/dl, p<0.001) and reduced p70S6 kinase activity in extensor digitorum longus muscle (% of kinase in phosphorylated state: 32±3 vs 19±3, p<0.02), but these effects were lost together with glucose lowering action in older rats (triglycerides: group II, 269±26 vs 297±26, ns; group III, 349±41 vs 314±38, ns; p70S6 kinase activity: group II, 25±5 vs 25±2, ns; group III, 22±3 vs 20±1, ns). In contrast, pioglitazone actions on weight gain, adiposity, and muscle glycogen persisted independently of metabolic improvement in all age groups. Furthermore, pioglitazone increased plasma adiponectin in all age groups, but this effect was clearly more distinct in group I (plasma adiponectin, mg/l: group I, 4.6±0.4 vs 17.8±0.4; group II, 3.6±0.2 vs 5.0±0.3; group III, 4.1±0.2 vs 7.1±0.6 mg/l; p<0.01 each), suggesting that the increase of adiponectin is in part a primary effect of the glitazone and in part secondary to metabolic improvement.

Conclusion: In line with evidence from the clinic, pioglitazone can prevent hyperglycaemia in ZDF rats, but loses its antidiabetic potential during progressive disease development. Whereas effects on plasma triglycerides and p70S6 kinase activity seem to be coupled to glucose lowering, effects on fat mass, muscle glycogen and, at least in part, plasma adiponectin, are primary effects that occur independently of metabolic improvement.

Astaxanthin transiently improves insulin resistance and affect skeletal muscle Akt signaling in Otsuka Long-Evans Tokushima Fatty rats (OLETF)

H. Kobayashi^{1,2}, H. Naito³, S. Kado¹, D. Ohmori⁴, Y. Iida⁵;

¹Dept of General Medicine, National Defense Medical College Hospital, Tokorozawa, ²Dept of Epidemiology and Environmental health, Juntendo University, Tokyo, ³Dept of Exercise Physiology, Juntendo University, Inba, ⁴Dept of Chemistry, Juntendo University, Inba, ⁵Research and Development Institute, Toyo Koso Kagaku Co.,Ltd, Yachimata, Japan.

Background and Aims: Insulin resistance is a key feature of type 2 diabetes. We hypothesize that supplementation of Astaxanthin, which is a potent Carotenoid antioxidant, in diabetic rats may prevent the onset of type 2 diabetes by antioxidant effects of Astaxanthin on skeletal muscle to restore insulin resistance.

Materials and Methods: Male Otsuka Long-Evans Tokushima Fatty (OLETF) and Long-Evans Tokushima Otsuka (LETO) rats at 5 weeks of age were obtained from the Otsuka Pharmaceutical Tokushima Research Institute and they were assigned to one of three groups: 1)LETO (non-diabetic control, n=32), 2)OLETF control (diabetic control, n=30), and 3)OLETF antioxidant (diabetic antioxidant, n=24). OLETF antioxidant were given to standard rat chow supplemented with 0.2% Astaxanthin daily since 6 weeks of age. Body weight and food intake were measured. Glucose tolerance tests (GTT) were performed by infusing glucose (1mg/kg BW) intraperitoneally under anesthesia at 6, 12, 25 and 52 weeks of age. Blood glucose and insulin level were measured at fasting and 30, 60 and 120 minutes after glucose infusion. Hindlimb muscles (soleus, EDL, plantalis and gastrocnemius muscle) were removed and weighed at 25 and 52 weeks of age. Phosphorylated Akt signaling and carbonylation in hindlimb muscles were analyzed.

Results: There was no significant difference in body weight and food intake between OLETF control and OLETF antioxidant. GTT at 12 weeks shows that blood glucose at fasting in OLETF control were significantly increased, but not in OLETF antioxidant group. GTT at 25 weeks shows that blood glucose at fasting and 30 minutes in OLETF control were significantly increased and insulin level at 30 and 60 minutes were also significantly increased, but not in OLETF antioxidant group (Fig.1). Hindlimb muscles in OLETF control at 25 weeks shows significant decrease of muscle weight and reduction of Akt phosphorylation (Fig.2), but not in OLETF antioxidant group.

Conclusion: Antioxidant supplementation of Astaxanthin for OLETF rats before onset of type 2 diabetes transiently improves insulin resistance and attenuates atrophy and reduction of Akt phosphorylation in hindlimb muscles.

High-fat diet decreases meal-induced insulin sensitivity by impairing hepatic parasympathetic pathway, which is responsible for insulin resistanceR. A. Afonso^{1,2}, W. W. Luttich³, J. Schafer³, D. J. Legare³, M. P. Macedo^{2,4};¹Biochemistry, Faculty Medical Sciences, Lisbon, Portugal,²Physiology, Faculty Medical Sciences, Lisbon, Portugal,³Pharmacology & Therapeutics, Faculty of Medicine, Winnipeg, Canada,⁴Portuguese Diabetes Association, (apdp), Lisbon, Portugal.

Background and Aims: Although the association between obesity and insulin resistance is well documented, the mechanisms involved remain unclear. Meal-induced insulin sensitisation (MIS) depends not only on insulin action per se, but also on hepatic parasympathetic nerve activation (HPN pathway) and glutathione content, which are impaired in several pathological models. We tested the hypothesis that obesity induced by high-fat diet (HFD) leads to the impairment of MIS, accounting for the insulin resistance.

Materials and Methods: Male Sprague Dawley rats were fed either standard diet (STD, n=7), HFD for 1 week (HFD-A, n=6) or HFD for 4 weeks (HFD-B, n=7). All animals were tested in the fed state at the age of 9 weeks. MIS was evaluated by measuring the hepatic glutathione content and by quantification of the HPN pathway-dependent insulin sensitivity. Insulin sensitivity was assessed using the modified euglycemic clamp RIST (Rapid Insulin Sensitivity Test, mg glucose/kg bw), in which glucose was given as a variable infusion (iv) in order to maintain euglycemia, after administration of a bolus of insulin (50mU/kg, iv). Insulin sensitivity was measured before (control RIST) and after HPN pathway blockade (post-atropine RIST, 1 mg/kg, iv). HPN-dependent component of insulin action was determined by subtraction of the post-atropine from the control RIST. Whole-body fat mass was estimated by tetrapolar bioelectric impedance analysis and visceral fat (sum of perinephric, epididymal and perienteric fat pads) was collected and weighed, at the end of the experiment.

Results: Hepatic glutathione levels were similar in all groups (STD, 6.2±0.2 μmol/g; HFD-A, 5.5±0.2 μmol/g; HFD-B, 5.4±0.3 μmol/g; non-significant). Insulin sensitivity decreased from the STD (189.2±5.3 mg glucose/kg bw) to the HFD-A animals (111.0±4.1 mg glucose/kg; *p*<0.001); the decrease in insulin sensitivity was further aggravated in the HFD-B rats (69.3±2.6 mg glucose/kg bw; *p*<0.001 vs STD and HFD-A). The HPN-dependent insulin action was also impaired by HFD (STD, 113.3±3.7 mg glucose/kg bw; HFD-A, 43.3±5.2 mg glucose/kg bw; HFD-B, 5.4±1.7 mg glucose/kg bw; *p*<0.001 between all groups), whereas the HPN-independent component (post-atropine RIST) was not affected by the diet. Both whole-body and visceral fat masses correlated negatively with total insulin action (control RIST, *r*²=0.82 and *r*²=0.85, respectively) and with HPN-dependent insulin action (*r*²=0.81 and *r*²=0.82, respectively).

Conclusion: Our results suggest that HFD-induced obesity affects the MIS by impairing the HPN pathway specifically, since it affected neither hepatic glutathione content nor insulin action per se. Thus, the HPN-pathway impairment seems to be responsible for the insulin resistance observed in the obese animals. Furthermore, the increase in fat content induced by HFD correlates with the HPN-dependent insulin action impairment and consequently with the overall insulin resistance.

Inverse relationship between triglycerides accumulation and glutathione production in the liver in nonobese and obese models of insulin resistance

O. Oliyarnyk, H. Malinska, M. Buresova, L. Kazdova;

Department of Metabolism and Diabetes, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Background and Aims: Excessive hepatic accumulation of triglycerides (Tg) is one of metabolic disorders in insulin resistance syndrome, contributing to increased production and secretion of VLDL, glucose, C-reactive protein and fibrinogen. These factors aggravate the risk of diabetes and non-alcoholic fatty liver disease but knowledge about mechanisms are still missing. Some studies suggested that oxidative stress, obesity and advancing age

might be involved. In this study we therefore investigated the relationship between Tg accumulation and glutathione (GSH) production in liver in an experimental model of insulin resistance – in old nonobese hereditary hypertriglyceridemic rats (HHTg) and in HHTg rats render obese by long term feeding with high sucrose diet (HHTg-OB). The liver is the main site of GSH synthesis from where GSH is transported to other tissues. GSH is not only the main intracellular antioxidant, but can affect prostaglandins synthesis, transmembrane transport of amino acids, gene expression and cytokine production.

Materials and Methods: The experiments were carried out in one year old male a) nonobese HHTg fed a standard laboratory chow and b) in HHTg rats with nutritional induced obesity by feeding with high carbohydrate diet (HS; 70% of sucrose) for 6 months (HHTg-OB). As a control group we used one year old Wistar rats (C). Liver Tg were measured by enzymatic assay (Pliva-Lachema, Brno, Czech Republic). GSH concentration and GSH-Px activity were determined spectrophotometrically by using Sigma assay kits.

Results: The body weight (HHTg: 380±12g; HHTg-OB: 531±34g; C: 481±24g) and epididymal fat pad weight of HHTg rats fed the HS diet for six months were significantly higher than those of HHTg rats fed the standard diet (Table). Compared with controls, the HHTg rats exhibited elevated serum Tg concentration. The liver Tg content was higher in HHTg rats and was increased more than twofold in diet induced obesity.

Liver Tg accumulation was associated with declined GSH level. A negative linear correlation between liver Tg and GSH concentrations was observed (*R* = -0.77, *p* < 0.001). We found reduced GSH-Px activity in the liver of obese and non-obese models of insulin resistance might be due to lower enzymes cofactor GSH concentration.

Conclusions: Our results suggest the association between liver Tg accumulation and decreased GSH production, which has an important function in antioxidant system, prostaglandin synthesis, and in the regulation of mitochondrial function and integrity. Elevated Tg accumulation in liver can contribute to decreased GSH transport to other tissues and so be involved in oxidative stress and its negative implications in insulin resistance and fatty acid liver disease.

	Wistar	Nonobese HHTg	Obese HHTg

Enhanced insulin action following subcutaneous co-administration of insulin and C-peptideY. Sato¹, O. Khookhor¹, M. Kubota², M. Nagasaki¹, T. Uno¹, K. Ekberg³, J. Wahren³;¹Department of Health Science, Aichi Gakuin University, Nisshin,Japan, ²Department of Health Science, Kyoto University, Kyoto, Japan,³Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and Aims: Recent in vitro observations demonstrate that C-peptide may interact with insulin, causing hexameric insulin to disaggregate into its biologically active monomeric form. Using the glucose clamp technique, we have evaluated the in vivo effect of C-peptide on whole body glucose utilization following s.c. co-administration of the two peptides in rats.

Material and Methods: Male Wistar rats (age 6 weeks, 145–165 g) were randomly divided into eight different treatment groups (*n*=7 per group). Either regular insulin (I) (1.2 U/kg Humulin, Eli Lilly) or an insulin analogue (IA) (1.2 U/kg Humalog, Eli Lilly) were injected s.c. as a physical mixture or separately into two depots with either 29 nmol/kg C-

peptide (C) or its C-terminal pentapeptide (P) (29 nmol / kg). The latter is known to exert effects similar to those of the full-length peptide. Rats were awake and allowed to move freely within a large cage throughout the study. During baseline (~60 min) the blood ambient glycemic level was established and subsequently clamped ± 0.3 mM throughout the experiment by frequent glucose monitoring and administration of a variable i.v. glucose infusion (GIR).

Results: Injection of a mixture of C+I resulted in a 30% greater amount of glucose being required ($p<0.01$) and a glucose infusion of longer duration (+13%, $p<0.05$) compared to when I and C were injected into separate depots. Likewise, after s.c. injection of a mixture of P+I, the amount of glucose infused was 54% greater ($p<0.01$) and the duration of the glucose infusion was longer (+27%, $p<0.001$) compared to the corresponding data after separate injections of P and I. Plasma concentrations of insulin were not significantly different after co-injection of C+I or P+I compared to subsequent separate injection of the peptides. Co-administration of either C+IA or P+IA into the same s.c. depot did not result in requirements of increased glucose infusion or prolonged infusion time compared to when the peptides were injected separately, possibly as a consequence of spontaneous disaggregation of the insulin analogue.

Conclusion: We conclude that co-administration of insulin plus C-peptide or its C-terminal pentapeptide causes enhanced insulin action, which may be attributed to augmented disaggregation of insulin hexamers into their active monomeric form.

PS 51 Metabolism: children

The decrease in insulin sensitivity is associated to the increase in blood pressure and post load glucose levels in prepubertal obese children

C. Invitti, L. Gilardini, A. Girola, L. Pasqualinotto, M. Croci;
Unit of Metabolic Diseases and Diabetes, Istituto Auxologico Italiano,
Milan, Italy.

Background and Aims: It is unclear to what the decrease in insulin sensitivity (IS) is associated before puberty. We examined the associations between different indexes of IS and cardiovascular and metabolic risk factors in prepubertal obese children.

Materials and Methods: 173 obese children at Tanner I stage (10 ± 1.9 yr, BMI 30.4 ± 4.8 kg/m², standard deviation score-BMI (SDS-BMI) 3.8 ± 0.8 , waist circumference 91.8 ± 10.8 cm) underwent an OGTT and a bioelectrical impedance. Insulin sensitivity was estimated using HOMA-IR (homeostasis model assessment), QUICKI (quantitative insulin sensitivity check index), ISI Comp (composite whole body insulin sensitivity index) and OGIS (oral glucose insulin sensitivity index). Metabolic syndrome (MS) was defined using the National Cholesterol Education Program's Adult Treatment Panel III (ATPIII) criteria modified for children (using age and sex specific cut-off derived from a group of normal weight children to define abnormal waist, lipids and BP levels).

Results: 3/173 had IGT, 1/173 IFG and 7.3% the MS. In the logistic regression analysis, dyslipidemia, hyperglycaemia, hypertension, and central obesity explained 41.2%, 6%, 1.5% and 0.8% respectively of the MS. None of the indexes of IS was significantly correlated with waist and fat mass. Among the indexes of IS, HOMA-IR was that associated with the highest risk of having MS [OR for unit increase in HOMA-IR 1.36 (1.02–1.81), $p<0.05$; OR for unit increase in QUICKI 1.33 (1.03–1.71), $p<0.05$; OR for unit increase in OGIS 1.01 (1.00–1.02), $p<0.05$; OR for increase in ISI Comp NS]. The Receiver Operating Characteristic analysis evidenced that the best cut off in identifying MS was HOMA-IR ≥ 2.7 (sensitivity 58.3% and specificity 68.6%). The increase in HOMA-IR was associated to an increased risk of hypertension [OR 1.41 (CI 1.01–1.22), $p<0.05$] and of increase in post load glycaemia [OR 1.35 (CI 1.01–1.62), $p<0.05$] but not of dyslipidemia and high waist circumference. This differs from what was observed in a group of 724 pubertal children in whom the increase in HOMA-IR was significantly associated to the risk of having each of the components of MS [OR 2.2 (1.2–4.1), 1.2 (1.1–1.3), 1.1 (1.0–1.2) and 1.1 (1.0–1.2) for high waist, high triglycerides, low HDL-cholesterol and high BP respectively, $p<0.0001$ for all].

Conclusion: In prepubertal obese children, the decrease in IS is associated to BP and post load glycaemia increase, but not to dyslipidemia and central distribution of fat, as observed after puberty.

0645

Relationship between leptin level and insulin resistance in children and adolescents with type 1 diabetes

A. Szadkowska, K. Wyka, W. Młynarski, I. Pietrzak, B. Mianowska,
J. Bodalski;
Department of Children Diseases, Institute of Pediatrics, Lodz, Poland.

Background and Aims: The aim of this study was to evaluate a relationship between leptin level and insulin resistance and components of metabolic syndrome in children and adolescents with type 1 diabetes.

Materials and Methods: 158 patients with type 1 diabetes mellitus (70 girls and 80 boys) aged from 8.2 to 18.4 years (mean \pm SD: 14.1 ± 3.1 years) were included into the study. The diabetes duration ranged from 1.6 to 14.7 years (3.8 ± 2.5 years). The height, weight, waist circumference (WC), skin folds and blood pressure were measured. Body mass index (BMI-SDS), body fat (BF) according to Slaughter formula, and daily dose of insulin were calculated. HbA1c (HPLC) and serum lipids (enzymatic method) concentrations were examined. Serum leptin concentration was measured by ELISA method. Euglycemic-hyperinsulinemic clamp by de Fronzo was performed to estimate insulin resistance. Glucose disposal rate (M value) determined during the last 30 min of the test was calculated as a surrogate of insulin resistance.

Results: Serum leptin levels ranged from 1.47 to 57.39 ng/ml (8.25 ± 8.27 ng/ml). M values were between 2.10–15.19 mg/kg/min (7.33 ± 2.4 mg/kg/

min). Leptin level positively correlated with BMI-SDS, WC, skin folds and BF. Leptin level, normalized to BMI-SDS or BF, was significantly higher in females than males at Tanner stages IV ($p=0.04$) and V ($p<0.001$), but not at earlier stages of pubertal development. Moreover, a negative correlation between leptin level and M value ($r=-0.26$; $p=0.001$ adjusted to sex and puberty) was found. However, after adjustment for BF or BMI-SDS this relationship became insignificant. No association between leptin level and HDL-cholesterol, SBP and DBP was also noted. Using the multivariate linear regression models, we found that plasma leptin level remained significantly associated with triglycerides.

Conclusion: It is likely that the observed relationship between leptin concentration and insulin resistance in young patients with type 1 diabetes is due to body fat composition rather than an independent association in this group.

Analysis of adiponectin, leptin, TNF- α levels in children and adolescents with type 1 diabetes

O. Sysoyeva¹, T. Mokhort², N. Karlovich¹;

¹Endocrinology, State Centre of Medical Rehabilitation,

²Endocrinology, Belarusian State Medical University, Minsk, Belarus.

Background and Aims: Adiponectin and leptin are adipocytokines secreted by adipose tissue. Adiponectin has important insulin-sensitizing, anti-inflammatory and cardioprotective properties. Adiponectin expression is regulated by TNF- α , which is also involved in metabolism of adipose tissue and glucose homeostasis. Leptin plays a crucial role in the regulation of food intake and metabolism. Adipocytokines play an important role in obesity and type 2 diabetes, but little is known about their role in type 1 diabetes (T1D). The aim of our research was to assess adiponectin, leptin, TNF- α levels in T1D children and lean non-diabetic controls.

Material and Method: The study group included 56 patients. There were 34 patients with T1D and 22 lean non-diabetic persons (control group), age and sex matched. Serum levels of adiponectin, leptin and TNF- α in both groups were measured by ELISA.

Results: Leptin levels in T1D patients (2.8 ng/ml [0.8; 8.1]) were higher than in the control group (1.8 ng/ml [0.3; 2.5]), $p=0.027$, while adiponectin levels were practically the same (21.1 mcg/ml [14.9; 26.1] and 22.1 [18.8; 26.0] respectively). Adiponectin to leptin ratio was lower in T1D patients (6.6 [3.1; 22.1]) compared to lean non-diabetic controls (11.6 [10.0; 55.9]). Difference between T1D patients and controls was significant ($p=0.032$). In T1D patients significant correlation of adiponectin and weight ($r=-0.35$; $p=0.039$) was found; adiponectin and adiponectin to leptin ratio negatively correlated with BMI ($r=-0.37$; $p=0.032$, $r=-0.35$; $p=0.049$ respectively). No significant difference in TNF- α levels between patients with T1D (2.63 pg/ml [1.64; 4.22]) and the control group (2.98 pg/ml [1.84; 3.98]) was observed. In the control group TNF- α correlated with the patients' age ($r=-0.64$; $p=0.001$), as well as weight ($r=-0.44$; $p=0.039$), while in T1D patients similar correlations were not found.

Conclusion: There was no impairment of adiponectin and TNF- α secretion in T1D patients. The leptin level was significantly higher compared to controls, while the adiponectin to leptin ratio was lower. Further investigation is required to study the influence of leptin on sensitivity to exogenous insulin in patients with T1D. As age and weight increase, TNF- α level decreases in healthy patients, while in T1D patients no such correlation was revealed.

0647

Opposing association of adiponectin and TNF-alpha versus IL-6 with clinical remission and glucose utilization in children with newly diagnosed type 1 diabetes mellitus

C. Pflieger¹, H. B. Mortensen², P. Hougaard³, L. Hansen⁴, H. Kolb¹, N. C. Schloot¹; the Hvidoere Study Group,

¹Clinical Diabetes Research, German Diabetes Center, Düsseldorf, Germany,

²Department of Paediatrics, Glostrup University Hospital, Glostrup,

Denmark, ³Statistical Department, University of Southern Denmark,

Odense, Denmark, ⁴Novo Nordisk A/S, Bagsvaerd, Denmark.

Background and Aims: Adiponectin, IL-6 and TNF-alpha have been shown to modulate glucose utilisation in experimental models. The aim of the

current study was to investigate whether circulating levels of adiponectin, IL-6 or TNF-alpha are associated with parameters of glucose metabolism in children with newly diagnosed type 1 diabetes (T1D) and during follow-up.

Material and Methods: Serum was obtained from 256 newly diagnosed children with type 1 diabetes (122 males/ 134 females, aged 9.6 years, range 0.2–16.8 years) one, six, and twelve months after diagnosis. Serum cytokines were measured by double sandwich ELISA and multiplex technology. Blood glucose was determined in the fasting state and 90 min after ingestion of a standard liquid mixed meal. We used a very strict definition of remission as HbA1c < 6.5 and insulin requirements < 0.5 U/kg/day. The difference of stimulated and fasting blood glucose levels reflecting glucose utilization was defined as delta blood glucose (dbg). For group comparison data were analysed by non parametric Wilcoxon test, for associations by multiple regression analyses adjusted for gender, age and BMI, adiponectin, IL-6, TNF-alpha.

Results: Adiponectin was positively associated with dbg at six ($p=0.03$) months whereas IL-6 was negatively associated with dbg at six ($p=0.0389$) and twelve ($p=0.047$) months. Adiponectin was the only cytokine showing associations (positive) with HbA1c at one ($p<0.0001$), six ($p=0.007$) and twelve ($p=0.002$) months. In support of these findings, children in clinical remission exhibited significantly different cytokine/adipokine levels than children not in remission. Adiponectin serum concentrations were lower at one ($p=0.006$), six ($p=0.0005$) and twelve ($p=0.0004$) months after diagnosis; IL-6 concentrations were higher after twelve months ($p=0.049$), and TNF-alpha concentrations were lower after one ($p=0.012$), six ($p=0.016$) and twelve ($p=0.013$) months.

Conclusion: IL-6 and TNF-alpha concentrations show opposing associations with clinical remission, with IL-6 concentrations being positively associated with better metabolic control and negatively with dbg. Our findings of increased adiponectin in T1D non-remitters, which also might be an age effect, seem to be in contrast to reduced adiponectin concentrations observed in T2D. One explanation would be that due to overnutrition of cells in T2D cells secrete less adiponectin. This would be in contrast to T1D where cells in bad metabolic control have a deficiency in energy and secrete increased amounts of adiponectin to compensate for energy homeostasis. Therefore adiponectin and IL-6 could serve as marker for metabolic control, glucose utilization, and disease progression.

Inflammation, obesity and insulin resistance in adolescents

C. Herder¹, S. Schneitler¹, W. Rathmann², B. Haastert², H. Schneitler³, H. Winkler³, R. Bredahl³, E. Hahloser³, S. Martin¹;

¹Institute for Clinical Diabetes Research,

²Institute of Biometrics and Epidemiology, German Diabetes Centre,

³Gesundheitsamt, Public Health Office, Duesseldorf, Germany.

Background and Aims: Subclinical inflammation is a characteristic feature of obesity, insulin resistance and type 2 diabetes in adults, but comparable data for youths are very limited. Therefore, it was the aim of this study to investigate the relationship between immune activation, indices of obesity and of insulin resistance in adolescents and to analyse whether the association between inflammation and insulin resistance is mainly explained by, or independent of, obesity.

Materials and Methods: In Düsseldorf (Germany), all school-leaving students from selected secondary schools are routinely invited to a medical check-up in their final year by the local Public Health Service. In 2005, we conducted a cross-sectional survey in 519 adolescents (293 boys, 226 girls) with a mean age of 15.5 years. We measured serum levels of cytokines, chemokines and adipokines that are related with obesity, insulin resistance and risk for type 2 diabetes in adults: interleukin (IL)-6, IL-18, tumour necrosis factor (TNF)- α , monocyte chemoattractant protein (MCP)-1, IL-8, interferon- γ -inducible protein (IP)-10 and adiponectin. We investigated the association between these novel biomarkers and body mass index (BMI), waist circumference (WC), fasting glucose, fasting insulin and insulin resistance (HOMA-IR).

Results: In age and sex-adjusted linear regression analyses, IL-6, IL-18, IP-10 and adiponectin (inversely) were significantly associated with both BMI and WC ($p\leq 0.001$ for all associations). None of the tested immune markers was related with fasting plasma glucose levels, but there were significant associations between IL-6, IL-18, IP-10 and adiponectin (inversely) with insulin and/or HOMA-IR. Most of these associations were considerably

attenuated when BMI or WC were added to the model, whereas associations between TNF- α and MCP-1 with HOMA-IR appeared more pronounced. Adjustment for age, sex and BMI or age, sex and WC indicated that IL-6, TNF- α and MCP-1 may be related with HOMA-IR (p between 0.03 and 0.08) independently of obesity.

Conclusion: We found a differential immune activation that is associated with parameters of obesity and insulin resistance in adolescents. Moreover, there is evidence that IL-6, TNF- α and MCP-1 may be associated with insulin resistance independently of BMI or WC and may represent novel inflammatory risk factors for the development of type 2 diabetes in youths. It remains to be shown in prospective studies whether or not inflammation plays a similar role in the pathogenesis of type 2 diabetes in youths as in adults.

Changes in circulating levels of leptin and soluble leptin receptor during OGTT in overweight/obese postmenopausal women

E. Kassi, G. Hroussalas, I. Delimaris, M. Dalamaga, K. Kazanis, A. Zachari, A. Dionyssiou-Asteriou;
Dept of Biological Chemistry and Dept of Clinical Biochemistry, University of Athens, Medical School, Greece.

Background and Aims: Adipose tissue plays a pivotal role in glucose homeostasis and insulin resistance by secreting adipokines. In overweight/obese postmenopausal women with normal glucose metabolism (NGT) and with impaired glucose tolerance (IGT) we assessed serum leptin and the soluble leptin receptor (sOB-R) levels during OGTT in order to investigate their response to acute changes in glucose and insulin in the abnormal glucose metabolism, as it is detected early by IGT.

Materials and Methods: In total, thirty overweight/obese postmenopausal women were included; fifteen with normal glucose metabolism (NGT), age 48–69 years, BMI 28–32, waist circumference 82–104 cm and fifteen with impaired glucose tolerance (IGT), age 53–69 years, BMI 29–40, waist circumference 87–115 cm. OGTT with 75gr was performed in the morning. Leptin and sOB-R were evaluated by ELISA at time 0–60–120 min of OGTT. Serum glucose and insulin were measured in an automated analyzer (Roche Diagnostics). Insulin resistance(HOMA)/sensitivity(QUICKI) indexes were also calculated.

Results: In fasting state: leptin and sOB-R did not differ between the two groups. In subjects with NGT leptin was positively correlated with BMI ($p=0.022$), insulin ($p=0.021$) and HOMA ($p=0.029$) and negatively correlated with sOB-R ($p=0.04$) and QUICKI ($p=0.05$). sOB-R was negatively correlated with HOMA ($p=0.032$) and positively correlated with QUICKI ($p=0.030$). A negative correlation between insulin fasting levels and sOB-R in both NGT ($p=0.003$) and IGT ($p=0.020$) group was also observed. During OGTT: in both groups there was an overall significant increase in serum leptin between 0 and 120 min, in subjects with normal OGTT from 44.4 ± 41 to 51.4 ± 45 ng/ml, ($p=0.007$) and in subjects with impaired OGTT from 71.4 ± 42 to 87 ± 49 ng/ml, ($p=0.001$). There was no change in sOB-R levels. The difference in serum leptin levels between two groups at 120min was significant ($p=0.042$).

Conclusion: The abnormal glucose metabolism as it is detected early by IGT is not accompanied by a disturbance in the basal secretion (baseline time in OGTT) of leptin and sOB-R. Leptin secretion is acutely regulated by insulin and glucose levels. Insulin seems to regulate leptin action via regulating the sOB-R levels. In the NGT group, there is an autoregulatory mechanism of leptin action through its receptor (sOB-R). The relationship between leptin and insulin or insulin resistance/sensitivity indexes in women with normal OGTT is not sustained in IGT women raising the hypothesis that a disruption of the normal communication between beta-cell and adipocyte has already occurred at this early stage of abnormal glucose metabolism.

TNF-alpha induces a marked proinflammatory phenotype in undifferentiated human preadipocytes

P. Isakson, A. Hammarstedt, U. Smith;

Department of Molecular and Clinical Medicine, Center of Excellence for Cardiovascular and Metabolic Research, Göteborg, Sweden.

Background and Aims: The adipose tissue is important for storage and release of lipids. However, in recent years, it has been shown that the adipose tissue also is an endocrine and secretory organ. It releases a wide range of important adipokines like adiponectin, leptin and retinol-binding protein-4 (RBP-4) as well as cytokines such as interleukin-6 (IL6) and monocyte chemo-attractant protein-1 (MCP-1) that are related to the innate inflammatory response and inflammation. Furthermore, the adipokines crosstalk with other tissues of the body and modulate insulin sensitivity and action. The adipose tissue becomes inflamed during obesity with cells expressing markers of macrophages. It has also been described that the low-grade inflammation, with elevated levels of the acute phase-reactants CRP and serum Amyloid A, is associated with insulin resistance type 2 diabetes as well as risk of cardiovascular disease. We

have examined if primary preadipocytes from the stromal vascular fraction of human adipose tissue are responsive to proinflammatory cytokines, in particular TNF- α , since this potent cytokine is released by infiltrating macrophages.

Materials and Methods: Abdominal subcutaneous adipose tissue was obtained from 11 different donors by needle biopsy. From the biopsy, the stromal vascular fraction was retrieved following collagenase digestion and removal of the primary adipocytes. The inflammatory cells were also removed by magnetic bead elution of CD 14 and CD 45 positive cells. The remaining part of the fraction was seeded and grown in six-well plates. The cells were either left untreated or grown in the presence of TNF- α (5ng/mL), IL-6 (20ng/mL) or resistin (50ng/mL) for 10 days. RNA was extracted and the gene expression was analyzed with real-time RT-PCR (Taqman). Protein secretion to the cell culture supernatant was analyzed with an enzyme-linked immunosorbent assay.

Results: The undifferentiated preadipocytes expressed various inflammatory cytokines as well as some macrophage related genes in the non-stimulated state. However, the secretion and gene expression of IL-6, IL-8 and MCP-1 was markedly and significantly increased by the addition of TNF- α . Interestingly, CCR-2, the receptor for MCP-1, was expressed at extremely low levels in human preadipocytes indicating that these cells produce MCP-1, as well as other cytokines, but they are not major target cells for MCP-1. Moreover, TNF- α also induced the expression of several genes known to be highly expressed in macrophages such as CD68, TLR2, GM-CSF, F4/80 and MIP-1a.

Conclusion: Our data show that TNF α , which is released by macrophages, leads to a marked inflammatory phenotype in human undifferentiated preadipocytes. This is also associated with high secretion of MCP-1, IL-6 and IL-8. Furthermore, our data also show that TNF α induces macrophage-specific genes in these cells. Thus, cells expressing CD68, F4/80, MIP-1a in the adipose tissue may not be infiltrating macrophages but may emanate from activated preadipocytes.

Evaluation of the D299G and T399I polymorphisms of toll-like receptor 4 on tumor necrosis factor (TNF)- α , TNF receptor 2 levels and insulin resistance

A. Jermendy¹, A. Korner¹, M. Kovacs², E. Kaszas³, J. Balazs³, A. Szocs³, L. Madacsy¹, K. Cseh³;

¹1st Department of Paediatrics, Semmelweis University,

²3rd Department of Medicine, Semmelweis University,

³1st Department of Medicine, Karolyi Sandor Hospital, Budapest, Hungary.

Background and Aims: The expression of Toll-Like Receptor 4 (TLR4) has recently been shown in adipose tissue. The hypomorphic mutations D299G and T399I of TLR4 may influence the cytokine secretion from adipocytes. The aim of our study was to compare Tumor Necrosis Factor (TNF)- α , soluble TNF Receptor 1 (sTNFR1), soluble TNF Receptor 2 (sTNFR2) levels in obese children, adults and control subjects. The association between allelic polymorphisms of TLR4 and cytokine levels as well as indirect parameters of insulin resistance was assessed.

Materials and Methods: The D299G and T399I allelic polymorphisms of TLR4 were determined with PCR-RFLP technique in 79 obese children (OCh group, age: 13.1 \pm 2.9 years; $x\pm$ SD; BMI: 31.1 \pm 5.4 kg/m²), 171 obese adult patients (OAd group, age: 57.2 \pm 11.2 years; BMI: 28.8 \pm 4.1 kg/m²). As for controls, age and sex matched 169 non-obese adult subjects (NOAd group) and 42 non-obese children (NOCh group) were investigated. Serum TNF- α , sTNFR1, sTNFR2 levels, plasma insulin levels were measured by ELISA (Biosource).

Results: In OCh group, TNF- α (5.5 \pm 0.9 pg/ml) and sTNFR2 (4.3 \pm 1.1 ng/ml) levels were significantly ($p<0.01$) higher compared to those in NOCh group (TNF- α : 3.9 \pm 0.7 pg/ml; sTNFR2: 0.5 \pm 0.3 ng/ml, respectively). Cytokine levels in the OCh group differed significantly ($p<0.01$) from those in OAd group (TNF- α : 6.1 \pm 1.7 pg/ml; sTNFR2: 6.7 \pm 1.9 ng/ml). However no significant difference was found between the two groups regarding the ratio of sTNFR2/sTNFR1 (OCh group: 2.4 \pm 0.7; OAd group: 2.6 \pm 1.0). Significant ($p<0.05$) positive linear correlations were observed between TNF- α , sTNFR2 levels, BMI and insulin resistance measured by HOMA-index. Allelic frequencies of D299G and T399I of TLR4 tended to be lower

in children as compared to control subjects (OCh group: 299G 3.79%; 399I 3.79%, versus NOAd group: 299G 5.0%; 399I 4.5%). In OAd group, the frequencies of the mutant alleles were 4.3% and 3.8%, respectively. Analysing obese groups (OCh and OAd groups), patients carrying the mutant alleles of TLR4 (299G and 399I) had lower values of cytokines levels and HOMA indices when compared to those patients carrying wild type alleles (299D and 399T) (OCh group: TNF- α 4.4 \pm 0.7 pg/ml versus 5.5 \pm 0.9 pg/ml; sTNFR2 2.9 \pm 1.2 ng/ml versus 4.4 \pm 1.1 ng/ml; HOMA-indices 1.1 \pm 0.9 versus 2.6 \pm 2.3; OAd group: TNF- α 5.0 \pm 1.2 pg/ml versus 6.2 \pm 1.7 pg/ml; sTNFR2 6.9 \pm 1.3 ng/ml versus 7.4 \pm 2.6 ng/ml; HOMA-indices 3.5 \pm 1.3 vs. 5.8 \pm 3.5).

Conclusion: Elevated TNF- α and sTNFR2 levels may contribute to insulin resistance in obese children similarly to adults. In obesity, cytokine concentrations and insulin resistance might be influenced by TLR4 allelic polymorphisms both in children and adult subjects.

Role of interleukin-6 in hepatic glucose production

L. Immel, H. Runge, R. Lehmann, H.-U. Häring, E. Schleicher, C. Weigert; Department of Internal Medicine IV, University Hospital Tuebingen, Germany.

Background and Aims: Besides its function in inflammatory processes IL-6 is a potent player in metabolism. It is known to regulate insulin action and to stimulate lipolysis. The aim of our work is to elucidate the function of IL-6 in gluconeogenesis in hepatocytes.

Materials and Methods: All experiments were conducted in Fao rat hepatoma cells (Fao). Cells were starved overnight in a serum and glucose free medium containing 2 mM lactate. On the following day cells were stimulated with various substances in a glucose- and serum-free medium containing 5 or 10 mM lactate. After indicated timepoints supernatant, protein and RNA was collected for subsequent analyses.

Results: Fao cells produced glucose when lactate as substrate was provided. Increasing insulin concentrations (0.1 – 100 nM) reduced the glucose production gradually, while the rate of glucose production was increased by 67% and 40 % under stimulation with dexamethasone and IL-6, respectively. Furthermore we found that IL-6 counteracts the insulin action on gluconeogenesis. After the overnight starvation in glucose-free medium no glucose production derived from glycogenolysis was detectable. Studying the putative underlying mechanism, we observed that IL-6 did slightly reduce insulin-induced Foxo-1 phosphorylation with no inhibitory effect on phosphorylation of Ser-473 of Akt. However, IL-6 did not abolish the inhibitory action of insulin on the expression of the gluconeogenic enzymes PEPCK and Glucose-6-phosphatase.

Conclusion: IL-6 is able to induce glucose production in Fao cells and to counteract the inhibitory action of insulin. This effect is not mediated by altered expression of gluconeogenic enzymes.

Dual role of interleukin-6 in regulating insulin sensitivity in murine skeletal muscle cells

M. Lorenzo, S. Fernandez-Veledo, C. De Alvaro, R. Vila, L. Garcia-Guerra, I. Nieto-Vazquez; Bioquímica y Biología Molecular II, Universidad Complutense, Madrid, Spain.

Background and Aims: Over the last decade it has been demonstrated that cytokines are elevated in various insulin-resistant states including type 2 diabetes and obesity. However, the role of the pro-inflammatory cytokine IL-6 in the induction of these diseases is controversial.

Materials and Methods: In this study we analyzed the impact of IL-6 on insulin action in murine skeletal muscle cell lines wild-type and PTP1B-deficient, and primary myotubes, by studying glucose transport and insulin signaling after different exposure time to IL-6.

Results: A dual effect was observed when cells were exposed to this cytokine. IL-6 *per se* increases glucose uptake by activating the AMPK pathway, and

whereas short-term IL-6 treatment had an additive effect on insulin-stimulated glucose uptake, chronic exposure produced insulin resistance. This effect was correlated with impaired GLUT4 translocation to the plasma membrane and defects in insulin signaling at the level of IRS-1 and AKT. Because this cytokine activated stress kinases, we explored whether the sustained activation of this pathways could mediate insulin resistance. This study demonstrated that pretreatment with SP600125, inhibitor of JNK, restored insulin signaling and normalized insulin-induced glucose uptake in the presence of IL-6. Moreover, treatment of muscle cells with IL-6 significantly increased PTP1B activity. Accordingly, PTP1B-deficient myocytes were protected against insulin resistance by IL-6. Finally, we evaluated the potential role of nuclear receptor activation in alleviating insulin resistance. In this way, GW3965, a synthetic LXR agonist, restored insulin action by down-regulating PTP1B activation induced by IL-6.

Conclusion: These findings indicate the important role of IL-6 in the pathogenesis of insulin resistance and further implicate PTP1B as a potential therapeutic target in the treatment of type 2 diabetes.

Visceral obesity and plasma glucose-insulin homeostasis: contributions of IL-6 and TNF- α

A. Cartier¹, I. Lemieux¹, N. Almeras¹, A. Tremblay², J. Bergeron³, J.-P. Despres¹;

¹Quebec Heart Institute, Hopital Laval Research Centre, ²Department of Social and Preventive Medicine, division of kinesiology, Universite Laval, ³Lipid Research Centre, CHUL Research Centre, Quebec, Canada.

Background and Aims: It is well known that abdominal obesity, especially excess visceral adiposity, is associated with metabolic alterations which include an inflammatory profile. It has been recently suggested that overexpression of proinflammatory molecules such as tumor necrosis factor (TNF)- α and interleukin (IL)-6 by adipose tissue in the context of visceral obesity could be due to macrophage infiltration. Many studies have also demonstrated that TNF- α and IL-6 is strongly linked to the insulin resistance state of abdominal obesity. The aim of the present study was to quantify the associations of these inflammatory markers with specific adipose tissue depots assessed by computed tomography as well as with several total adiposity variables. We were therefore interested to test the potentially additive contribution of TNF- α and IL-6 to the variation in indices of plasma glucose-insulin homeostasis and their respective contributions to plasma glucose-insulin homeostasis beyond visceral adiposity.

Materials and Methods: Plasma levels of IL-6 and TNF- α were measured in a sample of 189 untreated asymptomatic men covering a wide range of adiposity values (age: 43.7 \pm 7.8 years; body mass index (BMI): 29.0 \pm 4.3 kg/m²; waist girth: 98.6 \pm 10.3 cm). Weight, height and waist girth were measured whereas cross-sectional areas of abdominal adipose tissue were assessed at L4-L5 by computed tomography. Fasting blood samples were collected to determine a complete lipoprotein-lipid profile and a 75g oral glucose tolerance test was performed.

Results: Significant and positive associations were found between both cytokines, IL-6 and TNF- α , with total adiposity and adipose tissue distribution indices (0.15 \leq r < 0.32; p<0.05) as well as with plasma glucose-insulin homeostasis variables (0.22 \leq r < 0.28; p<0.05). Comparison of two subgroups of overweight men with similar BMI values (\geq 25 kg/m²) but with markedly different levels of visceral adipose tissue (< vs. \geq 130 cm²; n=32) revealed significant differences only in IL-6 levels (1.42 \pm 1.15 pg/mL vs. 0.86 \pm 0.52; p<0.02 for men with high vs. low visceral adipose tissue, respectively). Finally, when subjects were stratified on the basis of their respective concentrations of IL-6 and TNF- α (using the 50th percentile of the distribution of these cytokines), a 2X2 analysis of variance revealed an independent contribution of IL-6 to the variation of fasting insulin (p<0.01) and of each of these two cytokines to the variation of post oral glucose load insulin levels (p<0.01 for IL-6 and p<0.05 for TNF- α).

Conclusion: These results support the notion that circulating IL-6 concentration is influenced to a greater extent by visceral than subcutaneous adiposity in contrast to circulating TNF- α concentration which appeared to be more influenced by the amount of subcutaneous fat. However, both cytokines contributed to the variation in plasma insulin levels beyond the known independent contribution of visceral adiposity.

0655

Changes of endocrine function of adipose tissue in anorexia nervosa: dissociation of circulating adipokine levels vs. subcutaneous mRNA expression

R. Dolezalova¹, Z. Lacinova¹, M. Dolinkova¹, P. Kleiblova², D. Haluzikova^{1,3}, M. Mraz¹, D. Housa¹, J. Housova¹, H. Papezova⁴, M. Haluzik¹;

¹3rd Department of Medicine,

²Institute of Biochemistry and Experimental Oncology,

³Department of Sports Medicine,

⁴Department of Psychiatry, 1st Faculty of Medicine, Prague, Czech Republic.

Background and Aims: Adipose tissue-derived hormones exert not only systemic endocrine effects but also local paracrine effects within the adipose tissue. A significant part of adipokines produced in adipose tissue may not be released to the systemic circulation and exert only local paracrine rather than endocrine effects. Therefore, serum concentrations of adipose tissue-derived hormones can differ from its local concentrations in adipose tissue and their higher local levels can in turn affect adipose tissue metabolism without detectable changes of its circulating levels. The aim of this study was to evaluate the influence of chronic malnutrition in patients with anorexia nervosa on endocrine function of adipose tissue on both circulating and subcutaneous fat mRNA expression level.

Materials and Methods: 12 patients with anorexia nervosa (BMI 16.37 \pm 0.41 kg/m²) and 18 normal weight age-matched women (BMI 22.96 \pm 0.67 kg/m²) underwent anthropometric examination, single blood drawing and subcutaneous adipose tissue biopsy. Serum concentrations of high-sensitive CRP (hsCRP), leptin, soluble leptin receptor, adiponectin, resistin, interleukin-6 and insulin were measured by Luminex, ELISA and RIA kits. Subcutaneous adipose tissue mRNA expression of the same adipokines, adiponectin receptors 1 and 2 and immunocompetent cells marker CD68 was measured by real time PCR.

Results: Decreased body fat content of patients with anorexia nervosa was accompanied by reduced hsCRP and leptin (1.01 \pm 0.60 vs. 2.86 \pm 0.65 mg/l, p<0.001; 1.94 \pm 0.57 vs. 12.1 \pm 1.77 ng/ml, p<0.05) and increased adiponectin, soluble leptin receptor, MCP-1 and TNF- α levels. (38.23 \pm 5.32 vs. 24.94 \pm 2.92 μ g/ml, p<0.05; 39.32 \pm 2.63 vs. 29.74 \pm 2.0 IU/ml, p<0.05; 237.83 \pm 27.02 vs. 158.26 \pm 23.26 pg/ml, p<0.05; 4.22 \pm 0.4 vs. 3.12 \pm 0.28 pg/ml, p<0.05). Resistin, interleukin-6 and insulin levels did not differ from the control group. Fat mRNA adiponectin, leptin, interleukin-6, MCP-1 and CD68 expression was reduced (0.161 \pm 0.0344 vs. 0.405 \pm 0.0484, p<0.05; 8.21x10⁻³ \pm 2.97.10⁻³ vs. 52.2x10⁻³ \pm 8.21x10⁻³, p<0.05; 0.91x10⁻⁵ \pm 0.419x10⁻⁵ vs. 5.38x10⁻⁵ \pm 2.3x10⁻⁵, p<0.05; 9.15x10⁻⁴ \pm 2.93x10⁻⁴ vs. 34.4x10⁻⁴ \pm 4.3x10⁻⁴, p<0.05; 2.41x10⁻² \pm 0.266x10⁻² vs. 8.56x10⁻² \pm 1.4x10⁻², p<0.05), resistin mRNA expression was increased (9.22x10⁻⁴ \pm 2.4x10⁻⁴ vs. 1.83x10⁻⁴ \pm 0.581x10⁻⁴, p<0.05) and adiponectin receptor 1 and 2 expression were unchanged as compared to the control group. Gene expression data are presented as relative values normalized to beta-2 microglobulin.

Conclusion: Local perturbations in resistin, adiponectin, MCP-1 and interleukin-6 mRNA expression in subcutaneous adipose tissue are not reflected by its circulating levels. These changes could be involved in some local metabolic disturbances in subcutaneous adipose tissue of anorexia nervosa patients.

LPIN1 expression in HIV-associated lipodystrophy syndrome is associated with insulin sensitivity

M. Miranda¹, M. R. Chacón¹, L. Gallart¹, F. Vidal², J. Vendrell¹;

¹Research Unit,

²Internal Medicine, University Hospital Joan XXIII, Tarragona, Spain.

Background and Aims: HIV-associated lipodystrophic syndrome (HALS) is associated with morbidities normally found in obesity. It is characterized by metabolic abnormalities like hyperlipidemia and insulin resistance. *LPIN1* gene was described as the mutated gene in the mouse model for fatty liver dystrophy (*fld*) with features of human lipodystrophy. The relation of *LPIN1* with glucose homeostasis has been analysed in transgenic mice and in humans. Studies in humans suggest a positive association with insulin sensitivity and negative with body mass index (BMI). The aim of the study was to analyse *LPIN1* adipose tissue gene expression levels in HIV-associated

lipodystrophy and to study its relationship with insulin sensitivity, and adipogenic and inflammatory markers.

Materials and Methods: 37 HIV-positive patients (including 24 who developed lipodystrophy) and 21 HIV-negative subjects. Real Time PCR was used to evaluate *LPIN1*, and several inflammatory and adipogenic markers, gene expression. Frequently sampled intravenous glucose tolerance test (FSIGTT) was used to measure insulin sensitivity (S_i).

Results: HIV-positive groups had received highly active antiretroviral therapy (HAART) for 51.8 ± 28.7 months and duration of antiretroviral combination therapy was comparable in HALS-negative and HALS-positive groups. Time of evolution to HALS was 24.41 ± 15.09 months. All patients in both HALS-negative and HALS-positive groups were currently receiving nucleoside reverse transcriptase inhibitors (NRTI). There were no significant differences between HALS groups in the frequency of receiving non-nucleoside reverse transcriptase inhibitors (NNRTI) and protease inhibitors (PI). There were no significant differences in the length of treatment of each specific agent between groups. *LPIN1* mRNA levels were significantly higher (relative units in HIV-negative: 1.36 ± 0.64 , HIV-positive without lipodystrophy: 4.24 ± 2.68 and with lipodystrophy: 3.82 ± 2.40 ; $p < 0.001$) in HIV-positive patients compared to controls, but there were no differences between both HIV-positive groups. *PPAR γ* mRNA tended to be lower in the HIV-positive patients; this tendency was more evident in HALS-positive patients, compared to HIV-negative subjects. HIV-positive subjects had significantly higher *IL-6* mRNA and increased levels of *TNF α* compared to HIV-negative controls. HIV-positive patients who received PI showed a trend to have lower insulin sensitivity and expressed significantly lower levels of *LPIN1* mRNA ($p = 0.047$). *LPIN1* expression levels were positively correlated with S_i ($r = 0.496$, $p = 0.014$) and *PPAR γ* mRNA expression ($r = 0.636$, $p < 0.001$); and negatively with BMI ($r = -0.371$, $p = 0.037$), and cytokine mRNA expression (*IL-6*: $r = -0.458$, $p = 0.006$; *TNF α* : $r = -0.508$, $p = 0.002$). In multiple regression analysis, both *PPAR γ* ($\beta = 0.527$, $p = 0.006$) and *TNF α* mRNA expression ($\beta = -0.467$, $p = 0.011$) were determinants of *LPIN1* mRNA levels, independently of gender and presence of lipodystrophy.

Conclusion: *LPIN1* mRNA expression levels were significantly higher in HIV-infected patients and positively correlated with insulin sensitivity. Moreover, pro-inflammatory cytokines such *TNF α* and *IL-6* were found strongly negatively determinants of *LPIN1* expression. We suggest a possible role of *LPIN1* as a modulator of insulin-resistance induced by PI treatments. Supported by grants FIS 04/0377, FIS 05/1994, FIPSE 36610/06, REDIMET RD06/0015/0011

The role of osteoprotegerin in type 2 diabetes mellitus

E. P. O'Sullivan¹, D. Ashley², N. Devlin², R. Crowley¹, A. Agha¹, C. J. Thompson¹, D. O'Gorman², D. Smith¹;

¹Diabetes and Endocrinology, Beaumont Hospital,

²Metabolic Research Unit, School of Health and Human Performance, Dublin City University, Ireland.

Background and Aims: Osteoprotegerin (OPG) is a glycoprotein which acts as an anti-resorptive agent in bone. It does so by inhibiting the binding of Receptor Activator of Nuclear factor Kappa beta ligand (RANKL) to its constitutive receptor Receptor Activator of Nuclear factor Kappa beta (RANK). This system also appears to exert a role in the vasculature, as illustrated by the fact that mice who are deficient in OPG exhibit excessive vascular calcification as well as severe osteoporosis. Additionally, increased levels of OPG have been found in patients with cardiovascular disease. The purpose of this study was to examine further the possible role of OPG in patients with diabetes – a condition characterised by exaggerated vascular calcification.

Materials and Methods: OPG levels were compared between a group of patients with type 2 diabetes ($n = 38$) and an age, gender and BMI matched control group ($n = 37$). Subjects (23 male) had a median age of 63 years (Interquartile range 54.3–66.3) and a mean (\pm standard deviation) BMI of 30.2 ± 3.7 kg/m². Median duration of diabetes was 5.4 (IQR 2–8) years, mean HbA1c was $7.1 \pm 0.8\%$, and 7 patients had microvascular complications. Controls (22 male) had a median age of 55 years (IQR 50–65) and a mean BMI of 29.2 ± 2.8 kg/m². OPG was measured using a commercial ELISA assay. Statistical analysis was performed with JMP IN 5.1.

Results: Serum OPG was significantly elevated in the patients with type 2 diabetes (6.03 vs. 5.15 pmol/l; $p = 0.03$). OPG was higher in women than

men ($p = 0.02$), and was highest in postmenopausal women ($p = 0.02$). OPG correlated positively with age ($r = 0.5$; $p < 0.0001$). There were no other correlations between OPG and anthropological measurements.

Conclusion: Our results demonstrate that diabetes is associated with higher levels of OPG. This may be an important mediator of arterial calcification and cardiovascular disease in these patients, especially in post-menopausal women. Further research is necessary to elucidate the exact role of OPG in type 2 diabetes.

Pharmacological blockade of the ACC system prevents obesity but only marginally improves insulin sensitivity in mice fed a high fat diet

M. Schreurs, M. H. Oosterveer, T. H. van Dijk, R. Havinga, D.-J. Reijngoud, F. Kuipers;

Research lab Pediatrics, UMCG, Groningen, The Netherlands.

Background and Aims: The acetyl-CoA carboxylases (ACC) are enzymes that are very important in both lipid and glucose metabolism. This enzyme system with two isoforms, ACC1 and ACC2, catalyses the conversion of acetyl-CoA into malonyl-CoA. Malonyl-CoA is used for synthesis of fatty acids (ACC1) but is also an allosteric inhibitor of mitochondrial β -oxidation (ACC2). Pharmaceutical agents that inhibit ACC have been developed to assess their potential benefit in the prevention and treatment of obesity and insulin resistance. The aim of this study was to assess whether CP-640186 (CP), a general ACC inhibitor, prevents obesity and/or insulin resistance in mice fed a high fat (HF) diet.

Materials and Methods: Male C57Bl6/J mice were either fed a control (chow) diet, a high fat (60% energy) diet or a high fat diet containing CP (50 mg/kg/d) for 6 weeks. The fourth group of mice received the HF diet for 4 weeks and the HF diet including the CP-compound for 2 weeks (intervention group). Mice were provided with a permanent jugular vein catheter (5 days before the end of the dietary period) for measuring basal glucose production (2 hrs) and glucose metabolism during a hyperinsulinemic euglycemic clamp (4 hrs) at the end of the dietary period.

Results: Mice given the ACC inhibitor for 6 weeks showed a remarkable deficit in body weight gain from 32 days of feeding onwards compared to mice fed the diet. Such an effect was not seen for the intervention group: this group showed a similar weight gain as the HF-fed animals did. In liver, triglycerides and total cholesterol levels were not different between the HF and CP-fed animals, but significantly higher compared to the control mice. Plasma values of triglycerides in the four groups of mice did not differ. However, plasma cholesterol levels were significantly elevated in all HF-fed groups. Hepatic expression of genes involved in lipid metabolism was not affected in the intervention group compared to controls, while they were induced in the HF and CP-fed animals. Expression levels of genes involved in glycolysis were back at control levels in the intervention mice; in the other HF-fed animals no reduction was observed. During clamping, glucose infusion rate (GIR) was significantly lower in both HF, CP-fed and intervention animals than in controls, indicating impaired insulin sensitivity in the first three groups. However, in the CP-group the GIR was slightly but significantly (10%) higher than in HF-fed mice. Glucose disposal was lower in the three HF-fed groups compared to control mice, indicating that these mice have developed insulin resistance. CP-fed mice have a tendency towards improvement of the disposal rate, but were not back at control levels.

Conclusion: Treatment with CP-640186 prevents development of obesity by as yet unidentified mechanisms and is associated with marginal improvements of insulin sensitivity in HF-fed mice.

Effects of 11 β -hydroxysteroid dehydrogenase inhibition on body weight and glucose homeostasis in mice with diet-induced obesity

V. A. Gault, A. I. Taylor, N. Irwin, A. M. McKillop, P. R. Flatt; School of Biomedical Sciences, University of Ulster, Coleraine, United Kingdom.

Background and Aims: 11 β -hydroxysteroid dehydrogenase type 1 (11 β -HSD1) is a tissue specific regulator of cortisol metabolism that is under consideration as a potential drug target for type 2 diabetes and obesity. The present study examines the metabolic effects of daily administration of carbenoxolone (11 β -HSD inhibitor) in mice with high-fat diet-induced insulin resistance and obesity.

Materials and Methods: Young (8 week-old) male Swiss *TO* mice were divided into two groups (n=8) and placed on a synthetic high-fat diet (45% fat, 20% protein and 35% carbohydrate; 26.15kJ/g) for 150 days until obesity and diabetes were clearly manifest as judged by body weight, plasma glucose

and HbA_{1c} analyses. Age-matched control mice (n=8) with free access to standard rodent maintenance diet (12.99kJ/g) were used as untreated diet controls. High-fat fed mice received once daily intraperitoneal injections (17:00 h) of either saline vehicle (0.9%, w/v, NaCl) or carbenoxolone (10 mg/kg body weight) over a 16-day period. Food intake and body weight were recorded daily whilst plasma glucose concentrations were monitored at 2–3 day intervals. At the end of the treatment period, glucose tolerance (18 mmol/kg body weight glucose i.p.), insulin sensitivity (50 U insulin/kg body weight) and plasma corticosterone concentrations were assessed. Additionally, sections of omental adipose, gastrocnimius and liver were excised and snap frozen for measurement of gene expression.

Results: Daily administration of carbenoxolone had no effect (p>0.05) on food intake. From Day 12 onwards, high-fat fed mice receiving carbenoxolone had significantly lowered (1.1-fold; p<0.05) body weights compared to saline-treated high-fat fed mice. However, body weights of high-fat fed mice receiving carbenoxolone were still significantly greater (1.4-fold; p<0.001) than mice on a standard rodent diet. Non-fasting plasma glucose levels were significantly decreased (1.2-fold; p<0.05) in mice receiving carbenoxolone treatment from Day 4 and remained significantly lower (p<0.05 to p<0.01) throughout the treatment period. Plasma glucose concentrations were significantly reduced (1.4-fold; p<0.01) following an i.p. glucose load in high-fat treated mice compared with saline-treated controls. Similarly, exogenous insulin injection following a 16-day treatment with carbenoxolone evoked a significant reduction in glucose concentrations (1.4-fold to 1.8-fold; p<0.05 to p<0.001) in terms of AUC measures and post-injection values. No significant effect (p>0.05) on circulating plasma corticosterone concentrations was observed following treatment with carbenoxolone. Drug treatment also resulted in decreased expression of the glucocorticoid receptor in omental tissue, but not in gastrocnimius or liver

Conclusion: Once daily administration of the 11 β -HSD inhibitor carbenoxolone for 16 days resulted in improved body weight and metabolic control in mice with high-fat diet-induced obesity. These data indicate the potential value of selective 11 β -HSD1 inhibition as a new target for the treatment of type 2 diabetes and obesity

0660

Rosiglitazone as a therapeutic agent to reduce inflammatory risk in type 2 diabetic patients

A. L. Harte¹, N. M. Al-Daghri², K. Al-Rubeaan³, O. Al-Attas², N. F. da Silva¹, S. L. Sabico², S. Kumar¹, P. G. McTernan¹;

¹Unit for Diabetes and Metabolism, University of Warwick, United Kingdom, ²Biochemistry Department, King Saud University, Riyadh, Saudi Arabia, ³Diabetes Center, King Abdul-Aziz University Hospital, Riyadh, Saudi Arabia.

Background and Aims: Chronic low-grade inflammation is a significant factor in the development of obesity associated diabetes. This is supported by recent studies suggesting endotoxin, derived from gut flora, may be key to the development of inflammation by stimulating the secretion of an adverse cytokine profile from fat. The study investigated the relationship of endotoxin on various metabolic parameters of diabetic patients and aimed to determine if different anti-diabetic therapies exerted a significant effect on endotoxin levels and the adipocytokine profiles of subjects with Type 2 Diabetes Mellitus (T2DM).

Materials and Methods: Fasting blood samples were collected from consenting Saudi Arabian patients (BMI:30.2±5.6Kg/m², n=413), consisting of non-diabetics (controls, n=67) and T2DM subjects (n=346). The diabetics were divided into 5 subgroups based on their 1 year treatment regimes, which included diet-control (n=36), insulin (n=47), metformin (n=141), rosiglitazone (RSG, n=22) or a combined fixed dose of metformin/rosiglitazone (Avandamet n=100). Lipid profiles, fasting plasma glucose, insulin, adiponectin, resistin, TNF- α , leptin, C-reactive protein (CRP) and endotoxin concentrations were determined.

Results: Regression analyses revealed significant correlations between endotoxin levels and triglycerides (r²=0.40; p<0.0001); total cholesterol (r²=0.10; p<0.0001), glucose (r²=0.14; p<0.0001) and insulin (r²0.12; p=0.01). Endotoxin showed a strong inverse correlation with HDL-cholesterol (r²=0.10; p<0.0001). In addition, endotoxin levels were elevated in all of the treated diabetic subgroups compared to control, but only the RSG group did not differ significantly from control (Control:4.2±1.7, RSG:5.6±2.2 EU/mL). Both the Avandamet and RSG treated groups had significantly higher

adiponectin levels than all the other groups, with the RSG group expressing the highest levels overall.

Conclusion: We conclude that sub-clinical inflammation in T2DM may be mediated by endotoxin in serum. Furthermore, that whilst the endotoxin and adipocytokine profiles of diabetic patients treated with different therapies were comparable, the RSG group demonstrated significant differences in both adiponectin and endotoxin levels. We confirm an association between endotoxin and serum insulin and triglycerides and an inverse relationship with HDL. Lower endotoxin and higher adiponectin levels in the RSG treated group may be related and indicate another potential mechanism through which RSG may be mediating its effects on insulin sensitivity.

Efficacy of a novel CB₁ antagonist, GRC 10801, in improving glucose tolerance in combination with known antidiabetic drugs

R. Anupindi, B. Mahalingam, C. Misra, M. Natarajan, S. Narayanan; Biological research, Glenmark Pharmaceuticals Ltd., Navi Mumbai, India.

Background and Aims: Endocannabinoids stimulate food intake in animals and humans through their action on CB-1 receptors located both centrally and peripherally. Thus, CB-1 receptor antagonists have been shown to be useful in the treatment of obesity. Hyperglycemia and insulin resistance are frequently associated with human obesity. Administration of selective CB₁ antagonists, such as rimonabant, ameliorates obesity related glucose intolerance and insulin resistance and dyslipidemia. The present study describes the potential of a novel orally active CB-1 antagonist GRC 10801 in combination with known antidiabetic compounds metformin and rosiglitazone in DIO mice, a model widely used for the screening of antidiabetic and antiobesity compounds.

Materials and Methods: The ability of GRC 10801 (1mg/kg) in reducing body weight, food intake and improving glycemic profile was evaluated in DIO mice alone and in combination with metformin (300 mg/kg) and rosiglitazone (5 mg/kg).

Results: GRC 10801 showed an excellent *in vitro* profile and a favorable pharmacokinetic profile in rats and *in vivo* efficacy models. In DIO model in C57BL/6J mice, GRC 10801 produced a significant reduction ($p < 0.05$) in body weight, alone (11.1%) and in combination with metformin (16.2%) and rosiglitazone (10.4%), at the end of 14-day treatment. Greater improvement in glycemic control (>15% reduction in fed-state whole blood glucose) was seen in the animals that received a combination of therapies than either treatment alone. In a pair-fed study in DIO rats, GRC 10801 showed a significant reduction in body weight and food intake.

Conclusion: GRC 10801, a novel, highly selective, orally active CB-1 antagonist that has the potential in the treatment of obesity, may be of use in diabetes by inducing weight loss which may contribute to the improvement of glucose homeostasis.

Rimonabant prevents fat accumulation during a hypercaloric high-fat diet

O. O. Woolcott, J. M. Richey, L. N. Harrison, D. Stefanovski, D. Zheng, M. Lottati, S. P. Kim, K. J. Catalano, J. D. Chiu, I. R. Hsu, V. Ionut, M. Kabir, R. N. Bergman; Physiology & Biophysics, Keck School of Medicine, University of Southern California, Los Angeles, United States.

Background and Aims: Obesity is a known risk factor for diabetes. The accumulation of fat tissue, predominantly in the abdominal region, is correlated with insulin resistance. Rimonabant (RIM) is a new drug for the treatment of obesity. We evaluated the body distribution during RIM treatment in dogs fed a high-fat diet.

Materials and Methods: Nine dogs were fed a hypercaloric high-fat diet (HHFD) consisting of ~5400 kcal/day (53% kcal from fat), starting at week -6. After 6 weeks of HHFD (baseline: week 0), dogs were randomly divided in two groups: 5 dogs received RIM 1.25 mg/kg/day, P.O., and 4 dogs, placebo (PBO) during 16 weeks. HHFD was maintained until the end of the study. Magnetic resonance imaging was performed in the trunk and eleven slices 1-cm thick were analyzed at weeks -6, 0, 2, 6, 12 and 16. RIM and PBO groups

had similar baseline body weights (28.4 ± 2.4 and 30.1 ± 2.9 kg ($P = 0.67$); respectively, mean \pm SEM) and abdominal fat distribution. Total fat tissue was 989.3 ± 94.1 and 991.0 ± 256 g ($P = 0.99$), subcutaneous adipose tissue (SAT) 432.9 ± 73.1 and 474.0 ± 124 g ($P = 0.79$), and VAT 556.4 ± 35.8 and 518.0 ± 139 g ($P = 0.80$), in RIM and PBO groups, respectively.

Results: After treatment, body weight was not significantly increased in the RIM group ($P = 0.22$) compared with 11.2% in the PBO group ($P = 0.07$). Total tissue (total fat tissue plus non-fat tissue) estimated from the trunk was well correlated with body weight ($r^2 = 91.27\%$; $P < 0.0001$). In the RIM group, the increase in total tissue was accompanied by non-fat tissue accumulation (2190.0 ± 239 g at baseline vs. 2385.3 ± 214 g at week 16; $P = 0.025$). Conversely, in the PBO group there was no change in non-fat tissue (2231.1 ± 98.3 g at baseline vs. 2317.8 ± 93.6 g at week 16; $P = 0.11$). There was a significant increase on VAT with PBO by 36.2% ($P = 0.028$) at week 16. In contrast, VAT decreased by 5.8% with RIM ($P = 0.71$). Surprisingly, RIM reduced the percentages of total fat from 31.8% to 29.5% ($P = 0.017$) and VAT from 18.2% to 16.7% ($P = 0.034$) during the first 2 weeks, and the percentage of SAT from 13.6% to 11.2% ($P = 0.021$) during the first 12 weeks. There was no relationship between food intake and weight gain.

Conclusion: RIM prevented fat accumulation during HHFD and consistently decreased the percentage of SAT and, to a lesser extent, VAT. These changes were independent of food intake changes. These results suggest that RIM might have an important regulatory effect on fat tissue by modifying energy expenditure.

Cannabinoid receptor antagonist rimonabant increases insulin sensitivity independent of weight loss

J. M. Richey, O. Woolcott, D. Zheng, S. Kim, D. Stefanovski, V. Ionut, K. Catalano, J. Chiu, I. Hsu, L. Harrison, M. Lottati, M. Kabir, E. Zuniga, E. Kirkman, R. N. Bergman; Physiology & Biophysics, Keck School of Medicine of USC, Los Angeles, United States.

Background and Aim: Rimonabant (RIM), a cannabinoid receptor CB₁ antagonist, has been shown to have beneficial effects on glucose metabolism via promotion of weight loss and central adiposity reduction. However, recent data from clinical trials suggests that RIM's positive metabolic effects may not be due to weight loss alone. The aim of our study was to assess the effects of chronic RIM treatment on insulin sensitivity (SI) and adiposity in an animal model of obesity-induced insulin resistance.

Methods: Experiments were performed in male mongrel dogs ($n=9$) fed a high fat hypercaloric diet (~5400 kcal/d, 53% kcal from fat) for 6 weeks and subsequently treated orally with 1.25 mg/kg RIM ($n=5$) or placebo ($n=4$) for an additional 16 weeks, while being maintained on the high fat diet. Euglycemic clamps and MRIs were performed to assess SI and body adiposity, respectively, during pre-fat (week -6), post-fat (week 0) and 16 weeks (week 16) of RIM.

Results: The initial 6 weeks of fat feeding increased body weight ($+2.5 \pm 0.3$ kg, $p=0.04$) and reduced whole body SI by more than 40% ($p < 0.001$). Interestingly, by week 16 of RIM treatment, SI returned to normal pre-fat values in the treated group (3.1 ± 0.3 dl/min/kg/uU/ml at week -6 vs. 2.6 ± 0.5 dl/min/kg/uU/ml at week 16, $p=NS$). In contrast, the placebo group remained insulin resistant (4.4 ± 0.9 dl/min/kg/uU/ml at week -6 vs. 1.9 ± 0.4 dl/min/kg/uU/ml at week 16, $p=0.01$). The placebo group continued to gain additional weight throughout the 16 weeks ($+2.3$ kg, $p=0.03$), while the RIM group maintained body weight (29.1 ± 2.4 vs 20.3 ± 2.2 kg, $p=NS$). Similarly, central adiposity, represented as omental fat content did not change in the RIM group (619 ± 89 to 583 ± 156 cm³, $p=NS$) but was increased in the placebo group (572 ± 308 to 784 ± 408 cm³, $p=0.03$). Thus, RIM prevented further increases in fat accumulation and body weight even in the face of continued high fat feeding. RIM treatment on body fat was reflected in the plasma adiponectin levels. We found a rapid dramatic increase in plasma adiponectin in the RIM group, an increase that became significant by week 2 ($+32\%$, $p=0.04$) and remained elevated throughout the 16 weeks of RIM treatment ($+57\%$, $p=0.02$). Conversely, in the placebo group there was no change in adiponectin levels.

Conclusion: That RIM improved insulin sensitivity without significant reductions in either body weight or omental fat content supports a body-weight independent effect of rimonabant as an insulin sensitizer. Moreover,

given that plasma adiponectin levels were elevated with RIM treatment suggests that it may play a role in mediating rimonabant's insulin sensitizing effect.

Accumulation of large adipocytes in omental and subcutaneous fat depots during development of obesity in dogs is prevented by Rimonabant

I. R. Hsu, M. Kabir, D. Stefanovski, O. Woolcott, D. Zheng, K. J. Catalano, J. D. Chiu, S. P. Kim, L. N. Harrison, M. Lottati, V. Ionut, R. N. Bergman, J. M. Richey;

Physiology and Biophysics, Keck School of Medicine of the University of Southern California, Los Angeles, United States.

Background and Aims: The cannabinoid receptor antagonist rimonabant's (RIM) ability to reduce weight gain may be due to its direct effect on adipocytes. It has been shown that mild obesity leads to increased fat cell size, which is associated with insulin resistance. However, it is unknown whether RIM affects adipocyte morphology. In this study we determined the effects of RIM on adipocyte cell size and distribution in omental (OM) and subcutaneous (SQ) tissues in a well-characterized model of canine obesity.

Materials and Methods: Animals were fed a high fat diet fat-supplemented (52% fat) diet for a period of 6 weeks to induce mild obesity in both OM and SQ adipose depots. Animals were then continued on the fat-supplemented diet (FF) and treated for an additional 16 wks with either 1) placebo (PL; n=4) or 2) rimonabant (1.25 mg/kg per day; RIM; n=4). A separate group of animals fed only a standard diet (35% fat) were used as a control (CON; n=6). Biopsies from OM and SQ adipose tissues were obtained in CON, RIM and PL groups. Cell diameter was quantified in 400–500 cells per group. Cell size was defined as follows: small (20–50 μm), medium (50–120 μm), and large (120–250 μm).

Results: Fat cell size distribution was affected by both diet and drug treatment. After 6 weeks of FF, in OM adipocytes we observed the appearance of small cells in addition to medium sized cells seen in CON. In contrast, SQ adipocytes remained unchanged compared to CON. We observed the appearance of an additional population of large adipose cells in both OM and SQ tissue after 16 weeks of FF in the placebo group. Rimonabant prevented this increase in large cells in both OM and SQ depots. Analysis of cell numbers demonstrated that large cells contributed 9% to the total cell distribution for the OM depot after 16 wks of FF (PL) vs only 0.1% for the RIM group ($p < 0.001$). Similarly, in the SQ depot large cells contributed 5% to total distribution in PL vs 0% for the RIM group ($p < 0.001$). Thus, rimonabant completely prevented the formation of large cells with fat feeding in both OM and SQ depots.

Conclusion: Rimonabant may exert beneficial effects on diet-induced obesity by preventing the formation of large adipocytes, which may lead to the improvement of insulin sensitivity in obesity.

Functional analysis of newly identified obesity-related gene, secretogranin III (SCG3): possible role in regulation of appetite-related neuropeptides

K. Hotta, A. Tanabe;

Laboratory for Obesity, SNP Research Center, Riken, Kanagawa, Japan.

Background and Aims: Both genetic and environmental factors contribute to the development of obesity. Epidemiological studies showed that heritability of body weight is estimated to be between 60 and 70 %. We have performed a large-scale case-control association study using gene-based single nucleotide polymorphisms (SNP) and found that twelve SNPs in the secretogranin III (SCG3) gene were significantly associated with obesity. Among them, two SNPs (rs16964465, rs16964476) affected the transcriptional activity of SCG3: the DNA fragment containing minor alleles had higher transcriptional activity than those containing major alleles. Subjects with the minor allele seemed to be resistant to obesity (odds ratio=9.23, 95% confidence interval=2.77–30.80, $\chi^2=19.2$, $p=0.000067$). SCG3 immunoreactivity was detected in the paraventricular nucleus (PVN), lateral hypothalamic area (LHA) and arcuate

nucleus (ARC), and the protein co-existed with orexin, melanin concentrating hormone (MCH), and neuropeptide Y (NPY). SCG3 formed a granule-like structure together with these neuropeptides. Our aim is to investigate functions of SCG3 in order to clarify how SCG3 causes obesity.

Materials and Methods: In situ hybridization and immunohistochemical analysis were performed in whole brain, pituitary gland, adrenal gland and pancreas. Mice were provided with regular chow or high-fat diet (33% fat) for 4 weeks and hypothalamic regions were dissected from mice. The mRNA levels of SCG3 were measured using real time PCR. To isolate SCG3-binding proteins, we performed a yeast two-hybrid system.

Results: SCG3 was expressed mainly in the hypothalamus and pituitary gland and pancreatic islet. In pituitary gland, SCG3 were not detected in the cells expressing POMC. We also could not detect SCG3 in the adrenal gland. SCG3 may not play important roles in pituitary-adrenal axis. SCG3 was expressed both in β -cell and α -cell of the islet. SCG3 may also affect insulin secretion as well as appetite-related neuropeptides secretion and contribute to obesity. The mRNA levels of SCG3 were reduced in hypothalamus of high-fat diet induced obese mice. Reduced SCG3 expression would be related to food intake regulation at hypothalamus. Two genes that bound to SCG3 were isolated using yeast two-hybrid system. One of the genes was specifically expressed in the hypothalamus, especially in LHA. This gene was expressed in the orexin neuron, but not in the MCH neuron. The newly identified gene would interact with SCG3 and regulate orexin secretion.

Conclusion: SCG3 and newly identified SCG3-binding protein would play some important roles in regulation of appetite-related neuropeptides secretion.

Serotonin 2C receptor agonists improve type 2 diabetes via MC4 receptor signaling pathways

D. D. Lam¹, L. Zhou¹, G. Sutton², M. J. Przydzial¹, P. G. Clifton³, A. A. Butler², L. K. Heisler¹; J. K. Elmquist⁴,

¹Clinical Biochemistry, University of Cambridge, United Kingdom,

²Pennington Biomedical Research Center, Louisiana State University,

Baton Rouge, United States, ³Psychology, Sussex University, Brighton,

United Kingdom, ⁴Center for Hypothalamic Research, University of Texas Southwestern Medical Center, Dallas, United States.

Background and Aims: Substantial evidence exists for the regulation of energy balance and glucose homeostasis by central serotonin (5-HT) pathways. Mice lacking the 5-HT_{2C} receptor (5-HT_{2C}R) develop obesity, hyperinsulinemia and glucose intolerance. Conversely, 5-HT_{2C}R agonists produce potent reductions in food intake and body weight. We hypothesize that 5-HT_{2C}R agonists also produce beneficial effects on glucose homeostasis independent of effects on food intake and body weight. Moreover, we hypothesize that the effects of 5-HT_{2C}R agonists on energy balance and glucose are mediated by central melanocortin pathways.

Materials and Methods: For food intake studies, diet-induced obese (DIO) mice received an i.p. bolus of the highly selective 5-HT_{2C}R agonist BVT. X (various doses) 45 minutes before the onset of the dark cycle. Intake of palatable high fat diet was recorded for the first 6 hours of the dark cycle. For glucose homeostasis studies, DIO mice were treated with a sub-anorectic dose (causing no change in food intake) of the 5-HT_{2C}R agonist mCPP (i.p. bolus). Glucose tolerance and insulin tolerance were assessed by glucose tolerance test (GTT) and insulin tolerance test (ITT). To investigate the downstream pathways involved in effects on food intake and glucose homeostasis, in situ hybridization was used to demonstrate colocalization of 5-HT_{2C}R on melanocortin (POMC) neurons. Mice lacking either the melanocortin 3 (MC3R) or melanocortin 4 (MC4R) receptors were tested in the same paradigms as the DIO mice. To elucidate the peripheral mechanisms of 5-HT_{2C}R agonist-induced improvements in glucose homeostasis, effects of mCPP on hepatic glucose production were assessed by RT-PCR for gluconeogenic genes.

Results: The selective 5-HT_{2C}R agonist BVT.X produced a potent dose-dependent reduction in food intake in DIO mice. Another 5-HT_{2C}R agonist, mCPP, administered at subanorectic doses (producing no effect on food intake), improved glucose and insulin tolerance as assessed by GTT and ITT. In situ hybridization studies demonstrated that 5-HT_{2C}R are expressed on melanocortin (POMC) neurons of the hypothalamic arcuate nucleus, and thus are in a position to modulate the activity of melanocortin pathways.

Assessments performed in mice lacking either of the centrally expressed melanocortin receptors, the MC3R and MC4R, showed that effects of 5-HT_{2C}R agonists on food intake and glucose homeostasis were replicated in MC3R-deficient mice, but were abolished in mice lacking the MC4R. Treatment with mCPP was associated with an inhibition of PEPCK and glucose-6-phosphatase, genes of hepatic gluconeogenesis.

Conclusion: These findings show that 5-HT_{2C}R agonists produce independent reductions in food intake and improvements in glucose homeostasis. Furthermore, these effects are mediated by the central melanocortin pathway, and depend specifically on downstream MC4R, but not MC3R. Moreover, 5-HT_{2C}R agonists inhibit genes of hepatic gluconeogenesis, which suggests a possible peripheral mechanism for the observed improvements in glucose homeostasis. Taken together, these data suggest that 5-HT_{2C} receptor agonists warrant consideration as therapeutic agents for obesity and type 2 diabetes.

Glycaemic and insulinaemic response during lower abdominal surgery under general anesthesia in type 2 diabetic subjects

L. Ali¹, K. Sardar², U. H. S. Khatun², M. H. Rahman³, M. A. Rashid¹;

¹Department of Biochemistry and Cell Biology, BIRDEM,

²Dept of Anesthesiology, Dhaka Medical College Hospital, ³Department of Physiology and Molecular Biology, BIRDEM, Dhaka, Bangladesh.

Background and Aims: Diabetic patients are at increased risk of preparative morbidity and mortality due to enhanced hemodynamic and metabolic alterations under a stress response. The metabolic alterations in diabetic patients undergoing surgery are still matters of investigation. We have investigated the glycemic and insulinemic responses during total abdominal hysterectomy, under general anesthesia, in a group of type 2 diabetic patients.

Materials and Methods: A total number of 30 women (Age in yrs, M±SD, 44±6; BMI, kg/m², 24.4±3.0) admitted in the BIRDEM hospital (the central hospital of the Diabetic Association of Bangladesh) in fit physical condition (ASA Class I & II) were included in the present study. The anesthetic protocol was strictly maintained in all patients and consisted of an intravenous induction using thiopental sodium 5 mg/kg body weight, vecuronium 0.1 mg/kg body weight and fentanyl 1.5 mg/kg body weight. Once intubated with an endotracheal tube, anesthesia was maintained with inhaled O₂/N₂O (1:2) and appropriate dialing of halothane. Three samples were collected from each subject. The first sample (Control, PT₀) was collected just before anesthesia, the second sample (PT₁) was collected 10 minutes after incision and the third sample (PT₂) was collected 10 minutes after extubation. Plasma glucose was measured by glucose-oxidase method, serum electrolytes by dry chemistry, and serum C-peptide and cortisol were measured by chemiluminescence-based ELISA technique.

Results: As judged by serial measurements of the pulse rate, systolic & diastolic blood pressures and blood gas & serum electrolytes the patients remained hemodynamically stable throughout the period of the surgery. Plasma glucose values showed a continuous rise with significantly higher level in PT₂ (plasma glucose, mmol/l, M±SD, 5.86±1.9 in PT₀, 6.0±1.85 in PT₁ and 9.55±2.7 in PT₂; p<0.001 in PT₀ vs PT₂). The rise in plasma glucose was not accompanied by any change in serum C-peptide (ng/ml, M±SD, 2.16±0.90 in PT₀, 2.0±0.95 in PT₁ and 2.0±1.2 in PT₂), but it was paralleled by a rise of serum cortisol which already showed significantly higher value in PT₁ (serum cortisol, mmol/l, 11.77±4.74 in PT₀, 14.27±6.0 in PT₁ and 33.13±7.70 in PT₂, p<0.003 in PT₀ vs PT₁). The data was also analyzed after stratifying the patients into two groups based on their ongoing treatment by only insulin (the Insulin group) or by insulin combined with an oral hypoglycemic agents (the Insulin-OHA group). In contrast to 147% rise of blood glucose in the Insulin group at PT₂, the rise of blood glucose in the Insulin-OHA group was 196% at the same time point. Such a difference between the two treatment groups was not observed in case of serum C-peptide or cortisol.

Conclusion: The data suggest that a) lower abdominal surgery under general anesthesia in well controlled type 2 diabetic subjects is accompanied by a hyperglycemic response which results from a rise of insulin antagonists like cortisol and not by a fall in insulin secretion; and b) insulin treatment may be more effective than insulin-OHA combination to control blood glucose in type 2 diabetic subjects undergoing surgery under general anesthesia.

Insulin resistance during coronary surgery in diabetic and non-diabetic patients-parallel microdialysis and organ balance technique studying skeletal muscle (preliminary results)

Z. Szabó¹, R. Andersson², H. Arnqvist³;

¹Cardiothoracic and Vascular Anaesthesia, Östergötlands Heart Centre,

²Clinical Pharmacology, Pharmacology, Medical University

³Diabetes, Endocrinology, University Hosp Linköping, Sweden.

Background and Aims: During cardiac interventions the elevated FFA (free fatty acids) and consecutive decreased carbohydrate utilisation characterize

the intraoperative insulin resistance. Intraoperative insulin resistance is a dangerous milieu in case of any ischemic event because of higher tissue oxygen demand. Our aim was to combine the organ balance technique and microdialysis to study intra operative muscle metabolism and systematically relate the microdialysis data to the organ balance technique as golden standard.

Material and Methods: 9 diabetic and 9 non-diabetic patients after written informed consent were studied with microdialysis and organ balance technique using the brachio-radial muscle on their forearm and microdialysis in the pre-pectoral fat tissue. Concentration of glucose, lactate and glycerol was measured in the arterial / venous plasma and microdialysis rinse solution at time 3 points: before the heparin (and ECC), at the release of the aortic cross clamp and just before departure from the OR to the ICU.

Results: In the diabetic patients the changes in metabolism were more moderate having a pathological pattern compared with the non-diabetic group. The magnitude of the muscular blood flow was lower in the diabetics. The interstitial glucose level, glucose concentration in the muscle and plasma was higher from the beginning in diabetic patients.

No difference was noted in lipolysis between the groups as shown by the A-I concentration difference of glycerol concentration in the fat tissue, a reliable marker of lipolysis (Figure 1.).

Conclusion: Contrary to expectations the diabetic patients did not become more insulin resistant than the non diabetic group during cardiac operations. These preliminary data indicates that with regard to intra operative insulin resistance the non-diabetic patients behave as “diabetics” during coronary operations. Clinical implication: A strict blood glucose control already intraoperative seems advisable. We are not aware of similar studies in cardiac surgery.

Insuline resistance in febrile states

D. Z. Toljic Suluburic¹, D. D. Micic², M. Pavlovic³,

¹Internal medicine section, Health Center Cacak, ²Internal medicine section, Institute for Endocrinology, Diabetes and Metabolic Disorders, Belgrade,

³Institute for Infectious and Tropical Diseases, Belgrade, Serbia.

Background and Aims: The occurrence of insulin resistance during fever is a well-known phenomenon, but underlying mechanisms are incompletely understood. We aimed to evaluate the efficacy of the Minimal Model technique to calculate insulin sensitivity in febrile patients and to investigate if there is any relationship between the degree of insulin resistance and duration or degree of fever.

Materials and Methods: We studied twenty one patients with fever (body temperature 38,7+/-0,8 °C, age 32,19+/-10,17 yr., BMI=22,4+/-2,17 kg/m², and normal values of fasting glycemia, serum lipids, AST, ALT and creatinine) and ten normal subjects matched for age and BMI as control group. Insulin

sensitivity (Si, x10⁻⁴min/microU/ml) and glucose effectiveness (Sg, min⁻¹) were estimated using modified_Minimal Model technique. Patients were divided into groups according to degree (cut-off point of 38.5 °C) and/or duration (cut- off point three months) of fever.

Results: In febrile group of patients insulin resistance was shown to exist in twenty patients out of twenty-one (Si 1,67+/-1,0,Sg 0,32+/-0,14). In control group it existed only in one patient. Patients with a body temperature higher than 38,5 °C, n=6 had significantly (p<0,05) lower Si (0,99+/-0,85) than patients with a body temperature lower than 38,5 °C, n=15 (1,98 +/-0,95). Differences in Sg were not statistically significant between these two patient groups (Sg 0,29+/-0,08 vs. Sg 0,33+/-0,15 mg/min, p>0,05). The duration of fever itself did not significantly (p> 0,05) affect insulin sensitivity nor Sg (patients with fever longer than three months had Si 1,37+/-0,52,Sg 0,36+/-0,07 vs. Si 1,85+/-1,19 Sg 0,29+/-0,16 in patients with fever less than three months). According to both the degree and duration of fever, we divided patients into four groups: The first group (patients with body temperature below 38,5 °C, duration less than three months, n=6) had Si 2,63+/-1,05, Sg 0,32+/-0,21. The second group (patients with body temperature below 38,5 °C, duration of fever over three months, n=8) had Si 1,33+/-0,52, Sg 0,38+/-0,06. The third group (patients with body temperature above 38,5 °C, duration of fever less than three months, n=6) had Si 1,21+/-1,14, Sg 0,25+/-0,086. The fourth group (patients with body temperature over 38,5 °C, duration over three months, n=1) had Si 1,47+/-1,01, Sg 0,245+/-0,06. The first group had statistically significant higher values of Si, but not Sg, compared to other three groups. There were no significant differences between patients according cause of fever either in Si or Sg (bacterial: Si 1,4+/-0,83, Sg 0,29+/-0,08 vs. viral: Si 1,36 +/-0,77, Sg-0,3+/-0,08, and vs. others: Si 2,38+/-1,2,Sg-0,38+/-0,22).

Conclusion: It is concluded that the Minimal Model technique is valid for evaluation of insulin sensitivity in febrile patients. Also, it was found that degree, rather than duration of fever, influenced the level of insulin sensitivity. A possible explanation is that it is connected with higher increase of counterregulatory hormones, as well as higher increase of cytokines IL1 and TNF alpha. Finally, the degree of insulin resistance has not been found to be related to the causalities of infection.

0670

Constancy of relative insulin sensitivity and importance of absolute insulin sensitivity shift to develop insulin infusion protocol in critically ill patients

M. Matsuda, M. Shigeto, Y. Akiyama, M. Masuzawa, T. Okabe; Diabetes and Endocrine Department, Kameda Medical Center, Kamogawa, Japan.

Background and Aims: To keep blood glucose conc. (BG) lower than 140 mg/dl (~8 mM) in critically ill patients, it is necessary to use an insulin infusion protocol like the Yale Protocol (Diabetes Care 27:461, 2004). However its application is difficult as demonstrated in randomized controlled trials. To reduce hypoglycemic risks, we have developed a unique algorithm.

Materials and Methods: The input (X) and the output (Y) of this system to adjust the insulin infusion rate to keep BG are the insulin infusion rate (U/hr), and the difference of BG in a fixed amount of time (mg/dl per hr), respectively. These two values were plotted on a graph using X and Y axes. Glucose infusion rate (g/hr) is converted to the theoretical increase of BG (mg/dl per hr) assuming simple distribution in glucose space (20% and 25% of body weight in obese and lean subjects), and is added on the graph. BG was measured from 1 to 6 hrs intervals according to the expected Y value to have optimal BG by reading the graph. To determine the next X value to achieve optimal expected Y value, we have observed 50 diabetic cases (M/F = 36/14, age = 64 ± 12 y.o., BMI = 24 ± 4 kg/m²) before and/or after operation to keep BG from 90 to 140 mg/dl, by using the graph, resulting in no hypoglycemia (BG<60mg/dl). Operations included those in coronary artery bypass graft, orthopedics, abdominal, gynecological, and obstetric surgery. BG was measured by PCx (Abbott, USA), and human regular insulin (1 U/ml saline) and glucose were infused by infusion pumps for clinical use calibrated routinely. *In vivo*, it is possible that the whole body insulin resistance (IR) is defined as absolute amount of insulin to keep fixed glucose turnover and keep BG constant (IRI-abs: absolute Insulin Resistance Index). On the other hand, insulin sensitivity is defined as a decremental conc. of BG by a fixed increment of insulin (or delta insulin) (ISI-delta: relative Insulin Sensitivity Index). Glucose infusion and change of BG were approximated to calculate

insulin resistance by extrapolating the line of the graph, reading X (U/hr) on X-axis (Y=0) to calculate IRI-abs. ISI-delta (mg/dl per U) was the slope of the line on the graph, when IRI-abs became fixed.

Results: Total number of sampling of BG was 1626. BG before insulin infusion was 163 ± 58 mg/dl, and the average BG after insulin infusion was 126 ± 18 mg/dl. IRI-abs shifted from 0.4 ± 1.8 to 3.4 ± 10.2 U/hr. When insulin sensitivity is defined as relative amount of insulin to suppress a fixed level of BG, this ISI-delta was fairly constant during whole observation before and/or after operations. ISI-delta was roughly equal to the incremental BG (mg/dl) by basal endogenous glucose production (2.2 mg/kg lean body weight per min) divided by 1 unit/hr of incremental insulin infusion rate in almost all subjects with glucose infusion less than 5 g/hr, and the average was 57 ± 5 mg/dl per U.

Conclusion: We concluded that rapidity of shifts of IRI-abs (instability) is necessary to be added to the previous protocols like the Yale Protocol that used only absolute BG, change of BG, and absolute insulin infusion rate to reduce hypoglycemic risks in critically ill patients. In addition, a decremental conc. of BG by a fixed increment of insulin (ISI-delta) was relatively constant despite the stress of operations. This phenomenon may be often masked by the shift of the IRI-abs, and neglect of emergence of ISI-delta resulting in an unexpected change of insulin sensitivity may cause sudden hypoglycemic accidents.

0671

Evaluation of insulin action on glucose uptake and lipolysis in patients with ketosis-prone type 2 diabetes during remission

S. Choukem¹, E. Sobngwi², I. Hainault³, P. Vexiau¹, F. Calvo⁴, J.-F. Gautier^{1,3};
¹Endocrinology and Diabetes, Saint Louis Hospital, Paris, France,
²Obesity, Endocrinology and Diabetes, Yaounde Central Hospital, Yaounde, Cameroon, ³U671, INSERM, Paris, France, ⁴Clinical Investigations Centre, Saint Louis Hospital, Paris, France.

Background and Aims: Ketosis-prone type 2 diabetes (KPD), also known as idiopathic type 1 or type 1B diabetes, is a syndrome of unclear pathogenesis found mainly in people of sub Saharan African ancestry. It is characterised by an acute onset with sustained hyperglycaemia and ketosis or ketoacidosis that require urgent insulin treatment. This is followed by a prolonged long-term near-normoglycaemic remission without insulin treatment in more than 50% of patients. The aim of this study was to characterize insulin action during remission.

Materials and Methods: We studied insulin action on glucose uptake and lipolysis, and body composition after an overnight fast in 13 patients with KPD (12M/1F; age = 45.2 ± 8.8 (SD) years; BMI = 29.8 ± 1.2 kg/m²; HbA1c = 6.2%) in remission. They were compared to 13 (11M/2F; age = 43.2 ± 9.5 years; BMI = 24.6 ± 2.3 kg/m²) normoglycaemic control subjects. All patients and controls were of sub Saharan African origin. The diagnosis of KPD was considered for patients with acute hyperglycaemia with ketosis at onset without precipitating factors, and remission was defined as maintenance of HbA1c level $\leq 6.5\%$ on an oral antidiabetic drug or diet alone for at least 3 months. We performed a 2-step euglycaemic clamp with a $10\text{mUI}/\text{m}^2/\text{min}$ insulin infusion step of 100 min to evaluate the antilipolytic action of insulin (decrease in non-esterified fatty acid (NEFA) concentrations) followed by a $80\text{mUI}/\text{m}^2/\text{min}$ insulin infusion step of 100 min to measure glucose uptake (M-value). Results are expressed as percentage or mean \pm standard error. Comparison between groups was performed using the non-parametric Mann-Whitney U test.

Results: Whole body glucose uptake (M-value) was 7.4 ± 0.7 and 10.2 ± 1.1 mg/kg of fat-free mass/min in patients and controls respectively ($p = 0.04$). Plasma insulin levels were higher in patients at baseline (10.9 ± 2.0 mU/ml vs 6.2 ± 1.3 in controls; $p = 0.03$), but not at the end of the first step (T100min: patients 24.1 ± 5.6 mU/ml, controls 19.4 ± 1.9 mU/ml; $p = 0.46$). Patients had a baseline NEFA concentration 84% higher than controls (60.2 ± 6.5 vs. 32.8 ± 5.4 mg/dl in patients and controls respectively; $p = 0.004$). It decreased in both groups from baseline to the first step, but remained higher in patients compared with controls (24.7 ± 3.1 vs. 10.3 ± 2.9 mg/dl at T 100min: $p = 0.003$). However, there was no difference in percent decrement of NEFA concentration from baseline between groups (55.3% vs. 66.6% at T100 min in patients and controls respectively, $p = 0.16$).

Conclusion: During remission, patients with KPD have lower whole body glucose uptake, higher NEFA concentrations, and higher fasting insulinaemia. However the NEFA clearance rate in response to insulin infusion appears

similar. This suggests that patients with KPD in remission may be similar to those with type 2 diabetes.

PS 55 ER stress and insulin resistance

0672

Ectopic expression of insulin receptor substrates 1 or 2 in 3T3-L1 adipocytes counteracts endoplasmic reticulum stress-induced insulin resistance

L. Xu¹, B. Joblin¹, S. Boller¹, A. Egli¹, N. Boschetti¹, T. Trüb², G. A. Spinaz¹, M. Niessen¹;

¹Department of Internal Medicine, Endocrinology and Diabetes, ²Zentrale Dienste der Universität, Ausrüstung und Logistik, Zurich, Switzerland.

Background and Aims: Insulin receptor substrates (IRS) are important components of insulin signal transduction and indispensable regulators of glucose homeostasis. Endoplasmic reticulum (ER) stress has been shown to inhibit IRS via c-Jun N-terminal kinase (JNK)-dependent serine phosphorylation/downregulation thereby linking obesity with insulin resistance (1). ER stress has also been shown to impair insulin secretion (2). With this study we wanted to investigate the effects of ER stress on insulin signalling and function of 3T3-L1 adipocytes.

Materials and Methods: ER stress was induced with either tunicamycin or with thapsigargin. Expression levels of the chaperone Grp78/BiP were assessed to monitor ER stress. Intracellular insulin signal propagation was analysed by Western blotting with phospho-specific antibodies against the activated forms of the insulin receptor (IR), Akt/PKB and ERK1/2. The function of 3T3-L1 adipocytes was assessed by measuring the rate of insulin-dependent 2-deoxy-D-glucose uptake and the (constitutive) secretion of adiponectin, respectively. IRS1, IRS2 and GFP (as a control) were constitutively overexpressed from adenoviral constructs.

Results: ER stress strongly decreased the activation of the insulin receptor, Akt/PKB and ERK1/2 in 3T3-L1 adipocytes. However, total expression levels of the IR were also reduced under ER stress. Overexpression of full-length IRS1 or IRS2 restored insulin-dependent activation of Akt/PKB and ERK1/2 under ER stress without restoring expression levels/activation of the IR. Secretion of adiponectin from 3T3-L1 adipocytes and insulin-induced 2-deoxy-D-glucose uptake were both reduced by 50 % under ER stress. Ectopic expression of IRS significantly improved insulin-induced 2-deoxy-D-glucose uptake by 30 % under ER stress compared to controls (GFP), while secretion of adiponectin was improved by 25 %.

Conclusion: Our study confirms that ER stress induces insulin resistance in 3T3-L1 adipocytes. In addition to the previously described downregulation of IRS proteins we find that in 3T3-L1 adipocytes ER stress also impairs the expression of the IR. This observation might explain why in our experiments constitutive high-level expression of IRS1 or IRS2 can only partially rescue insulin sensitivity under ER stress. Furthermore, ER stress inhibited the secretion of adiponectin. Lower circulating levels of adiponectin due to obesity-induced ER stress could contribute to the development of insulin resistance and hyperglycemia *in vivo*. Ectopic expression of IRS proteins improved the production of adiponectin from 3T3-L1 adipocytes under ER stress indicating a link between insulin signalling and adiponectin production.

4-PBA(4-phenylbutyrate) reduced palmitate-induced endoplasmic reticulum stress and apoptosis in HUVEC

H.-J. Jang¹, J. Jung¹, E.-S. Ha¹, S.-E. Choi¹, S. Jung², H. Kim², D. Kim², Y. Kang¹, K.-W. Lee²;

¹Institutes for Medical Sciences, ²Endocrinology and Metabolism, Ajou University School of Medicine, Suwon-Si, Republic of Korea.

Background and Aims: The death of endothelial cells may play a critical role in the development of various vascular diseases, including atherosclerosis. While free fatty acids (FFAs) may stimulate endothelial apoptosis, the detailed molecular and cellular mechanisms of this effect have not been studied. To elucidate the mechanisms involved in FFA-induced endothelial cell apoptosis, we investigated the effects of different pharmacological inhibitors on palmitate-induced apoptosis in endothelial cells. Interestingly, 4-PBA (4-phenylbutyrate), a chemical chaperone, had a protective effect.

Materials and Methods: To examine endothelial cell apoptosis, endothelial cells were first treated with different concentrations of palmitate, and then endothelial cell apoptosis was measured using a Cell Death ELISA assay kit. Palmitate dramatically increased endothelial cell apoptosis in a mitochondria- and caspase -dependent manner. To examine the involvement of endoplasmic reticulum (ER) stress in palmitate-induced endothelial cell apoptosis, induction of the unfolded protein response (UPR) in response to palmitate treatment was monitored, using immunoblotting and RT-PCR.

Results: Endothelial cells exposed to palmitate for 12 h increased the protein levels of phosphorylated eukaryotic translation initiation factor 2 alpha (eIF2alpha), X box-binding protein 1 (XBP-1), and C/EBP homologous transcription factor (CHOP) compared to control cells. In addition, palmitate treatment markedly increased the levels of the ER chaperone proteins Grp78, suggesting that palmitate highly regulates the unfolded protein response (UPR). Interestingly, pretreatment with a chemical chaperone, such as 4-PBA, reduced palmitate-induced CHOP and BIP expression and had protective effects against palmitate-induced endothelial cell apoptosis.

Conclusion: ER-stress is involved in palmitate-induced endothelial cell apoptosis.

Effect of acute hyperinsulinaemia and AT-1 receptor blockade on androstane metabolites in men with impaired glucose tolerance and/or impaired fasting glucose

K. Zidkova¹, E. Krusinova¹, J. Vrbkova^{1,2}, M. Hill², T. Pelikanova¹;

¹Diabetes Center, Institute for Clinical and Experimental Medicine,

²Department for Steroid Hormones, Institute of Endocrinology, Prague, Czech Republic.

Background and Aims: The association between lower testosterone levels and type 2 diabetes in men was delineated; however the responsible mechanisms were not identified till now. It is not clear which steps of androgen metabolism could be influenced by hyperinsulinaemia/insulin resistance in men. The aim was to study the effect of acute hyperinsulinaemia with and without AT-1 receptor blockade on the plasma

Tab. 1

Serum concentrations of androstane metabolites during HIC. Median (lower quartile;upper quartile).

	HIC-Placebo		HIC-Telmisartan	
	0 min	120 min	0 min	120 min
Testosterone (nmol.l ⁻¹)	21.7 (11.9;26.5)	19.7 (14.8;30.4)	18.3 (14.9;22.2)	20.2 (13.3;29.6)
Dihydrotestosterone (nmol.l ⁻¹)	1.67 (1.16;2.8)	1.81 (1.18;2.7)	1.41 (0.77;1.69)	1.22 (0.87;2.33)
Etiocholanolone (nmol.l ⁻¹)	0.42 (0.31;0.58)	0.34 (0.29;0.43)	0.27 (0.22;0.41)	0.25 (0.21;0.48)
Etiocholanolone-conjugate (nmol.l ⁻¹)	161 (96.3;213)	103 (77.9;167)	162 (111;215)	118 (81.6;224)

levels of androstanes in men with impaired glucose tolerance (IGT) and/or impaired fasting glucose (IFG).

Materials and Methods: 12 men with IGT and/or IFG underwent a double-blind, cross-over study with 3 weeks of either telmisartan 160 mg or placebo administration. At the end of each period, serum concentrations of selected androstane metabolites were measured using GC/MS method before and at 120 minutes of hyperinsulinaemic (1 mU.kg⁻¹.min⁻¹) euglycaemic (5 mmol.l⁻¹) clamp (HIC). ANOVA with repeated measures, followed by least significant difference multiple comparisons, were used for data evaluation, $p < 0.05$ was considered statistically significant.

Results: Testosterone levels did not differ either after telmisartan treatment or during HIC. Telmisartan treatment resulted in a decrease in dihydrotestosterone (DHT) levels ($p < 0.03$), without any significant changes during HIC. Telmisartan decreased etiocholanolone ($p < 0.02$) and increased etiocholanolone-conjugate levels ($p < 0.05$), the latter one decreased significantly during HIC ($p < 0.002$). AT-1 receptor blockade increased the androsterone-conjugate levels ($p < 0.0002$), that also declined during HIC ($p < 0.02$). There were no changes in androsterone levels.

Conclusion: Plasma levels of conjugated etiocholanolone and androsterone are decreased by acute hyperinsulinaemia. Telmisartan treatment, compared to placebo, resulted in a significant decrease of free androstane metabolites, whereas their conjugates were increased. Our results suggest a potential role of telmisartan in androgen metabolism. (Tab. 1)

The role of endoplasmic reticulum stress on insulin-resistance induced by glucosamine in the L6 skeletal muscle cells

G. A. Raciti¹, L. Ulianich¹, F. Paturzo¹, C. Iadicco¹, A. Lombardi², F. Andreozzi³, A. P. M. Barbagallo¹, B. Di Jeso², F. Beguinot¹, P. Formisano¹, C. Miele¹;

¹Dip. Biologia e Patologia Cellulare e Molecolare e IEOS-CNR, University of Naples Federico II, Naples, ²Dip. Scienze e Tecnologie Biologiche e Ambientali, University of Lecce, ³Dip. Medicina Sperimentale e Clinica, University of Catanzaro Magna Graecia, Catanzaro, Italy.

Background and Aims: The endoplasmic reticulum (ER) is responsible for the quality control of proteins. When the productive folding process in the ER is perturbed by environmental stress conditions, eukaryotic cells activate a homeostatic response, termed the unfolded protein response (UPR). Dysfunction of the UPR plays an important role in several human diseases, including Type 2 diabetes (T2D). Indeed, recent discoveries reported that ER stress is involved both in pancreatic beta-cell dysfunction and in peripheral insulin resistance. Hyperglycaemia has been reported to cause insulin resistance and, in some tissues, this process appears to be linked to UPR activation. Even glucosamine, generated by the activation of the hexosamine pathway during hyperglycaemia, causes insulin resistance and disturbances similar to glucose toxicity in muscle cells. Thus, in the present work we sought to evaluate the possible role of ER stress on the insulin-resistance induced by glucosamine in L6 skeletal muscle cells.

Materials and Methods: L6 skeletal muscle cells were incubated either with 10 mM glucosamine (GLC) or 0.5 microM thapsigargin (THA) in the presence or in absence of insulin (100nM). mRNA and protein expression were measured respectively by Real Time PCR and Western Blot. Glucose uptake was measured using the glucose analogue 2-deoxy-D-[3H]-glucose (2DG).

Results: We evaluated if GLC was able to activate the UPR in L6 cells. The mRNA levels of BiP and CHOP, two ER stress markers, were increased respectively up to 14-fold and 12-fold in a time-dependent manner upon GLC treatment. The same results were also obtained upon THA treatment, a commonly used ER stressor. Next we analyzed phosphorylation of protein kinases known to be activated by ER stress in several cellular systems. Among the MAPKs, p38, JNK and ERK were all activated upon both GLC and THA stimulation. Furthermore, phosphorylation of the translation initiation factor eIF2alpha by PERK was evident as early as after 15 min of GLC treatment. We then evaluated the effect of GLC- and THA-induced ER stress on the insulin signalling. Both GLC and THA blunted insulin induced activation of Akt measured as phosphorylation of Akt on both Thr308 and Ser473. Furthermore, insulin was unable to inhibit GSK3beta upon GLC as well as THA treatment. Finally, given that ER stress cause a transcriptional reprogramming of cells, we hypothesized that GLUT4 expression could be

susceptible to variation in stressed L6 cells. Real Time PCR and Western blot experiments, indeed, showed that both GLC and THA induced respectively a 60% and 85% decrease of both GLUT4 mRNA and protein levels. Decrease of GLUT4 expression levels was paralleled by the reduced capability of L6 cells to uptake the 2DG, when measured in the presence of insulin stimulation.

Conclusion: We show for the first time that glucosamine is able to activate the UPR in L6 skeletal muscle cells. This pathway may play a role in insulin resistance through inhibition of Akt activity and Glut4 expression.

N^ε-(Carboxymethyl)lysine (CML) is increased in human adipose tissue: Biological effects of AGE-adducts

K. H. J. Gaens¹, M. P. H. van de Waarenburg¹, J. Nijhuis², J. Scheijen³, C. D. A. Stehouwer¹, C. G. Schalkwijk¹;

¹Internal Medicine / CARIM, ²General Surgery,

³Clinical Genetics, Maastricht University, The Netherlands.

Background: A dysregulation of adipocytokines in adipose tissue has been associated with an increased cardiovascular risk. However, factors by which obesity leads to such a dysregulation have not been elucidated. Because of local conditions in adipose tissue, i.e. increased fatty acids and oxidative stress, we speculate that an increased formation of the major advanced lipoxidation/ glycation endproduct (ALEs/AGEs) N^ε-(carboxymethyl)lysine (CML) accumulates in adipose tissue and that this increased formation of CML causes dysregulation of adipocytokines production. We therefore examined the presence and accumulation of CML and the receptor for AGE (RAGE) in adipose tissue and we performed experiments in 3T3 cells to examine the biological effects of AGE-adducts on the expression of adipocytokines.

Methods: Accumulation and localisation of CML and RAGE in human adipose tissue was determined by immunohistochemistry. Subjects were recruited from a population of obese patients. To investigate colocalisation with macrophages and endothelial cells, serial sections of adipose tissue were analysed by antibodies against CD68 and CD31, resp. Plasma concentrations of CML and CEL were determined by HPLC-MS/MS. For the gene expression experiments, we used 3T3-L1 murine cells that were differentiated to adipocytes. After incubation of 3T3 adipocytes with different AGE-adducts (CML-, glucose-, glucose-6-phosphate- and methylglyoxal-modified human serum albumin) (0.5 μM, 1.5 μM and 4.5 μM) for 0h, 8h, 24h and 48h, changes in gene expression of leptin, adiponectin, resistin, RAGE, PAI-1, PPAR-γ, IL-6 and Iκ-Bα were analysed by RT-PCR.

Results: Immunohistochemical staining demonstrated accumulation of CML and RAGE in adipocytes, macrophages and endothelial cells in adipose tissue of obese patients. Plasma CML concentrations did not, but CEL did, differ between obese patients and a control group (1.46 ± 0.4 μM and 1.55 ± 0.2 μM, resp and 1.69 ± 0.6 μM and 0.80 ± 0.2 μM, resp, $p < 0.05$). Moreover, weight loss had no effect on plasma AGE concentrations in obese patients. The CML concentration was significantly higher in 3T3 adipocytes as compared to 3T3 fibroblasts and oxidative stress further increased CML levels in adipocytes. Western blot analysis showed that exposure of 3T3 adipocytes to oxidative stress during 0h, 2h, 8h and 24h resulted in a progressive increase of CML in a major CML-modified protein of 36 kDa. Incubation of 3T3 adipocytes with different AGE-adducts demonstrated positive and negative effects on the expression of adipocytokines.

Conclusions: This study provides evidence for the accumulation of CML in adipocytes, endothelial cells and macrophages in human adipose tissue. The accumulation of CML is a local process, since plasma CML concentrations showed no difference between obese patients and a control group. In contrast, plasma CEL was higher in obese patients. As shown in 3T3 adipocytes, incubation with AGE-adducts caused a dysregulated expression of adipocytokines. These experiments support the hypothesis that the accumulation of CML in adipose tissue of obese patients has important biological consequences regarding the dysregulation of adipocytokines.

Direct non-genomic actions of progesterone on isolated rat skeletal muscle: inhibition of cell respiration and induction of insulin resistance

B. Brunmair, F. Gras, L. Quarré, Z. Szöcs, W. Waldhäusl, C. Fürnsinn; Department of Medicine III, Division of Endocrinology & Metabolism, Medical University of Vienna, Austria.

Background and Aims: In search of mechanisms responsible for the adaptations of glucose metabolism to pregnancy, we have previously reported that progesterone, which circulates at increased concentrations during late pregnancy, affects fuel metabolism of rat skeletal muscle via a direct, rapid, and non-genomic mechanism. The present study was to better define this action by sorting out, how acute progesterone exposure modulates basal and insulin-stimulated substrate fluxes through the major pathways of cellular glucose metabolism.

Materials and Methods: Strips of freshly isolated soleus muscle from healthy Sprague-Dawley rats were exposed to 1, 10, or 50 μM progesterone for 5h. During the last hour, rates glucose oxidation, lactate production, glucose transport, and pyruvate oxidation were measured under basal and insulin-stimulated (25 nM) conditions. Glycogen content was determined at the end of the experiments.

Results: Under basal conditions, progesterone distinctly and dose-dependently reduced the rate of glucose oxidation (nmol* g^{-1} * h^{-1} : control, 819±76; 1 μM, 745±113; 10 μM, 499±55, $p < 0.002$; 50 μM, 230±18, $p < 0.001$; all p -values vs control), which was accompanied by an increase in lactate release (μmol* g^{-1} * h^{-1} : control, 8.0±0.5; 1 μM, 9.8±0.5; 10 μM, 13.2±0.7; 50 μM, 20.6±0.5; $p < 0.002$ each). Higher carbohydrate requirements for anaerobic than aerobic energy supply were reflected by increased glucose transport (cpm 3H -deoxy-glucose transported* mg^{-1} * h^{-1} : control, 279±10; 1 μM, 378±29, $p = 0.06$; 10 μM, 364±29, $p < 0.05$; 50 μM, 517±29, $p < 0.001$) and glycogen depletion (glycogen content after incubation, μmol glucosyl units/g: control, 9.7±0.9; 1 μM, 8.2±1.0, $p < 0.05$; 10 μM, 3.9±0.8, $p < 0.001$; 50 μM, no detectable glycogen). This characteristic response clearly indicated progesterone-induced inhibition of cell respiration, which was likewise seen under insulin-stimulated conditions (nmol glucose oxidation* g^{-1} * h^{-1} : control, 1706±131; 1 μM, 1566±93; 10 μM, 1030±72, $p < 0.005$; 50 μM, 340±64, $p < 0.001$). Inhibition of respiration occurred obviously distal to glycolysis (i.e., at the mitochondrion), since progesterone also markedly inhibited the oxidation of pyruvate (cpm ^{14}C -pyruvate oxidised* mg^{-1} * h^{-1} : control, 1411±31; 1 μM, 1012±31; 10 μM, 636±56; 50 μM, 184±37, $p < 0.001$ each). At variance to what was seen under basal conditions, progesterone did not increase and, at a concentration of 50 μM, even impaired insulin-stimulated glucose transport (cpm* mg^{-1} * h^{-1} : control, 901±52; 1 μM, 892±42, ns; 10 μM, 1013±58, ns; 50 μM, 715±47, $p < 0.05$), which obviously limited substrate availability for glycolysis (lactate release, μmol* g^{-1} * h^{-1} : control, 18.1±0.5; 1 μM, 23.1±0.7, $p < 0.001$; 10 μM, 28.5±1.7, $p < 0.001$; 50 μM, 20.7±2.5, ns). This effect was seen only under insulin stimulation and hence indicated that progesterone, in addition to its effect on the mitochondrion, impaired insulin-dependent glucose uptake.

Conclusion: Taken together, our results show that the acute non-genomic effects of progesterone on skeletal muscle have two overlapping effects on cellular fuel metabolism, which are (i) inhibition of cell respiration at the mitochondrion, and (ii) impairment of insulin-dependent glucose uptake (i.e., insulin resistance). These actions of progesterone could contribute to changes in glucose homeostasis seen during late pregnancy.

0678

Dehydroepiandrosterone (DHEA) prevented obesity-induced acceleration of senescence in adipose tissue

K. Kajita, T. Ikeda, I. Mori, K. Fujioka, Y. Uno, H. Morita, T. Ishizuka; General Internal Medicine, Gifu University, Gifu, Japan.

Background and Aims: Numerous research indicates that DHEA administration decreases fat mass in human and rodent. We reported previously that DHEA decreased the expression of PPAR γ and related genes in primary cultured adipocyte. These results can partially explain the mechanism of weight reducing effect of DHEA, however other mechanisms may be involved. On the other hand, some studies suggest the possibility

that longevity might be associated with high blood level of DHEA, although conflict results have been published. Actually, few data have been provided whether DHEA administration affects life span or cell senescence. Moreover, biological mechanisms of anti-aging effects of DHEA have not been clarified. In this context, we evaluated the effects of DHEA treatment on biological markers in adipose tissue.

Materials and Methods: Male Otsuka Long Evans Fatty (OLETF) rats, hereditary obese animals derived from Long Evans Tokushima (LETO) rats, LETO rats and Wistar rats were fed with or without (control) 0.4% DHEA containing food for 52 wk, and then killed by decapitation. Epididymal fats, livers, kidneys and skins were harvested and kept at $-80^{\circ}C$. Epididymal fat pads were minced and digested with type 1 collagenase to obtain stromal vascular fraction (SVF). Frozen skin and SVF were cut, and thin (5mm) sections were mounted on slide glass. These sections were stained for senescence-associated β -galactosidase (SA- β -Gal). Protein levels of CUG binding protein-1 (CUGBP-1), which bind to (CUG) $_n$ triplet repeat RNA to modulate translation, in each organs were measured with Western blot. Cell proliferation was assessed with BrdU uptake in 3T3-L1 preadipocyte.

Results: Treatment with DHEA for 52 wk reduced body weight and fat weight, but not food consumption, in Wistar, LETO and OLETF rats. These results clearly indicated that treatment with DHEA for 52 wk decreased fat mass without affecting food intake. Fasting plasma IRI, triglyceride and free fatty acid levels were significantly decreased in Wistar rats, but not in LETO and OLETF rats. SA- β -Gal was detected in SVF isolated from control OLETF rats, whereas it was not observed in other animals including Wistar and LETO rats, both fed with and without DHEA containing food and OLETF rats treated with DHEA. Considering the fact that SA- β -Gal is expressed in fibroblast sampled from aged animals or cultured cells in late passage, these results suggested that an obesity-induced elevated turnover of preadipocyte was prevented with DHEA treatment. CUGBP-1 protein levels were decreased in fat, liver and kidney in rats treated with DHEA. As it has been reported that aging results in CUGBP-1 accumulation in fat and liver, these results will support the idea that DHEA suppressed senescence. To investigate the possibility that DHEA might decrease cell proliferation, we evaluated the effects of DHEA on BrdU incorporation during DNA synthesis in 3T3-L1 cells. Treatment with insulin increased preadipocyte proliferation, whereas DHEA significantly decreased its proliferation in a dose response manner (100 nM DHEA, $p < 0.02$).

Conclusion: These results suggested that DHEA -induced suppression of cell proliferation, including preadipocyte, might lead to anti-obesity and have an anti-senescence effect.

Estradiol treatment decreases body weight and improves insulin sensitivity in aged female mice fed on a high fat diet

G. Bryzgalova¹, L. Lundholm², H. Gao², A. Khan¹, K. Dahlman-Wright², J.-A. Gustafsson², S. Efendic¹;

¹Molecular Medicine and Surgery, Karolinska Institute, Stockholm,

²Biosciences and Nutrition, Karolinska Institute, Huddinge, Sweden.

Background and Aims: It has been shown that estradiol (E2) treatment in menopausal women reduced fasting levels of glucose and insulin, and in women with type 2 diabetes hormone replacement promoted insulin sensitivity and glycemic control. In many spontaneous rodent models of type 2 diabetes, E2 displays powerful antidiabetic properties. Therefore, in this study, we have explored the effect of E2 on phenotype and insulin sensitivity in female mice fed on a high fat diet (HFD).

Materials and Methods: C57BL female mice were fed on a HFD for 10 months, with daily 17 β -estradiol (50 μg/kg, s.c.) or vehicle (sesame oil) given during the last month of feeding. Glucose and insulin tolerance tests were performed. Plasma hormone levels were determined by RIA. Real-time PCR was employed to measure gene expression profiles.

Results: Feeding mice with a HFD resulted in obesity (body weight was increased by 83 %) and severe insulin resistance (plasma glucose and insulin levels were elevated by 2.0- and 4.8-fold, respectively). Furthermore, mice on a HFD had significantly elevated plasma leptin and resistin levels. E2 administration to HFD mice decreased body weight by 22%, improved glucose tolerance and increased insulin sensitivity. Plasma insulin levels, as well as levels of leptin and resistin, were significantly decreased after E2 treatment. The expression of the genes encoding resistin and leptin were reduced in WAT in E2-treated animals. Furthermore, TG levels were lowered in WAT,

although they were not changed in the liver. Expression levels of lipogenic genes such as SCD1, FASN and SREBP1c were significantly decreased in WAT, whilst in liver, only expression of SCD1 was reduced to the same extent after E2 treatment.

Conclusion: HFD induces obesity and insulin resistance in aged female mice. Treatment with E2 markedly reduces these changes. These effects of E2 are probably mediated by down-regulation of lipogenic genes in WAT and liver. Supported by Swedish Research Council, KaroBio AB

Progesterone increases glucose tolerance in STZ-induced glucose intolerant rats

M. M. Faas, G. van der Schaaf, P. de Vos;
Division of Medical Biology, Dept of Pathology and Laboratory Medicine,
University Medical Centre Groningen, The Netherlands.

Background and Aims: The normal pancreas has a high regenerative capacity: during pregnancy the beta cell mass increases, which is due to an increased insulin demand, but also to stimulation by the pregnancy hormone, progesterone. Although studies into the regenerative capacity of the diabetic pancreas are scarce, it has been suggested that the diabetic beta cell mass can increase, but does not respond to an increased insulin demand. We hypothesize that the diabetic pancreas can grow, if appropriately stimulated. Therefore in the present study we treated STZ-induced glucose intolerant rats with progesterone.

Materials and Methods: Glucose tolerance was induced by STZ (30 mg/kg b.w.) (GI-rats) and after 4 weeks rats were treated with progesterone implants or sham implants; control untreated rats were also used. One, 2 and 3 weeks after the start of the progesterone/sham treatment, IVGTT were done and 3 weeks after the start of the progesterone/sham treatment rats were sacrificed, pancreata snapfrozen and percentage proliferating beta cells (KI-67 immunostaining), percentage beta cell area and stem cell number (nestin, c-kit and c-met positive cells) in the pancreas was evaluated.

Results: Progesterone treatment decreased the area under the curve (AUC) for glucose significantly after 3 weeks of treatment as compared with AUC before progesterone treatment (fig 1). The AUC for insulin after the IVGTT increased with time after treatment with progesterone as compared with before treatment (fig 1).

Despite the increase in insulin response during the IVGTT, 3 weeks after progesterone treatment the percentage beta cell area was only slightly increased (GI-rats: 0.55±0.11% vs GI-rats treated with progesterone 0.59±0.12% (not significant)). For comparison percentage beta cell area of control untreated rats was 0.72±0.074%. The slight increase in percentage beta cell area may be due to a significant increased number of proliferating beta cells in GI-rats treated with progesterone as compared with untreated GI-rats (1.08±0.077% vs 0.58±0.1% respectively, $p < 0.05$; control rats: 0.13±0.05%). Neogenesis was increased in progesterone treated GI rats, since the percentage of small beta cells clusters (1–5 beta cells) was significantly increased in GI rats treated with progesterone as compared with untreated GI rats (49.6±1.4% vs 40.6±3.9%, respectively, $p < 0.05$; control rats: 43±2.1%). Moreover, increased numbers of nestin or c-met positive cells in the islets and increased numbers of c-met positive cells around the ductules were found in progesterone treated GI-rats as compared to sham treated GI-rats.

Conclusion: The present results show that progesterone treatment of GI rats increased glucose tolerance and insulin responses. This may be due to proliferation of beta cells and neogenesis, resulting in a slightly increased beta

cell mass at the time of sacrifice. It seems therefore that the beta cell mass of diabetic rats can grow with appropriate stimulation, such as progesterone.

Effects of estrogen replacement therapy on tissue antioxidant status: impact of OVX in diabetic state

A. Ceylan-Isik¹, O. Erdogan-Tulmac², F. Aktan³, N. Ari¹, G. Ozansoy¹;
¹Pharmacology, University of Ankara, Faculty of Pharmacy, ²Gynecology, Zekai Tahir Burak Women Helath, Education and Research Hospital, ³Biochemistry, University of Ankara, Faculty of Pharmacy, Ankara, Turkey.

Background and Aims: Diabetes is closely related with the generation of reactive oxygen species (ROS) and ovarian hormone deficiency is also related with this phenomenon. The excess production of ROS induces oxidative stress which results in cell damage or death. The aim of the present study is to investigate the effects of 17- β estradiol (E_2) on antioxidant status of aorta, uterus, liver and kidney from diabetic- and nondiabetic-ovariectomized (OVX) rats.

Materials and Methods: OVX (n=8), OVX+E₂ (n=8), OVX+DIA (n=8), OVX+DIA+E₂ (n=8) were used as experimental groups. Bilateral ovariectomy was applied to the animals under anesthesia. Diabetes was induced by streptozotocin (STZ; 45 mg/kg i.p.) a week after the operation, and rats having blood glucose ≥ 150 mg/dl were accepted as diabetic. After 8 weeks rats were anesthetized and the tissues were removed, weighed and frozen at liquid nitrogen. Blood glucose (BG), total cholesterol (CH), triglyceride (TG) and plasma E_2 concentrations have been measured as final values. Malondialdehyde (MDA) levels, glutathione peroxidase (GPx) and catalase (CAT) activities were measured by fluorimetric and spectrophotometric methods.

Results: Although BG concentration was not affected ($P > .05$ vs. OVX+DIA+E₂), CH and TG concentrations were significantly reduced in diabetic group by the treatment ($P < .05$ vs. OVX+DIA+E₂). The treatment also increased plasma E_2 concentrations in the treated groups ($P < .05$ vs. OVX and OVX+DIA). (Tab. 1–3)

Conclusion: Ovarian hormone deficiency led to alteration in lipid peroxidation and free radical scavenging enzyme systems, and diabetes has a major contribution in this situation. This study demonstrated that E₂ replacement therapy has therapeutical importance to regulate in alteration of free radical-induced changes of OVX in both diabetic and non-diabetic condition.

0682

A study of the serotonergic tone in healthy subjects and diabetic patients treated by a clinical-paedagogic approach (Group Care) or traditional care

M. Trento¹, P. Tibaldi¹, M. Balbo², C. Kucich¹, M. Basile¹, M. Tomellini¹, P. Passera¹, R. Giordano², F. Cavallo³, E. Arvat², M. Porta¹;

¹Internal Medicine, Laboratory of Clinical Paedagogic,

²Internal Medicine, Division of Endocrinology, Italy,

³Department of Public Health and Microbiology, Department of Public Health and Microbiology, University of Turin, Italy.

Background and Aims: Alterations of mood and depression may be associated with type 2 diabetes (T2DM) and impaired glucose metabolism in non-diabetic people. Central serotonergic activity may modulate glucose tolerance via neuroendocrine effectors. The serotonergic tone was assessed by measuring the hormonal response to a selective serotonin reuptake inhibitor, citalopram, in non-diabetic subjects and patients with T2DM followed by either a traditional approach or a clinico-paedagogic intervention (Group Care) proven to improve quality of life and reduce anxiety.

Materials and Methods: Ten healthy subjects (age 53.20±3.92; males=5) and 13 patients with T2DM (age 60.92±3.52, known duration 17.38±5.85, males=10), 7 followed by Group Care and 6 by traditional care, underwent infusions of either citalopram 20 mg or saline over 120 min, in random order, at 8.30–9.00 am after overnight fasting. Samples were taken from an antecubital vein every 15 min for 4 hrs to measure circulating glucose, insulin, ACTH, free cortisol, DHEA, growth hormone (GH) and prolactin. Hormonal responses were calculated as differences between the areas under the curves after saline and citalopram (Δ-AUC).

Results: Citalopram increased ACTH and cortisol more than saline in healthy subjects (p<0.026 and p<0.011, respectively) and diabetic patients treated by Group Care (p<0.056 and p<0.038) but not in those followed by traditional care. The responses of DHEA, GH, prolactin, insulin and glucose to citalopram did not differ significantly from those to saline in any of the 3 groups. However, in the healthy subjects, basal glucose levels correlated directly with the GH Δ-AUC (r=0.820; p<0.004) and inversely with the insulin Δ-AUC (r=-0.822; p<0.003). The correlation between basal glucose and GH Δ-AUC was preserved in diabetic patients (r=0.637; p<0.026), in whom HbA1c correlated with basal glucose (r=0.657; p<0.015) and the insulin Δ-AUC (r=0.864; p<0.012), and the glycaemic Δ-AUC correlated with that of cortisol (r=0.698; p<0.012).

Conclusions: These results suggest that serotonergic tone may modulate glucose metabolism through opposite effects on ACTH, cortisol, insulin and GH secretion. Diabetes may blunt the response of the pituitary-adrenal axis, though not in patients followed by a long-term intervention model that encompasses clinical as well as cognitive and emotional factors.

Melatonin inhibits lipopolysaccharide-induced activities of cytokines and the hypothalamus-pituitary-adrenal axis in diabetic rats

L.-Y. Zhong;

Department of Endocrinology, Beijing Tiantan Hospital, Capital Medical University, Beijing, China.

Background and Aims: The relationship between melatonin (MLT) and the neuroendocrine-immune network is well characterized; however, little is known regarding the effects of MLT on stress such as severe infection in diabetes. The aim of this study was to determine the effects of MLT on lipopolysaccharide (LPS)-induced activities of serum cytokines and the hypothalamus-pituitary-adrenal (HPA) axis in streptozotocin (STZ)-induced diabetic rats and to analyze the parameters related to diabetes and oxidative stress.

Materials and Methods: A total of 50 male Sprague-Dawley rats were assigned to 5 groups. Four groups simultaneously received a single dose of STZ (50 mg/kg) intraperitoneally (i.p.). The diabetic group received STZ alone; the LPS group received STZ plus LPS (0.5 mg/kg) i.p. after induction of diabetes with STZ; the LPS+MLT_{0.1mg} and LPS+MLT_{1mg} groups received 0.1 and 1 mg/kg melatonin i.p., respectively, q6h for 12 h after LPS administration; and the remaining 10 rats served as control.

Results: LPS significantly increased the serum levels of tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6) in diabetic rats; it also dramatically increased the plasma concentrations of corticotropin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and corticosterone. Both 0.1 and 1 mg/kg MLT doses significantly decreased the serum levels of TNF-α and IL-6. Significant inhibitory effects of melatonin (1 mg/kg) were observed on the plasma concentrations of CRH, ACTH, and corticosterone of the HPA axis. The beneficial effects of MLT, such as the antioxidative stress effect and maintaining glucose homeostasis, were also observed in this study.

Conclusion: MLT significantly inhibited the increase in the serum levels of cytokines and appropriately ameliorated LPS-mediated HPA axis activation, which this resulted in a protective effect against the damages caused by LPS in STZ-induced diabetic rats. This finding provides a new approach for preventing the undesirable effects of the vicious cycle of hyperglycemia and stress factors such as severe infection in diabetic patients.

Neuroendocrine markers in streptozotocin (STZ)-induced type 1 diabetes

Y. Revsin^{1,2}, M. S. Oitzl¹, F. E. Saravia², A. F. De Nicola², E. R. de Kloet¹;

¹Division of Medical Pharmacology, LACDR, Leiden University,

The Netherlands, ²Laboratory of Neuroendocrine Biochemistry, IBYME, Buenos Aires, Argentina.

Background and Aims: Type 1 diabetes (T1D) is a common metabolic disorder characterized by profound dysregulations in the hypothalamic-pituitary-adrenal (HPA) axis and severe disturbances in central nervous system (CNS) functions related to stress and adaptation. Reports from diabetic humans and animals showed HPA dysregulations, which become manifest as increased basal secretion of glucocorticoids. Among the alterations in the CNS functions, we previously described in uncontrolled streptozotocin (STZ)-induced diabetic mice changes in markers for astrogliosis and increased oxidative stress among others. Based on these results we hypothesize that glucocorticoids are the major trigger of these alterations.

Materials and Methods: Three months old C57BL/6J male mice were injected with STZ (170 mg/kg i.p.). Six days after diabetes onset, oral administration of high dose of RU486 (200mg/kg in 100μl p.o.) or vehicle was given during 4 days. We examined morphological-like numbers of hippocampal astrocytes and proliferative cells in the dentate gyrus, as well as molecular markers for key processes of HPA axis activation that control glucocorticoid hypersecretion such as MR, GR AVP and CRH mRNAs and circulating corticosterone and ACTH levels.

Results: In our model the HPA axis reached a new setpoint characterized by higher circulating corticosterone. Diabetic mice show increased plasma corticosterone, while plasma ACTH is decreased, and the expression mRNA of AVP in the paraventricular nucleus (PVN) of the hypothalamus is elevated

and hippocampal MR is decreased. These changes in HPA axis regulation suggest adrenal hypersensitivity. Adrenal function analysis exhibited increased expression of ACTH receptors and corticosterone hypersecretion from adrenal gland cell cultures challenged to ACTH- in diabetes. GR antagonist (RU486) treatment resulted in partial restoration of astrogliosis and neurogenesis alterations found in the brain of diabetic mice.

Conclusion: The profound disturbance in the HPA axis regulation, characterized by adrenal hypersensitivity to ACTH, provides evidence of the GR-mediated central role of glucocorticoids in diabetic neuropathology. A better understanding of these mechanisms may open up new avenues for therapeutically useful strategies to normalize neuronal disturbances and improve cognitive disabilities of diabetic patients.

Insulin resistance, beta cell function and glucose intolerance in acromegaly

R. Lichiardopol¹, M. Coculescu², D. Niculescu², C. Pencea¹, M. Vladica¹;

¹Clinic of Diabetes, Nutrition and Metabolic Diseases, "N.C. Paulescu" Institute, ²Neuroendocrinology, "C.I. Parhon" Institute of Endocrinology, Bucharest, Romania.

Background and Aims: Insulin resistance and glucose intolerance frequently occurs in acromegaly. Although excess secretion of growth hormone (GH) can reduce insulin sensitivity, it is unclear if insulin resistance per se may induce glucose intolerance. We aimed to evaluate the insulin resistance and beta-cell (β -cell) function, as the main mechanisms leading to glucose intolerance, in a group of patients with confirmed acromegaly.

Materials and Methods: This is a cross-sectional study of one hundred and twenty-six consecutive patients with acromegaly (80 women, 46 men) admitted in hospital between 2003–2006. Basal and 30 min plasma insulin (IRI), growth hormone (GH) levels (basal, 30, 60, and 120 min) during a 75 g OGTT, HbA_{1c} and anthropometric measures were determined. Insulin resistance (HOMA-IR) was estimated using the HOMA2 (computer-solved) model. The insulinogenic index (Ins index), normalized for insulin resistance [Δ IRI (30–0) μ U/ml*100/ Δ BG (30–0)mg/dl]/ HOMA-IR, was used to estimate the β -cell function. Data are presented as mean (\pm SEM) values. Kruskal-Wallis or ANOVA (as appropriate) was used to compare data across groups. Simple and multiple regression between variables and logistic regression analysis were performed. The EpiInfo software was used for analysis. A $p < 0.05$ was considered significant.

Results: According to WHO criteria, there were 41 subjects (23 women, 18 men) with glucose intolerance (GINT): 21 with IFG or IGT and 20 with diabetes. The remaining 85 subjects had normal glucose tolerance (NGT). As compared to NGT, the GINT group had greater mean values for age (56.1 ± 1.7 vs. 49.2 ± 1.4 yrs; $p < 0.003$), HbA_{1c} (6.6 ± 0.2 vs. $5.4 \pm 0.07\%$; $p < 0.001$), waist to hip ratio (0.917 ± 0.01 vs. 0.877 ± 0.008 ; $p < 0.015$) and reduced values for Ins index (40.8 ± 7.1 vs. 111.4 ± 20.2 ; $p < 0.001$). Compared to the third tertile, the patients within the first tertile of the Ins index distribution were seven times as likely to have prevalent glucose intolerance (Odds ratio= 7.4; 95% CI: 1.84–35.3; $p < 0.002$). Between the two groups (GINT vs. NGT), there were no significant differences regarding mean values for HOMA-IR (2.1 ± 0.3 vs. 1.7 ± 0.1 ; $p = 0.31$), basal GH (15.7 ± 2.7 vs. 16.3 ± 4.7 ng/ml; $p = 0.92$) and minimal GH levels during OGTT (13.1 ± 2.4 vs. 13.6 ± 2.2 ng/ml; $p = 0.88$), duration of the disease (5.9 ± 1.4 vs. 6.8 ± 0.85 yrs; $p = 0.58$), BMI (30.2 ± 0.8 vs. 29.1 ± 0.6 Kg/m²; $p = 0.28$), waist circumference (988.4 ± 22.4 vs. 937.9 ± 15.1 mm; $p = 0.08$). In simple linear regression analysis, HbA_{1c} was significantly correlated to area under the curve of plasma glucose levels during OGTT ($r = 0.557$; $n = 80$; $p < 0.001$), age ($r = 0.224$; $n = 95$; $p < 0.035$), Ins index ($r = -0.332$; $n = 69$; $p < 0.006$) and HOMA-IR ($r = 0.224$; $n = 83$; $p < 0.035$). In multiple regression analysis with a change of HbA_{1c} as the dependent variable, the following variables were significant: Ins index ($p < 0.03$), HOMA-IR ($p < 0.001$). In logistic regression analysis only Ins index was significantly correlated ($p < 0.03$) to glucose tolerance.

In conclusion, our data suggest that reduced insulin response, reflecting the failure of β -cells adaptation to increased insulin resistance, leads to glucose intolerance in acromegaly.

Experimental metabolic syndrome strengthens age-related hormonal changes in Syrian hamsters

A. L. Zagayko¹, L. N. Voronina¹, N. S. Krasova², V. V. Poltorak²;

¹Department of Biological Chemistry, National University of Pharmacy,

²Laboratory for Pathophysiology and Medical Genetics, Institute of Endocrine Pathology Problems, Kharkiv, Ukraine.

Background and Aims: It has been shown, that half unsaturated fat and fructose-enriched diet induces metabolic syndrome in Golden Syrian hamsters. The development of hyperinsulinaemia depends both of sex and age of animals: in the young, insulin resistance (IR) more significantly educes in males, but in the adult – in females. The aim of the study was to investigate the sex and age differences of steroid hormones content in Syrian hamsters with experimental metabolic syndrome (MS).

Materials and Methods: 72 Golden Syrian hamsters (males/females: 1/1) were investigated. The experimental groups (4-wk-old animals were formed the 1st group, 20-wk-old animals – the 2nd group and 1-y-old ones – the 3rd, 12 animals each) were submitted for 4 weeks to a diet containing 29 % vegetable and animal oils and fructose (2 g/100 g b. w./ day) – MS groups. A control group ($n = 36$, matched for age) was submitted to a standard diet. Plasma hydrocortisone, estradiol and testosterone levels were determined by ELISA. Fasting blood glucose and insulin (by RIA) were measured. Homeostasis Model Assessment (HOMA) was used to estimate IR. Statistical analyses were carried out using SPSS and Microsoft Excel.

Results: Hyperglycaemia, hyperinsulinaemia and IR were developed in hamsters fed a half unsaturated fat and fructose-enriched diet compared to controls. Both males and females of MS groups showed enhance of hydrocortisone levels (males: by 38 %, 40 %, 75 %; females: by 53 %, 21 % and 54 % in the 1st, 2nd and 3rd group, respectively, as compared to controls, $p < 0.05$). Thus, the tendency to hypercortisolaemia strengthened during aging. Age changes of estradiol content in MS groups demonstrated a typical trend, but were more pronounced. Estradiol levels in 4- and 20-wk-old hamsters with MS were higher in comparison with controls ($p < 0.05$), but in 1-y-old animals the estradiol levels were decreased (by 30 and 32 % in males and females, respectively, $p < 0.01$). In control males levels of testosterone were the highest at 20 weeks, whereas in MS males – at 4 weeks. Thus, 20-wk- and 1-y-old males with MS showed the reduction of testosterone content (by 18 and 16 %, respectively, $p < 0.05$), that could be explained due to transformation of the hormone to estradiol in fat tissue at 20 weeks, and downstroke of secretion in 1-y-old animals (that was accompanied by decrease in estradiol content).

Conclusion: Thus, the experimental metabolic syndrome strengthens age-related alterations of steroid hormones secretion in Golden Syrian hamsters of both sexes. The data suggest that not only an increase of predisposition to metabolic syndrome takes place with age, but also the development of the metabolic syndrome causes hormonal changes typical for aging.

PS 57 DPP-4

OGTT modulates GLP-1 but not DPP-IV levels in different glucose tolerance degree patients

I. Dicembrini¹, L. Pala¹, G. Bardini¹, S. Ciani¹, A. Pezzatini¹, B. Cresci¹, L. Buci¹, S. Giannini¹, E. Mannucci², C. M. Rotella¹;

¹Dep. of clinical Pathophysiology, Unit of Endocrinology,

²Geriatric Unit Dept of Critical Care, University of Florence, Italy.

Background and Aims: Glucagon-like peptide 1 (GLP-1) is a gut-derived incretin hormone that stimulates insulin and suppresses glucagons secretion, inhibits gastric emptying, and reduces appetite and food intake. A few minutes after its synthesis, GLP-1 is degraded by dipeptidylpeptidase-4 (DPP-IV). The reduced GLP-1 levels after an oral glucose load in type 2 diabetic patients could depend on a reduced synthesis or on an increased degradation; anyway GLP-1 and DPP-IV level during an OGTT are never studied. The aim of our study is to investigate GLP-1 and DPP-IV levels during a OGTT in different tolerance degree patients.

Materials and Methods: OGTT using 75 gr of glucose in a 50% water solution are performed in 46 subjects (30 F; 16 M), aged 58,9±11,4 ys; BMI 31,08±6,15 KG/m²; Waist 104±13 cm. After OGTT: Normal glucose tolerance (NGT) resulted in 22 subjects; Impaired glucose tolerance (IGT) in 10 subjects and Type 2 Diabetes (DMT2) in 14 subjects. GLP-1 assay was performed with an ELISA kit and DPP-IV assay was performed with a colorimetric method.

Results: Our data show a significant difference in the Area Under Curve (AUC) for glycemia among the three groups: NGT vs IGT ($p < 0.0001$), NGT vs DMT2 ($p < 0.0001$) and IGT vs DMT2 ($p = 0,007$). The AUC for GLP-1 results significantly different among the three groups, in particular there is a significant difference between NGT and IGT (199,1 pmol/L*min [117;343] vs 105,2 pmol/L*min [28,8;125,5] $p = 0.004$); between NGT and DMT2 (199,1 pmol/L*min [117;343] vs 84,7 pmol/L*min [52,03;184,07]), but not between IGT and DMT2. On the contrary, DPP-IV AUC presents no significant difference among the groups.

Conclusion: These results could suggest a different role between impaired GLP-1 synthesis and degradation in the preclinical and clinical evolution of Type 2 Diabetes. In particular, a reduction of GLP-1 synthesis could be involved in the early stages of diabetes and perhaps also in the preclinical phases while an increase of GLP-1 degradation could have a role in the late stages of diabetes or in metabolic failure.

Metformin is a GLP-1 secretagogue, not a dipeptidyl peptidase-4 inhibitor

R. Sinha Roy¹, R. Bergeron², L. Zhu¹, H. He¹, G. Jiang¹, F. Liu¹, K. Lyons¹, K. Pryor¹, J. Yao¹, B. B. Zhang¹, N. Thornberry¹;

¹Merck & Co., Inc., Rahway, United States,

²Department of Kinesiology, University of Montreal, Canada.

Background and Aims: Treatment of type 2 diabetic patients with a combination of metformin (MET) and a dipeptidyl peptidase-4 (DPP-4) inhibitor improves glucose control better than with either drug alone. The combined effects of MET and the DPP-4 inhibitor desfluorositaagliptin (DF-SITA) on plasma GLP-1 levels were studied in mice using immunoassays selective for active and inactive GLP-1 (truncated by DPP-4 cleavage).

Materials and Methods: Lean, diet-induced obese (DIO) C57BL/6N, or *db/db* mice were dosed orally with vehicle (0.5% carboxy-methylcellulose), MET (500 mg/kg), DF-SITA (100 mg/kg), or MET+DF-SITA with or without oral administration of glucose (3 g/kg). Plasma DPP-4 activity and active/inactive GLP-1 levels were measured for up to 6 hrs post-dose.

Results: MET rapidly increased plasma inactive GLP-1 3-5 fold for as long as 6 hrs in both fed and fasted animals. Active GLP-1 was not significantly increased, reflecting rapid cleavage by DPP-4. During this period, preproglucagon mRNA was increased in the gut but not in the pancreas of MET-treated animals. MET treatment appeared to inhibit plasma DPP-4 activity in DIO mice. *In vitro* studies, however, demonstrated that MET does not directly inhibit DPP-4. MET+DF-SITA consistently increased active GLP-1 levels 2-3 fold in both fed and fasted animals, but some inactive GLP-1 remained in circulation. Combination treatment produced lower levels of

total GLP-1 than with MET alone. The improvement in glucose tolerance with MET treatment was not further improved by DPP-4 inhibition, and was not dependent on GLP-1 receptor signaling.

Conclusion: Metformin increases plasma GLP-1, which can be protected from rapid inactivation by co-administration of a DPP-4 inhibitor. Metformin reportedly decreases shedding of membrane-associated DPP-4, which can decrease plasma enzyme activity *in vivo*. MET increases plasma glucagon in mice, which counteracts the glucose lowering effects of elevated plasma GLP-1. The absence of additive glucose lowering effects is likely a murine-specific phenomenon given the additive effects of metformin and DPP-4 inhibitors in the clinic.

Pharmacodynamic characteristics of SK-0403, a novel highly selective dipeptidyl peptidase IV inhibitor, in animal models

Y. Yasuda¹, M. Goto¹, K. Nakaya¹, S. Kawamura¹, S. Furuta¹, M. Tamura¹, N. Kato¹, T. Ishida², Y. Matsumoto¹;

¹Pharmaceutical Research Laboratories, SANWA KAGAKU KENKYUSHO CO.,LTD., Mie, ²Project Development Dept., SANWA KAGAKU KENKYUSHO CO.,LTD., Nagoya, Japan.

Background and Aims: Dipeptidyl peptidase-IV (DPP-IV) inhibitor is well known as a new class of oral agent for type 2 diabetes (T2D). It is generally accepted that 80% inhibition of plasma DPP-IV is sufficient to elevate intact incretins and improve glycemic control. However, it is unknown whether the IC₅₀ of DPP-IV inhibitor in systemic circulation is sufficiently high to protect the rapid degradation of glucagon-like peptide-1 (GLP-1), which is secreted from the intestine in response to nutrient ingestion. The aims of the present studies were to investigate the *in vitro* and *in vivo* profiles of SK-0403, a novel DPP-IV inhibitor currently under development for the treatment of T2D, and to clarify the relationship between higher DPP-IV inhibition (over 80%) and degradation of intact GLP-1.

Materials and Methods: In an *in vitro* study, the inhibition for DPP-IV and selectivity for DPP-IV related peptidases including DPP8, DPP9, fibroblast activation protein α (FAP) and other enzymes were investigated. In an *in vivo* study, the effects of SK-0403 on plasma DPP-IV activity were assessed in rats and dogs. A glucose lowering action in rats and mice and an active GLP-1 enhancement in rats was investigated. To evaluate systemic metabolism of GLP-1 by DPP-IV, GLP-1 was infused to rats from the femoral vein after oral administration of SK-0403. Plasma DPP-IV activity and active GLP-1 were measured before and after administration of SK-0403 and GLP-1.

Results: SK-0403 showed an IC₅₀ of 3.3 ± 0.3 nmol/L (mean ± SD) for recombinant human DPP-IV and more than 17,000-fold higher selectivity with recombinant human DPP8, DPP9, FAP and other enzymes. In dogs, a single oral dose of SK-0403 dose-dependently suppressed plasma DPP-IV activity, and DPP-IV inhibition was long-lasting compared with vildagliptin (66% for 10 mg/kg SK-0403 vs. 13% for 30 mg/kg vildagliptin at 24 h after administration). In C57BL6 mice, potency of SK-0403 in reduction of plasma glucose excursion during OGTT was almost equal to that of sitagliptin at doses of 0.3 to 3 mg/kg. Furthermore, in diabetic rats, SK-0403 (1, 3 and 10 mg/kg) exhibited the dose-dependent improvements of plasma glucose and insulin during OGTT. When GLP-1 was intravenously infused to rats after oral administration of SK-0403, active GLP-1 in plasma significantly increased to 353 ± 20 pmol/L at IC₅₀ for DPP-IV of SK-0403 compared with control (129 ± 3 pmol/L). In addition, active GLP-1 was increased with SK-0403 (from 1- to 10-fold IC₅₀) in a concentration-dependent manner and reached a maximum of 445 ± 33 pmol/L at 10-fold IC₅₀ ($p < 0.05$ vs. IC₅₀). The concentration-dependent effect of SK-0403 on GLP-1 degradation was also confirmed based on the experiment in which endogenous active GLP-1 after an oral carbohydrate load increased 1.9 times at 10-fold IC₅₀ compared to the IC₅₀.

Conclusion: SK-0403 is a potent and highly selective DPP-IV inhibitor. SK-0403 at IC₅₀ for DPP-IV activity in circulation may not be sufficient to protect degradation of GLP-1 because metabolism of GLP-1 is attributed to DPP-IV hydrolysis in tissues as well as plasma. These results show for the first time that over 80% inhibition of plasma DPP-IV is required to more effectively avoid systemic degradation of GLP-1, and they suggest that SK-0403 with appropriate dose-titration is promising for the treatment of T2D.

0690

Increased beta cell replication and mass in 95% pancreatectomized rats treated with a DPP-IV stabilized GLP-1 analogue

G. Joanny, N. Téllez, E. Estil-les, M. Nacher, S. Rodríguez-Mulero, E. Montanya;

Lab. Diabetes and Experimental Endocrinology, IDIBELL, L'Hospitalet de Llobregat, Spain.

Background and Aims: The incretin hormone GLP-1 has a well known insulinotropic action and some more recently reported positive effects on beta cell viability and proliferation. The very short life of GLP-1 makes it unsuitable as a therapeutic agent, and has fostered the search for GLP-1 analogues with extended action. The aim of this study was to determine the effects of a new DPP-IV stabilized GLP-1 analogue on beta cell growth and metabolic control in partially pancreatectomized rats, a model of beta cell regeneration.

Materials and Methods: The GLP-1 analogue used in this study is a DPP-IV stabilised GLP-1 analogue which has been derivatised with a chemical moiety that binds to albumin in a reversible manner thereby extending the plasma half life to at least one day. SD rats underwent 95% partial pancreatectomy (95%-Px) and were treated with the GLP-1 analogue (100 µg/kg · day, IP once daily) or vehicle from day 1 (when 95% Px was performed), to day 15 (when pancreatic remnants were harvested). Allocation of pairs of same day pancreatectomized animals to gastrin- and vehicle-treated groups was blinded. Blood glucose and body weight were monitored on days 1, 3, 7, 10 and 15. A group of animals of similar body weight underwent a 95% Px and had the pancreatic remnant harvested immediately after surgery. An additional control group of sham-Px rats (n=6), had the pancreas harvested after 15 days of follow up. Beta cell mass and cross-sectional individual beta cell size was determined by morphometry, and beta cell replication by BrdU incorporation, in insulin stained sections of harvested pancreatic remnants and pancreases.

Results: 95%-Px rats treated with vehicle developed severe hyperglycemia (day 15: 516 ± 41 mg/dl) that was prevented in GLP-1 analogue-treated rats (day 15: 216 ± 36 mg/dl, $p < 0.05$). Beta cell mass after 95% Px was 0.34 ± 0.09 mg, and was 34% higher (0.45 ± 0.13 mg, $p = ns$) in vehicle-treated rats. GLP-1 analogue treatment increased significantly the beta cell mass (0.90 ± 0.08 mg) ($p < 0.05$). Beta cell replication in 95%-Px rats treated with vehicle was 40% higher than in the normal pancreas of sham-Px rats (vehicle: 1.02 ± 0.2%; sham: 0.72 ± 0.2%, $p = ns$). GLP-1 analogue increased beta cell proliferation (1.64 ± 0.2%, $p < 0.05$ vs sham-Px and vehicle). The individual beta cell size was similar in GLP-1 analogue- and vehicle-treated 95%-Px rats (260 ± 14 µm² vs 251 ± 24 µm²) and higher than sham-Px rats (197 ± 16 µm²), indicating that GLP-1 analogue had no effects on beta cell hypertrophy. The number of scattered beta cells (groups of <5 beta cells) considered an indirect marker of islet neogenesis, was similar in GLP-1 analogue-treated (6.81 ± 0.5%), vehicle-treated (6.16 ± 0.7%) Px rats.

Conclusion: The treatment with the long-acting GLP-1 analogue stimulated beta cell replication, increased beta cell mass in 95%-Px rats, and prevented the development of severe hyperglycemia, supporting its potential in the treatment of diabetes.

The dipeptidyl peptidase 4 inhibitor vildagliptin has no acute effect on the endocrine secretion in the isolated perfused porcine pancreasK. R. Hjøllund¹, T. E. Hughes², J. J. Holst¹;¹Department of Biomedical Sciences, The Panum Institute, Copenhagen, Denmark,²Novartis Institutes for biomedical research, Cambridge, United States.

Background and Aims: Inhibitors of dipeptidyl peptidase 4 (DPP-4) are being developed as a treatment for type 2 diabetes because they enhance the metabolic stability of glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) in the body and improve glycemic control. It is not known, however, whether the inhibitors influence the pancreatic islets directly or influence the activity of pancreatic neuropeptides such as pituitary adenylate cyclase-activating peptide (PACAP) which is a known DPP-4 substrate. The effects of DPP-4 inhibition on direct metabolic stimulation of islet secretion by glucose and arginine are also unknown.

Material and Methods: The effect of DPP-4 inhibition was examined using isolated perfused porcine pancreas with (n = 10) or without (n = 15) intact vagal innervation. Insulin, glucagon, somatostatin and vasoactive intestinal peptide (VIP) secretion were measured in response to electrical vagus stimulation at 8 Hz, and during PACAP (1 nM), arginine (5mM) and glucose (11mM) infusion. All stimuli were applied 3 times namely before, during and after vildagliptin (1 µM) infusion. In addition, control experiments (n = 7) with identical protocols but no addition of vildagliptin during the middle stimulation period were carried out for comparison.

Results: Vagus stimulation and PACAP increased insulin, glucagon and VIP secretion ($p < 0.05$), but the presence or absence of vildagliptin had no influence on these responses. Arginine strongly stimulated the release of all three islet hormones, which was not altered by vildagliptin. Glucose increased the secretion of insulin and somatostatin ($p < 0.05$) and inhibited glucagon secretion, again unchanged by vildagliptin. A comparison of the control experiments with no vildagliptin infusion and that involving vildagliptin infusion during the middle stimulation period similarly indicated that addition of vildagliptin did not modify the responses to any applied stimulus.

Conclusion: Taken together, these findings indicate that DPP-4 expressed in the pancreas does not exert any influence of pancreatic endocrine secretion whether stimulated by cholinergic or noncholinergic neural mechanisms or by metabolic stimuli. Rather vildagliptin acts by prolonging the circulating half-life and thereby increasing the circulating plasma concentration of L- and K-cell derived incretin hormones.

Retrograde intracolonic infusion of free fatty acids as a novel approach to directly stimulate GLP-1 release by rat intestinal L-cells in vivo

R. Iakoubov^{1,2}, P. L. Brubaker^{1,3},

¹Physiology, University of Toronto, Canada,

²Internal Medicine I, Merheim Medical Center, Cologne, Germany,

³Medicine, University of Toronto, Canada.

Background and Aims: Glucagon-like peptide-1 (GLP-1) is a potent stimulator of glucose-dependent insulin secretion that is secreted by the distal intestinal L-cell in response to nutrient ingestion. Our lab has identified long-chain monounsaturated fatty acids (LC-MUFA) as particularly important regulators of GLP-1 secretion, not only initiating a neural pathway from the duodenum to enhance release, but also exerting direct stimulatory effects on the ileal and colonic L-cells. To avoid the complicating effects of the neural regulation of the L-cell in vivo, we have investigated the influence of LC-MUFA on GLP-1 secretion in rats following intracolonic (IC) infusion of the LC-MUFA, oleic acid (OA).

Materials and Methods: Male Wistar rats (250–300 g) were fed a bowel cleansing solution (Klean-Prep®) for 48 hours and fasted for the last 12 hours. The rats were then anesthetized with isoflurane and the bowel further cleansed with saline solution. The appropriate volume of the IC infusate and its distribution within the rat distal intestine was established by barium sulfate-assisted X-Ray imaging. The carotid artery was cannulated for blood sampling and an enema was then performed using a silicone catheter with 25 ml OA (125 mM) or vehicle (16% TWEEN 80); each group consisted of 4 animals. Blood samples were collected at 0, 5, 15, 30 and 60 min, and plasma levels of bioactive GLP-1, insulin and glucose were determined by ELISA, RIA and glucose analyzer, respectively. Statistical analysis was performed with GraphPad Prism software using one-way ANOVA followed by Tukey's HSD post hoc test.

Results: IC infusion of barium sulfate followed by X-Ray imaging showed that administration of 25–30 ml of solution allowed complete coverage of the colon, caecum and terminal ileum, the known locations of most intestinal L-cells, and did not cause any damage to the animals as determined by lack of leakage and normal recovery for several days thereafter. The basal plasma concentration of bioactive GLP-1 in fasted rats was 7.5 ± 3.3 pM. IC infusion of OA induced a progressive increase in plasma GLP-1 levels, by up to 316 ± 42% of basal at 60 min ($p < 0.05$). The OA treatment also increased the GLP-1 AUC, as compared with controls ($p < 0.05$). Vehicle alone did not increase GLP-1 levels. Plasma insulin and glucose concentrations did not differ between the groups, although insulin levels slightly decreased in both groups directly after initiation of the IC infusion.

Conclusion: Intracolonic OA infusion directly stimulates GLP-1 release in vivo, independent of changes in insulin and glucose levels. These experiments demonstrate that retrograde intracolonic infusion is a reliable and non-invasive approach to directly stimulate GLP-1 release by the intestinal L-cell. *Supported by Banting and Best Diabetes Centre, the Canadian Diabetes Association and the Canada Research Chairs Programme*

0693

Cyclic AMP triggers glucagon-like peptide-1 secretion from GLUTag cells

F. Reimann, A. K. Simpson, P. S. Ward, A. M. Habib, K. Wong,

F. M. Gribble;

Dept. of Clinical Biochemistry, University of Cambridge, United Kingdom.

Background and Aims: Glucagon-like peptide-1 (GLP-1) is an incretin hormone secreted from enteroendocrine L-cells in response to food ingestion, which enhances insulin release from pancreatic β -cells. Understanding the pathways involved in GLP-1 release is essential for the development of oral GLP-1 secretagogues, which would add to the group of GLP-1 based therapies for the treatment of type 2 diabetes. Some of the most reliable stimuli for GLP-1 release in different model systems act by increasing intracellular cyclic AMP (cAMP) concentrations, but the downstream signalling mechanisms remain unclear. The aim of the current study was to investigate the pathways by which cAMP stimulates GLP-1 secretion, using the GLUTag cell line.

Materials and Methods: GLP-1 release from GLUTag cells was assayed by ELISA following 2 hour incubations in the presence of test agents. cAMP concentrations were measured by ELISA after 15 min test agent incubations in the presence of IBMX (10 μ M). Intracellular calcium ($[Ca^{2+}]_i$) was monitored by single cell fluorescence imaging in cells loaded with fura-2 AM. Electrophysiology was performed by perforated patch experiments.

Results: Pituitary Adenylate Cyclase-Activating Polypeptide (PACAP) dose-dependently stimulated GLP-1 release to a maximum of ~2-fold from GLUTag cells, and at 100 nM increased cAMP levels 1.5-fold. PACAP (100 nM) or forskolin plus IBMX (fsk/IBMX, 10 μ M each) triggered a rise in $[Ca^{2+}]_i$ and enhanced the response to glucose by increasing both the number of responsive cells and the magnitude of the calcium rise in individual cells. Fsk/IBMX also stimulated GLP-1 release and $[Ca^{2+}]_i$ elevation in the absence of added nutrients. In patch clamp experiments no significant effect was observed on the magnitude of voltage gated calcium currents. Fsk/IBMX triggered membrane depolarisation of $+5.3 \pm 1.1$ mV ($n=6$, $p < 0.01$) and an increase in the mean action potential frequency from 0.07 ± 0.05 to 0.4 ± 0.1 Hz ($n=6$, $p < 0.05$). This was associated with changes in the properties of two ion conductances. Hyperpolarisation activated currents (I_h) exhibited a right shift in their voltage-dependence: $V_{0.5}$ shifting from -85.7 ± 1.9 mV to -72.1 ± 1.7 mV ($n=6$; $p < 0.001$). Inhibition of I_h currents by ZD7288 (10 μ M), did not however, prevent fsk/IBMX-triggered membrane depolarisation. In the presence of ZD7288 we found that fsk/IBMX also closed a background potassium conductance. This was distinct from K_{ATP} as it was still observed in the presence of tolbutamide (500 μ M). In addition to its direct effect on the membrane potential, fsk/IBMX potentiated secretion downstream of membrane depolarisation, as it stimulated GLP-1 secretion 2.3 ± 0.2 -fold ($n=4$) in the presence of 30 mM KCl plus diazoxide (340 μ M).

Conclusion: cAMP acts as both a trigger and a potentiator of GLP-1 release from GLUTag cells. The triggering pathway is associated with a shift in the voltage-dependence of hyperpolarisation activated currents and closure of a background potassium conductance, both of which tend to depolarise the membrane and make cells more responsive to other depolarising stimuli. The ability of cAMP to trigger GLP-1 release in the absence of nutrient could provide a pathway for the indirect stimulation of L-cells lower in the gut, where levels of luminal nutrients are low. Cyclic AMP elevating pathways and the cAMP modulated conductances in L-cells present important targets for the development of therapeutic GLP-1 secretagogues.

0694

Regulation of peptide hormone release from neuroendocrine cells in the gut and the pancreas

S. Leicht, P. Eickelmann, S. Mayet;

Boehringer-Ingelheim, Biberach, Germany.

Background and Aims: GLP-1 (Glucagon-like-peptide 1) is an important incretin hormone released by L-cells in the small intestine and upper colon in response to nutrients and hormones. GLP-1 has different metabolic effects; one important task is the stimulation of insulin release in the β -cells of the pancreas. L-cells and β -cells exhibit similarities in their receptor expression profiles and in their signaling pathways which are responsible for the GLP-1 and insulin release. Recently, a number of G-protein coupled receptors have been deorphanized as receptors for different nutrient factors like fatty acids, peptides or lipids and bile acids, which play a physiological role in GLP-1 and/or insulin release. Focus of the current study are GPR40, GPR120 and GPR119 and their signal transduction pathways in L-cells and β -cells for the GLP-1 and insulin release.

Materials and Methods: The receptor expression of the GPCRs was determined in STC-1, NCI-H716, INS-1E and Min6 cell lines as well as in rat ileum, colon and islets using Taqman analysis. Protein expression was investigated with Western blots as well as immunofluorescent staining in the various tissues. GLP-1 release from STC-1 cells and colon slices upon stimulation with different receptor ligands was measured using ELISA (Linco). Insulin release from INS-1E, Min6 cells and isolated rat islets was measured by ELISA as well. Direct measurements of receptor activation was measured using the Calcium 3 FLIPR kit (Molecular Devices) or the HTRF IP1 kit (GBO) for Gq-coupled receptors GPR40 and GPR120, elevation of cAMP by activation of GPR119 was examined by cAMP Alpha Screen (Perkin Elmer).

Results: The Taqman analysis showed that GPR40, GPR119 and GPR120 are expressed in all investigated cell lines, in primary islets and in the intestine. The protein expression of the receptors could be confirmed by Western Blot analysis in colon, ileum and STC-1 cells. In the STC-1 cells as well as in colon slices stimulation of GPR119, GPR40 and GPR120 by their natural or small molecule ligands led to a GLP-1 release in a concentration-dependent manner. Activation of GPR40 and GPR120 by their natural or small molecule ligands caused an increase in Ca^{2+} and IP1 levels in cell lines stably transfected with the human receptors. In STC-1 cells increase in IP1 concentration could also be measured. In INS-1E, Min6 cells and isolated islets, activation of the receptors led to an increased, glucose dependent insulin secretion. Whereas stimulation of the Gq signaling pathway with increase in intracellular Ca^{2+} seems to have direct effects on insulin and GLP-1 release, Gs-coupled increase of cAMP has only modulatory effects on either glucose-stimulated insulin secretion from β -cells or Calcium-mediated GLP-1 secretion from L-cells.

Conclusion: These results show that GPR120 and/ or GPR40 contribute to the GLP-1 release from L-cells and insulin release from β -cells via generation of IP3 and release of intracellular Calcium. The Gs-coupled receptor GPR119 also plays an important role in modulation of primary secretagogue effects of nutrients and glucose, respectively.

0695

Expression of glucose-sensing machinery in intestinal GLP-1 secreting cells

A. M. Habib, F. Reimann, H. E. Parker, F. M. Gribble;
Clinical Biochemistry, Cambridge University, United Kingdom.

Background and Aims: Glucagon-like peptide 1 (GLP-1) is secreted from intestinal L-cells in response to oral carbohydrate and promotes insulin secretion from pancreatic β -cells. The ability of L-cells to sense glucose directly is controversial because L-cells lie scattered throughout the intestinal epithelium, therefore restricting investigations to partially enriched primary cell cultures or cell lines. The aim of this study was to generate transgenic mice with fluorescently labeled L-cells, and to use this model to investigate the expression in L-cells of genes implicated in glucose sensing.

Materials and Methods: Transgenic mice expressing yellow fluorescent protein (Venus) driven by the proglucagon promoter were made using a bacterial artificial chromosome containing the proglucagon gene. Colocalization of Venus and GLP-1 was confirmed by immunofluorescence (IF) microscopy. Venus-positive and control negative gut epithelial cells were separated by FACS, and used to isolate RNA and cDNA. Expression of genes of interest in sorted cells was measured by real time PCR and expressed relative to that of β -actin.

Results: Several transgenic founders were obtained, from which six lines were established with different transgene copy number. All lines showed Venus-expression in the gut restricted to GLP-1 positive cells by IF. When colonic tissue was digested to single cells and sorted by FACS, ~0.3 % of the cell population exhibited Venus fluorescence. Real time PCR revealed that FACS-sorted positive cells contained ~27000-fold more glucagon mRNA than non-fluorescent (control) cells collected in parallel, confirming the identity of Venus positive cells as L-cells. Our previous studies on the GLP-1 secreting cell line, GLUTag, showed that both ATP-sensitive potassium (K_{ATP}) channels and sodium-glucose cotransporters (SGLTs) contribute to the glucose-triggered depolarisation that initiates GLP-1 release. In FACS-positive colonic cells, expression of the K_{ATP} channel subunit Kir6.2 was 250-fold higher than that in negative cells, and 9-fold higher than in GLUTag cells. Expression of the sulphonylurea receptor (SUR1) was also enhanced 200-fold in L-cells relative to negative cells, and 14-fold relative to GLUTag cells. SGLT1 was expressed in negative cells from ileum and colon, consistent with its function in glucose absorption. Its expression was enhanced 5-fold in ileal L-cells and 10-fold in colonic L-cells compared with respective negative cells, and 6-14-fold relative to GLUTag cells. SGLT3a expression in ileal L-cells was 2-fold higher than in GLUTag cells, but was barely detectable in control ileal cells or in colonic cells. Of the facilitative transporters, GLUT1 was detectable in all cell types, GLUT2 and GLUT3 were expressed at low levels in all ileal and colonic cells, whilst GLUT5 expression was enhanced 58-fold in colonic L-cells relative to controls, and 1.5-fold relative to GLUTag cells. We were unable to detect the sweet taste receptor Tas1R2 in gut epithelial cells, while its partner, Tas1R3, was expressed at similar (low) levels in both positive and negative cells from ileum and colon.

Conclusion: We have developed transgenic mice exhibiting L-cell-specific expression of Venus. Real time PCR revealed expression in FACS-sorted L-cells of K_{ATP} channel subunits (Kir6.2 and SUR1), SGLTs (1 and 3a) and GLUT1 and 5. Our results indicate that glucose-sensing machinery similar to that found in GLUTag cells, is present in native murine L-cells.

Evidence for the role of the phosphodiesterase (PDE) isoform PDE4D in regulating glucagon-like peptide (GLP-1) secretion in the GLUTag cell line

W. Ong¹, M. D. Houslay², M. J. Lynch², G. S. Baillie³, N. J. Pyne¹, B. L. Furman¹;

¹Strathclyde Institute of Pharmacy & Biomedical Sciences, University of Strathclyde, United Kingdom, ²Institute of Biomedical and Life Sciences, University of Glasgow, United Kingdom.

Background and Aims: The reported increase in the synthesis and secretion of the major incretin GLP-1 in response to activation of adenylyl cyclase suggests a role for cyclic AMP (cAMP). Previous work indicated that PDE4 was probably the most important cAMP phosphodiesterases (PDE) relevant to GLP-1 secretion present in GLUTag cells, in which the PDE4 selective inhibitor rolipram potently inhibited PDE activity and augmented glucose-induced GLP-1 secretion. The present study aimed to determine which PDE4 isoform was functionally important.

Materials and Methods: GLUTag cells were transfected with a dominant negative PDE4D5 (PDE4D5DN; Asp556Ala) construct, containing a neomycin resistance gene and selected in 0.9 mg/ml geneticin (G418) for stable PDE4D5DN-transfected clones.

Results: In one clone (C3), RT-PCR with PDE4 primers showed elevated levels of PDE4 amplicons. This clone showed marked elevation in basal GLP-1 secretion relative to wild-type (WT) GLUTag cells (pmol/10⁶ cells/2h WT 0.114±0.016; C3 0.427±0.028 P<0.0001). Evidence for the role of cAMP in mediating the effects of the PDE4D5DN was obtained using the protein kinase A (PKA) inhibitor H89. In WT GLUTag cells, H89 failed to modify basal or glucose elevated GLP-1 secretion during a 2h incubation. GLP-1 secretion was increased in response to glucose (10mM) in C3 and glucose-induced, but not basal, GLP-1 secretion was suppressed by incubation with the PKA inhibitor H89 (10 μ M) [GLP-1 secretion (pmol/10⁶ cells/2h) basal 0.34±0.017; basal + H89 0.224±0.034; 10mM glucose 0.493±0.045; 10mM glucose + H89 0.3±0.021; ANOVA P<0.0001; H89 + glucose 10mM vs glucose 10mM P<0.01; n=6–8 wells from at least 2 separate experiments]. In both WT cells and cells stably transfected with PDE4D5DN, 24h pre-incubation with H89 (10 μ M) markedly suppressed basal and glucose induced GLP-1 secretion (e.g. in WT pre-treated with H89 for 24h, GLP-1 secretion (pmol/10⁶ cells/2h); basal 0.172±0.024; basal + H89 0.058±0.03 P<0.05 – Dunnett's post hoc).

Conclusion: These data suggest that GLUTag cells express functional PDE4D5, since abrogation of the activity of this isoform using a stably transfected dominant negative construct markedly augments both basal and glucose-induced GLP-1 secretion. The inhibition of glucose-induced GLP-1 secretion by H89 suggests that a role for PKA in the response to glucose in these cells. The marked inhibition of basal GLP-1 secretion by prolonged treatment with H89 in WT cells and in cells expressing the dominant negative PDE4D5 may suggest a role for cAMP in regulating GLP-1 synthesis.

Glucagon-like peptide 1 response to meals and post-prandial hyperglycaemia in type 2 diabetic patients

E. Mannucci¹, M. Monami¹, L. Pala², S. Ciani², L. Da Vico¹, C. Lamanna¹, G. Bardini², N. Marchionni¹, C. M. Rotella²;

¹Critical Care Medicine and Surgery, Unit of Gerontology

²Clinical Pathophysiology, Section of Endocrinology – University of Florence, Italy.

Background and Aims: The response of the intestinal insulinotropic hormone Glucagon-like peptide-1 (GLP-1) to meals is impaired in type 2 diabetic patients; this could contribute to the pathogenesis of impaired insulin secretion and post-prandial hyperglycemia. This study is aimed at

the assessment of the relationship between meal-induced GLP-1 and postprandial hyperglycemia in type 2 diabetic patients.

Materials and Methods: 21 drug-naïve type 2 diabetic patients aged (m±SD) 58.2±11.1 years and with a BMI of 32.1±7.2 kg/m² were studied. Blood glucose and active GLP-1 levels were measured 0, 30, 60, 90, and 120 min after a standard test meal. A continuous glucose monitoring (CGM) system with a subcutaneous sensor measuring glucose every 5 min was applied for the following 3 days, during which patients were invited to self-monitor accurately their food intake. Nutrient intake at each meal was calculated on the basis of patients' food records. For each patient, postprandial 120 min glucose incremental area under the curve (iAUC) was included in linear regression model exploring its relationship with total energy and carbohydrate intake, and the angular coefficient for total energy (EAC) and carbohydrate (CAC) was calculated.

Results: GLP-1 levels peaked 30 min after the test meal. Logarithmically transformed 60-min GLP-1 iAUC showed a significant inverse correlation with HbA1c (p<0.01). A significant inverse correlation of 60-min GLP-1 iAUC was also observed with EAC and CAC (both p<0.01), meaning that patients with a lower GLP-1 response to the test meal had a higher increment of postprandial glucose for each additional unit of total energy or carbohydrate intake.

Conclusion: In type 2 diabetic patients, a lower GLP-1 response to meals is associated with a higher HbA1c, and with a greater degree of meal-induced hyperglycaemia, both in a meal test and during CGM in "real-life" conditions.

Increased growth and elevated IGF-1 serum concentrations in mice with an adipose tissue specific deletion of the Igf-1 receptor

N. Klötting¹, L. Koch², T. Wunderlich², M. Kern¹, K. Ruschke¹, J. C. Bruning², M. Blüher¹;

¹Department of Internal Medicine III, University of Leipzig, Germany,

²Department of Mouse Genetics and Metabolism, University of Cologne and Center of Molecular Medicine Cologne, Germany.

Background and Aims: Insulin-like growth factor-1 (IGF-1) and the IGF-1 receptor have been implicated in the regulation of adipocyte differentiation and lipid accumulation *in vitro*. To investigate the role of IGF-1 receptor *in vivo*, we created mice with fat-specific disruption of the IGF-1 receptor gene (FIGF-1RKO mice) using the Cre-loxP system.

Materials and Methods: Ten mice of each genotype of both sexes were studied from an age of 4 weeks up to 32 weeks of life. Body weight was recorded weekly up to an age of 14 weeks, and thereafter in 2-week intervals, body length (naso-anal length) was measured once at week 32. At an age of 16 weeks both sexes of a subgroup of twenty (10 FIGF-1RKO and 10 controls) underwent a food intake measurement over a time period of one week. The daily food intake was calculated as the average intake of chow within the time stated. Intraperitoneal (i. p.) glucose tolerance tests (GTT) and insulin tolerance tests (ITT) were performed at the age of 12 and 24 weeks.

Results: At an age of 14 weeks the FIGF-1RKO mice have remarkably increased somatic growth, most likely as a consequence of significant elevated IGF-1 serum concentrations compared with control mice. Higher circulating IGF-1 levels could be due to increased IGF-1 expression both in liver and epigonadal adipose tissue, suggesting that adipose tissue plays a role in the regulation of IGF-1 serum concentrations. FIGF-1RKO mice exhibit increased adipose tissue mass with a predominantly increased lipid accumulation in epigonadal fat pads. Insulin-stimulated glucose uptake into adipocytes was unaffected by the deletion of the IGF-1 receptor.

Conclusion: Thus, IGF-1 receptor signalling in adipocytes is not crucial for the development and differentiation of adipose tissue, but seems to participate in the regulation of IGF-1 serum concentration.

0699

Tumour necrosis factor (TNF) α induces canonical Wnt signaling and de-differentiation of mature 3T3-L1 adipocytes

B. Gustafson, U. Smith;

The Sahlgrenska Academy at Goteborg University, Lundberg Laboratory for Diabetes Research, Center of Excellence for Cardiovascular Research, Department of Molecular and Clinical Medicine/Diabetes, Goteborg, Sweden.

Background and Aims: Obesity is a central and causal part of insulin resistance and type 2 diabetes. Enlargement of adipocytes induces inflammation and macrophage recruitment into the adipose tissue with induction of a variety of inflammatory markers which can exert local effects or systemic effects in other tissues, such as liver and muscle. The source of secreted TNF α in adipose tissue is probably infiltrated macrophages. We have recently shown that TNF α maintains the canonical Wnt-signalling during differentiation of preadipocytes and, thereby, keeps the preadipocytes in a proliferating and undifferentiated state. In mature adipocytes, TNF α is able to activate the Toll like receptor 4 and NF κ B and, thereby, induce an inflammatory phenotype. In this study, we examined the effects of TNF α on the Wnt signalling pathway and inflammation in fully differentiated adipocytes.

Materials and Methods: Differentiated 3T3-L1 adipocytes (differentiation day 8) were incubated with or without TNF α (20 ng/mL) for 16 days. RNA was extracted and analysed with real-time PCR and immunoblots were performed on cell lysates. The effect of TNF α on adipocyte morphology was followed with microphotographs.

Results: TNF α induced de-differentiation of the adipocytes with a decrease in adipogenic genes such as peroxisome proliferator-activated receptor (PPAR) γ 2, CCAAT/enhancer binding protein (C/EBP) α , aP2, adiponectin and the glucose transporter (GLUT)4. During initiation of the

normal preadipocyte differentiation, the canonical Wnt-signalling is down-regulated combined with the degradation of the transcriptional activator beta-catenin. However, within 24 hrs, TNF α induced the expression of Wnt10b and stabilisation of beta-catenin in mature adipocytes. The Wnt signalling inhibitors Dickkopf (DKK)1 and soluble frizzled-related protein (sFRP)2 were down-regulated within 2 days of TNF α stimulation which is in agreement with the induction of beta-catenin. Surprisingly, however, the rate-limiting protein for beta-catenin degradation, Axin, was still present in spite of the fact that beta-catenin expression was stabilized. The presence of TNF α induced a number of proinflammatory molecules such as BMP4, Wisp2, MCP-1 as well as the macrophage-specific protein colony stimulating factor (CSF)2.

Conclusion: Unexpectedly, TNF α is able to induce canonical Wnt signalling with stabilisation of beta-catenin in mature 3T3-L1 adipocytes. At the same time, the adipocytes undergo de-differentiation with a decreased expression of adipocyte-specific markers and transcription factors such as PPAR γ 2 and C/EBP α . A proinflammatory and insulin-resistant phenotype is achieved with decreased GLUT4 expression and induction of proinflammatory molecules such as MCP-1. Thus, induction of Wnt secretion by cells in the adipose tissue leads to a dysregulated state with impaired differentiation and function of the mature adipose cells.

Wnt-signaling is maintained and adipogenesis inhibited by TNF α but not MCP-1 and resistin

A. Hammarstedt, P. Isakson, B. Gustafson, U. Smith;

Dept of Molecular and Clinical Medicine/Diabetes, Medicine, Göteborg, Sweden.

Background and Aims: Type 2 diabetes and obesity with enlarged fat cells are associated with low-grade systemic inflammation and impaired adipogenesis, as well as the recruitment of inflammatory cells into the adipose tissue. Cytokines like TNF α and IL-6 are secreted by the inflammatory cells and have been shown to impair normal adipocyte differentiation. An important mechanism whereby these cytokines inhibit adipogenesis is by maintaining an active Wnt-signaling pathway. Also other cytokines, like MCP-1 and resistin, are involved in the inflammatory process and are secreted by macrophages. If these cytokines also affect Wnt-signaling and adipocyte differentiation is currently unclear.

Materials and Methods: 3T3-L1 cells were differentiated to adipocytes under basal conditions or in the presence of TNF α , MCP-1 or resistin alone or in combination with a thiazolidinedione, pioglitazone. Cells were harvested at various time points during the adipocyte differentiation process and mRNA and protein expression levels quantified to study the effect of these cytokines on inflammation, Wnt-signaling and adipogenic markers. Each experiment was repeated 6 times and Wilcoxon's non-parametric test for paired comparison was used to evaluate differences between the various conditions.

Results: In the presence of TNF α , there was a marked reduction in lipid accumulation after 4 days when the first lipid droplets are seen, and an almost complete absence of lipid droplets in fully differentiated adipocytes after 8 days. Furthermore, the gene expression of adipogenic markers, such as aP2, adiponectin, LPL, perilipin and GLUT4, was significantly reduced. In contrast, no significant effect was seen in the presence of MCP-1 or resistin. The presence of TNF α inhibited axin expression, which is the rate-limiting scaffold-protein for the degradation of the Wnt-signaling responsive transcriptional co-factor beta-catenin. As a result, Wnt-signaling and the expression of Wnt-signaling responsive genes were maintained. Again, no effect was seen in the presence of MCP-1 or resistin. The addition of pioglitazone antagonized the effect of TNF α on Wnt-signaling and adipogenesis. In addition, pioglitazone had beneficial effects on inflammation, Wnt-signaling and adipogenesis per se.

Conclusion: In the present study, we show that while TNF α is able to maintain an active Wnt-signaling, induce inflammation and completely block adipose cell differentiation, no effect was found by either MCP-1 or resistin on these processes. Addition of the thiazolidinedione, pioglitazone, was found to antagonize the effect of TNF α on the Wnt-signaling process and, consequently, promote adipogenesis.

The sumo-conjugating enzyme Ubc9 regulates adipocyte differentiation

M. Melchiorre, A. Cignarelli, S. Miccoli, C. Caccioppoli, F. De Stefano, M. R. Orlando, A. Natalicchio, S. Perrini, L. Laviola, F. Giorgino; Endocrinology & Met. Diseases, University of Bari, Italy.

Background and Aims: Ubc9, the E2 enzyme implicated in conjugation of the small ubiquitin-like modifier SUMO to intracellular substrates, has recently been shown to participate in the regulation of eukaryotic cell differentiation. The objective of this study was to examine the role of Ubc9 in the differentiation of adipose cells.

Materials and Methods: To evaluate potential changes in Ubc9 expression during adipogenesis, Ubc9 protein and mRNA levels, as well as the intracellular localization of Ubc9, were analyzed in 3T3-L1 cells by immunoblotting, real-time PCR, and immunofluorescence analyses, respectively, at different times after induction of differentiation. Selective knock-down of Ubc9 in 3T3-L1 preadipocytes was obtained by transfection of a Ubc9-specific siRNA at day -2 and +2 of the differentiation protocol. Achievement of adipocyte differentiation was assessed by visual inspection, Oil-O-Red staining, gene expression analysis by real-time PCR, and evaluation of adipocyte-specific metabolic responses, including FFA release into the culture medium and 2-deoxy-D-glucose uptake.

Results: Ubc9 mRNA and protein levels were found to be increased at day 2 (2.5-fold vs. baseline, $p < 0.05$) and then gradually declined to basal levels at day 8 of differentiation. In addition, the Ubc9 protein, visualized by immunofluorescence analysis, was expressed predominantly in the nucleus of preadipocytes, whereas, beginning from day 4 after induction of differentiation, the majority of the enzyme was evident in cytoplasmic compartments, in which it partially co-localized with the glucose transporters GLUT4. To evaluate the role of Ubc9 in adipogenesis, a Ubc9-specific siRNA to reduce Ubc9 expression was transfected in 3T3-L1 preadipocytes prior to induction of cell differentiation; this resulted in 80% reduction of both mRNA and protein levels of Ubc9 at day 2 after induction of differentiation compared to control. In the presence of Ubc9 gene silencing, mRNA levels of various adipocyte transcription factors and adipocyte-specific proteins, including C/EBP δ ($p < 0.05$ at days 2, and 4), C/EBP α ($p < 0.001$ at day 4), PPAR γ ($p < 0.001$ at day 4), GLUT4 ($p < 0.05$ at day 8) and FAS ($p < 0.05$ at day 8), were significantly decreased as compared to control. In addition, knock-down of Ubc9 resulted in inhibition of the clonal expansion that physiologically occurs during the early phases of differentiation, since the siRNA-treated 3T3-L1 cells were reduced by 30% compared to control cells ($p < 0.05$). At the end of differentiation, Oil-Red-O staining demonstrated accumulation of large triglyceride droplets in >90% of control adipocytes, whereas cell triglycerides were evident as minute lipid droplets in only 60% of the 3T3-L1 adipocytes treated with the Ubc9-specific siRNA. Consistent with these results, following Ubc9 gene silencing, FFA release into the culture medium was reduced by 35% ($p < 0.05$) and both basal and insulin-stimulated glucose uptake rates were reduced by 40% ($p < 0.05$) compared to control.

Conclusion: In conclusion, Ubc9 expression and localization are regulated during adipocyte differentiation. Ubc9 may play an essential role in the differentiation program by affecting mitotic clonal expansion of the pre-adipocytes and induction of adipogenic transcription factors.

Gene expression profiling identifies molecular pathways that cause decreased differentiation of preadipocytes in type 2 diabetes patients

F. H. J. van Tienen¹, C. J. H. van der Kallen², P. J. Lindsey¹, H. J. M. Smeets¹;

¹Department of Genetics & Cell Biology,

²Department of Internal Medicine, Maastricht University, The Netherlands.

Background and Aims: The important role for white adipose tissue in the development of type 2 diabetes mellitus (T2DM) has only recently been recognized. Insulin resistance and T2DM are associated with increased adipocyte size, altered secretory patterns and decreased differentiation of preadipocytes. Molecular processes have already been identified by gene expression profiling in white adipose tissue and isolated adipocytes of T2DM patients. To characterize the role of preadipocytes in further detail we performed gene expression profiling in cultured subcutaneous preadipocytes of T2DM and BMI matched controls.

Materials and Methods: Preadipocyte cell cultures were prepared from subcutaneous fat biopsies of T2DM patients (n=7, age 52.7±12.0 yr, BMI 34.2±5.3 kg/m²) to age and BMI matched control subjects (n=9, age 50.5±12.1 yr, BMI 29.5±3.2 kg/m²). Gene expression analysis was performed on two-colour 70-mer oligo arrays (21521 features, Operon) followed by linear regression modelling and gene ontology analysis using GenMAPP/MAPPFinder and GOTree Machine.

Results: Normal linear regression modelling indicated 499 transcripts to be differentially expressed between T2DM patients and controls, 344 were down-regulated and 155 transcripts were up-regulated. Gene ontology analysis showed a decreased activity of genes involved in differentiation related processes, including adipogenesis, extracellular matrix adhesion, actin cytoskeleton and RNA polymerase II transcription factor activity. In addition, genes in pathways involved in lipid metabolism including biosynthesis and beta-oxidation were also down-regulated in preadipocytes of T2DM patients.

Conclusion: The down-regulation of genes involved in differentiation is possibly an explanation for the already earlier described decreased differentiation of preadipocytes of T2DM subjects, which leads to a reduction of newly formed adipocytes in subcutaneous fat depots, ultimately leading to ectopic fat storage, e.g. in muscle and liver. Since the cells are cultured for some weeks, our data indicate that these changes can be an intrinsic property of the cultured preadipocytes and, therefore, not related to changed in vivo signalling from macrophages and adipocytes in insulin resistant adipose tissue. Whether the down-regulation of lipid-metabolism is cause or consequence needs to be validated by functional studies, which will be performed for all the relevant processes.

Orphan nuclear receptor DAX-1 interacts and represses PPARgamma transactivation

H.-S. Choi, G. Kim, B. Nedumaran;

Hormone Research Center, Chonnam National University, Gwangju,, Republic of Korea.

Background and Aims: DAX-1 (*NROB1*) is an atypical nuclear receptor (NR) which functions primarily as a transcriptional corepressor of other NRs through heterodimerization. Peroxisome proliferator-activated receptor (PPAR; *NRI3*) gamma is a ligand-dependent NR that plays a key role in lipid metabolism, inflammation, and adipogenesis. In this study, we examined the novel cross-talk between DAX-1 and PPARgamma and elucidated the role of DAX-1 in adipocyte differentiation.

Materials and Methods: GST-pull down assay and immunoprecipitation assay was used to confirm the direct interaction between DAX-1 and PPARgamma. Transient transfection assay was used to examine the role of DAX-1 on PPARgamma transactivation. Adenoviral vector mediated overexpression of DAX-1 was used to the effect of DAX-1 on 3T3L1 adipocyte differentiation.

Results: Transient transfection assay demonstrated that DAX-1 inhibited the transactivity of PPARgamma in a dose-dependent manner. Further, DAX-1 directly interacted with DNA binding domain (DBD)/hinge region of PPARgamma in a ligand-independent manner, and showed the competitive interaction with PPARgamma coactivator (PGC)-1alpha in PPARgamma binding. Compared to preadipocytes or stromal vascular cells, the endogenous level of DAX-1 was significantly lower in differentiated 3T3-L1 adipocytes or primary adipocytes. Intriguingly, adenoviral overexpression of DAX-1 down-regulates the expression of PPARgamma target genes, resulting in attenuation of adipogenesis in 3T3-L1 cells.

Conclusion: Overall, our results suggest that DAX-1 acts as a novel corepressor of PPARgamma via PGC-1alpha competition and has the potential role on the regulation of the PPARgamma-mediated cell differentiation.

Deficiency of the neuronal transcription factor NSCL-2 results in an increased number of preadipocytes in WAT

K. Ruschke^{1,2}, M. Blüher¹, N. Klötting¹, T. Braun²;

¹Medical Clinic III, University of Leipzig,

²Cardiac Development and Remodelling, Max-Planck-Institute for Heart and Lung Research, Bad Nauheim, Germany.

Background and Aims: The basic helix-loop-helix protein NSCL-2, a neuronal transcription factor, is widely expressed in different areas of the CNS and PNS during embryonic and fetal development. During postnatal life the expression decreases significantly but is specifically maintained in hypothalamic areas known for control of food intake and energy expenditure. In particular, the expression of NSCL-2 co-localizes with POMC and NPY in neurons of the arcuate and paraventricular nucleus. NSCL-2 mutant mice show adult onset of obesity and leptin resistance.

Materials and Methods: We measured serum insulin, adiponectin and resistin concentrations by ELISA Kit from Linco Research. Histological studies and analysis of isolated adipocytes were performed using four male mice at the age of 6 months of the four genotype groups: NSCL-2 *-/-*; ob/ob; NSCL-2 *-/-* x ob/ob and C57/BL/6J WT controls.

Results: NSCL-2 *-/-* mice, unlike ob/ob mice, are characterized by low insulin ($F = 5.98$; $p < 10^{-4}$), high adiponectin serum levels and normal glucose tolerance. We investigated glucose uptake, lipolysis and glucose metabolism in isolated adipocytes of NSCL-2 x ob/ob double mutants and in ob/ob mice. Interestingly, adipocytes derived from NSCL-2/ob/ob compound mice show a decreased insulin resistance compared to insulin resistant ob/ob or NSCL-2 mutant adipocytes. Epigonadal adipose tissue showed a bimodal distribution with two populations of adipocytes, a small preadipocyte (<50 µm) and a large mature adipocyte (>100 µm) form. Furthermore, the number of preadipocytes was 7 times higher compared to wild type and ob/ob mice ($F=250.71$; $p<10^{-4}$). In addition, we found increased serum resistin level in NSCL-2 *-/-* and NSCL-2 *-/-* x ob/ob mice compared to WT and ob/ob mice when normalized to the bodyweight on the animals ($F = 6.33$; $p < 0.0009$).

Conclusion: We anticipate that resistin might participate in the control of adipocyte differentiation.

Insulin vascular action in skeletal muscle is attenuated with insulin resistance and features of the metabolic syndrome

M. J. Turzyniecka¹, J. C. C. Ung², A. J. Krentz¹, G. F. Clough², C. D. Byrne¹;
¹Endocrinology and Metabolism, University of Southampton,
²IRR Division, University of Southampton, United Kingdom.

Background and Aims: The relationship between total muscle blood flow, capillary recruitment and skeletal muscle insulin sensitivity remains unclear. The aim of this study was to investigate insulin-induced changes in muscle microvascular blood flow using a novel non-invasive laser Doppler surface probe in individuals with features of metabolic syndrome

Materials and Methods: Twenty one volunteers (age range 37 – 67years; mean 51.5 ± 1.5y; 8 men) were recruited. All gave written informed consent. Blood flux in muscle and skin was measured by laser Doppler fluximetry (DRT4 Moor Instruments Ltd, UK) using a 785 nm, 20 mW, 4 mm separation (muscle) and a 1 mW, 0.5 mm separation (skin) probe placed above the anterior tibialis muscle. Measurements were made at rest and during a reactive hyperaemia (RH) to arterial occlusion, before and during stepped hyperinsulinaemic euglycaemic clamp at low (0.2 mU/kg/min) and high dose insulin (1.5 mU/kg/min). Insulin sensitivity was measured as the rate of glucose disposal ($M = \text{mg/kg/min}$) during the steady state of the clamp.

Results: Resting blood flux in muscle and skin was 80±3 and 9±0.3 AU (arbitrary perfusion units), respectively. The insulin-induced increase in resting muscle blood flow was positively related to insulin sensitivity ($r=0.45$ $p<0.05$). The relative increase in RH from baseline was negatively correlated with percentage body fat measured by DEXA ($r=-0.59$, $p<0.02$).

Conclusion: We conclude that insulin's vascular action within skeletal muscle, as measured by non-invasive laser Doppler fluximetry, is attenuated with insulin resistance and with increased body fat. We speculate that an impaired insulin response within skeletal muscle microvasculature may contribute to whole body insulin resistance and to decreased glucose disposal by muscle in these patients.

The influence of very low calorie diet on serum concentrations and subcutaneous mRNA expression of endothelial cell adhesion molecules in obese, insulin-resistant women

M. Haluzik, L. Bosanska, D. Haluzikova, R. Dolezalova, T. Roubicek, M. Mraz, M. Dolinkova, M. Matoulek, Z. Lacinova;
 3 Department of Medicine, 1 Faculty of Medicine, Prague 2, Czech Republic.

Background and Aims: Endothelial cell adhesion molecules (CAM) are proteins expressed on the surface of endothelial cells that participate in the development of endothelial dysfunction and/or atherosclerosis. One of the possible sources of increased circulating levels of CAM in obese subjects is adipose tissue. The aim of our study was to test the hypothesis that adipose tissue significantly contributes to the increased levels of CAM in obesity and to explore how is this production influenced by diet intervention.

Material and Methods: Twelve obese women (mean BMI 45.7±6.7 kg/m²) and twelve lean healthy subjects (C) (mean BMI 24±4.3 kg/m²) were included into the study. None of the subjects suffered from diabetes. Blood drawing and subcutaneous adipose tissue (SAT) biopsy were performed after an overnight fasting. The same procedure was repeated in obese subjects after three weeks of very low calorie diet (VLCD) with energy intake of 550 kcal/day. Serum concentrations of insulin, ICAM-1, VCAM-1 and E-selectin were measured using RIA kit – insulin (Cis Bio International, France) and Lincoplex kit – CAM (Linco Research, USA). CAM mRNA expression in SAT was measured using RT PCR (ABI PRISM 7500, USA) and normalized to β -2-microglobulin mRNA expression.

Results: At baseline, BMI, serum insulin levels, HOMA index, ICAM-1 and E-selectin concentrations of obese group were significantly higher relative to C (ICAM 138±72 vs. 78±28 ng/ml; E-selectin 23.7±10.8 vs. 9.1±4.7 ng/ml, $p<0.05$). Serum concentrations of VCAM-1 levels did not differ. On the contrary, mRNA expression of E-selectin in SAT was significantly lower in obese relative to C group while ICAM-1 and VCAM-1 mRNA expression did

not differ. Three weeks of VLCD significantly decreased BMI, serum insulin levels, HOMA index and E-selectin levels but it did not affect VCAM-1 and ICAM-1 levels. Three weeks of VLCD significantly increased SAT mRNA expression of ICAM-1 and VCAM-1. SAT mRNA expression of E-selectin was not significantly affected by VLCD.

Conclusion: We conclude that three weeks of VLCD had favorable effect on metabolic parameters and circulating levels of some of CAM in obese, insulin-resistant women. SAT mRNA expression of CAM differed from its circulating levels and VLCD increased, rather than decreased its SAT mRNA expression. Our data suggest that SAT is not a principle source of increased CAM in obese patients and that the local regulation of CAM mRNA expression in SAT is different from its systemic concentrations.

Identification of molecules underlying human aortic smooth muscle cells phenotypic change in hyperglycaemia and hyperlipidaemia

L.-D. Popov¹, E. Constantinescu²;
¹Vascular Dysfunction in Diabetes,
²Cerebrovascular dysfunction in ageing and disease, Institute of Cellular Biology and Pathology, Bucharest, Romania.

Background and Aims: Several lines of evidence suggest that in diabetes arterial smooth muscle cells (SMCs) play a key role in the atherosclerotic process. In this study we questioned on: (i) phenotypic changes of human aortic SMCs induced in vitro by high glucose concentration and by sera of obese type 2 diabetic patients, (ii) identification of signaling molecules underlying metabolic dysregulations of the cells subjected to either hyperglycemia or hyperlipidemia-hyperglycemia.

Materials and Methods: Human aortic SMCs were cultured to confluence in: (i) DMEM with 10% fetal calf serum and 30 mmol glucose (in controls, 5 mmol glucose), and (ii) DMEM with 10% serum of obese type 2 diabetic patients of BMIs 35-39 kg/m², mean plasma glucose: 298 mg/dl, cholesterol: 294 mg/dl, triglycerides (TGs): 234 mg/dl (in controls, 10% serum of healthy subjects of BMIs 19-21 kg/m², with normal plasma glucose, cholesterol and TGs levels). Electron microscopy was used to examine SMCs structure, fluorescence microscopy, to observe Oil red O stained lipid droplets and immunostained vinculin and type IV collagen, and immunoblotting, to evaluate expression and phosphorylation of STAT-3(Tyr 705), ERK1/2(Thr202/Tyr204), IRS-1(Tyr), Ob-R and HSL.

Results: The presence of 30 mM glucose conducted to the following modifications of human aortic SMCs: (i) enrichment in biosynthetic organelles, indicating a secretory phenotype (in controls: a contractile phenotype), (ii) organization of vinculin plaques at the cells periphery, supporting spreading and focal adhesions formation (in controls: intracytoplasmic distribution), (iii) production of an extensive extracellular matrix, with intensely immunostained type IV collagen (in controls: a faint labeling), (iv) proliferation (as demonstrated by the presence of centrioles) associated with significantly increased protein expression of pSTAT-3 (~2.54 fold) and pERK1/2 (~2.12 fold) above the levels in controls, (v) addition of 10-100 nM insulin reduced IRS-1 phosphorylation, in a time-dependent process, suggesting negative regulation of insulin receptor-mediated signaling, a process restricted to the SMCs with secretory and proliferative phenotype (controls: no insulin, and SMCs in 5mmol glucose). 30 mmol glucose did not induced lipid loading of human aortic SMCs. The presence of serum of obese type 2 diabetic patients conducted to: (i) accumulation of Oil red O stained lipid droplets, indicating a phenotypic switch towards differentiation into foam cells, and storage of TGs and cholesteryl esters (CEs)(in comparison with controls), (ii) protein expression of HSL, an enzyme involved in hydrolysis of TGs and CEs within the lipid droplets, that was not detected in controls, (iii) protein expression and activation of Ob-R, STAT-3, and ERK1/2 underlying metabolic dysregulations in lipid laden-cells.

Conclusion: Although expression of transcription factors from insulin signaling is in common to phenotypic changes of human aortic SMCs grown in medium supplemented with either high glucose or serum of obese diabetic patients, each of these insults induced definite metabolic peculiarities: a biosynthetic metabolism in high glucose conditions, and an active lipid metabolism associated with cells differentiation into foam cells, in hyperglycemic-hyperlipidemic environment.

New insights into the molecular mechanisms involved in the resistance to nitric oxide occurring in vascular smooth muscle cells from an animal model of insulin-resistance

G. Doronzo, I. Russo, L. Mattiello, P. Del Mese, G. Anfossi, M. Trovati; Department of Clinical and Biological Sciences, University of Turin, Diabetes Unit, San Luigi Gonzaga Hospital, Orbassano-Turin, Italy.

Background and Aims: Nitric Oxide (NO) plays a critical role in the pathogenesis of atherosclerosis and arterial hypertension, by inhibiting steps of atherogenic process and by inducing vasodilation. In particular, NO stimulates production of guanosine 3',5'-cyclic monophosphate (cGMP), which regulates several functions of Vascular Smooth Muscle Cells (VSMC). The major substrate for cGMP in VSMC is the cGMP-dependent Protein Kinase (PKG), that catalyzes phosphorylation of many signalling proteins. We previously observed that in aortic VSMC from lean, insulin-sensitive and obese, insulin-resistant Zucker rats (a classical animal model of insulin resistance), the NO donor DETA NONOate and the cGMP analog 8-Br-cGMP phosphorylate Akt (a key molecule the PI-3K/Akt pathway) and ERK1/2 (key molecules of MAPK family). We also demonstrated that activation of Akt and of ERK1/2 induced by the NO/cGMP pathway is impaired in VSMC from obese Zucker rats. Aim of this study is to evaluate whether NO and cGMP: i) activate molecules downstream PI-3K/Akt, such as p70S6K, involved in VSMC proliferation and post-angioplasty restenosis; ii) activate other molecules of the MAPK family, such as p38 MAPK and JNK1/2, correlated with cell stress, and whether PKG is involved in the NO/cGMP-induced activation of PI3K/Akt/p70S6K pathway and of MAPK family molecules.

Materials and Methods: In cultured aortic VSMC from lean and obese Zucker rats, we measured the influence of the NO donor DETA NONOate and of the cGMP analog 8-Br-cGMP on the activating phosphorylation of p70S6K, p38 MAPK, JNK1/2 (western blots, n=6) and whether activation of all these signalling molecules are blunted by KT5823, a selective PKG inhibitor.

Results: In VSMC from lean Zucker rats, DETA NONOate (500 microM) and 8-Br-cGMP (500 microM) increased phosphorylation of p70S6K (at 2 hours, p=0.007 and 0.0001) and of p38 MAPK (at 2 hours, p=0.0001 for both). Activation of p70S6K and p38 MAPK was induced by DETA NONOate and 8-Br cGMP also in VSMC from obese Zucker rats (p=0.0001 and 0.02), but the extent of activation was significantly lower. In particular, i) at 2 hours of VSMC incubation with DETA NONOate: i) phosphorylation of p70S6K was 171.9±7.8% of baseline in lean vs 128.9±2.5% in obese Zucker rats (p=0.0001); ii) phosphorylation of p38 MAPK was 273.3±4.6% of baseline in lean vs 181.6±5.4% in obese Zucker rats (p=0.0001); b) at 2 hours of VSMC incubation with 8-Br-cGMP: i) phosphorylation of p70S6K was 140.5±4.8% of baseline in lean vs 121.7±5.5% in obese Zucker rats (p=0.028); ii) phosphorylation of p38 MAPK was 371.5±20% of baseline in lean vs 195.8±3.5% in obese Zucker rats (p=0.0001). No influence was exerted by DETA NONOate and 8-Br-cGMP on JNK1/2 in VSMC from lean and obese Zucker rats. The influence of DETA NONOate and 8-Br-cGMP on Akt, ERK1/2, p70S6K and p38 are blunted by 1 hour pre-incubation with the PKG inhibitor KT5823 in VSMC from lean and obese Zucker rats (p=0.0001).

Conclusions: The NO/cGMP pathway activates -via PKG- the PI-3K/Akt/p70S6K pathway and the MAPK family molecules ERK1/2 and p38 -but not JNK1/2- in lean Zucker rats and the effects are reduced in VSMC from the obese Zucker rats. These results provide new insights in the molecular mechanisms characterizing the nitric oxide resistance occurring in VSMC in insulin resistant states.

Palmitate and stearate are potent inducers of inflammatory genes in human coronary artery endothelial cells

A. O. Krogmann; Medizinische Klinik IV und Poliklinik, Universitätsklinikum Tübingen, Germany.

Background and Aims: Obesity-linked insulin resistance is associated with increased lipolysis and elevated plasma levels of free fatty acids (FFA). We asked whether common plasma FFA contribute to vascular inflammation via induction of inflammatory genes in human coronary artery endothelial cells (CAEC), as was previously shown for interleukin-6.

Materials and Methods: CAEC were treated with 0.5mM palmitate (C16:0), stearate (C18:0), oleate (C18:1 ω9), or linoleate (C18:2 ω6), respectively, for 20 hours. Gene expression was assessed by macroarrays, real-time RT-PCR, and/or Western blot.

Results: Using macroarrays, qualitative analysis of palmitate-treated CAEC revealed a broad inflammatory response. As quantified by RT-PCR, treatment of CAEC with palmitate or stearate, but not with oleate or linoleate, respectively, resulted in significant mRNA induction of IL8, CCL20, CXCL3, IL1α, and SPP1 (p<0.05 for all, N=3). Similar results were obtained for the inflammatory transcription factor C/EBPβ, as verified by Western blot. Using pharmacological inhibitors, we furthermore demonstrate that palmitate-induced expression of IL8, CCL20, and CXCL3 (p<0.05 for all, N=3) depends on the activation of the transcription factor NFκB. In addition, Palmitate-induced expression of IL8, CXCL3, IL1α, and SPP1 (p<0.001 for all, N=3) is mediated by c-Jun kinase. P38 MAP kinase was not found to be involved in these gene regulations.

Conclusion: Here, we show that the saturated FFA palmitate and stearate, but not unsaturated FFA, such as oleate and linoleate, induce a broad inflammatory response in human coronary artery endothelial cells. These events are mediated by NFκB and c-Jun kinase. Our findings point to a potential contribution of saturated FFA to vascular inflammation.

Action of insulin and insulin-like growth factors in human aortic smooth muscle cells

S. I. Chisalita, E. Liefvendahl, G. S. Johansson, H. J. Arneqvist; Cell Biology, Biomedicine and Surgery, Linköping, Sweden.

Background and Aims: Vascular smooth muscle cells play an important role in the development of atherosclerosis. Circulating levels of insulin-like growth factor-I (IGF-I) and insulin-like growth factor-II (IGF-II) are lowered in diabetic subjects. Little is known about direct effects of IGF-II on human aortic smooth muscle cells (HASMC). Our aim was to characterize effects of IGF-II in relation to insulin and IGF-I in HASMC.

Materials and Methods: Cultured HASMC were used. Receptor mRNA expression was measured by quantitative real time- polymerase chain reaction (RT-PCR) analysis. Receptor proteins, hybrid IR/IGF-IR (hybrid insulin receptor/ insulin-like growth factor-I receptor) and phosphorylation of receptor β-subunits were analyzed by immunoprecipitation and Western blot. Metabolic and mitogenic effects were assessed by D-[U-¹⁴C]-glucose accumulation and ³H-thymidine incorporation into DNA, respectively.

Results: The mRNA expression of insulin-like growth factor-I receptor (IGF-IR) was approximately 5 fold higher than that of insulin receptor (IR) in HASMC (P < 0.02). Insulin receptor isoform A (IR-A), which has approximately 10 fold higher affinity for IGF-I and IGF-II than IR-B, was 13 fold more expressed than insulin receptor isoform B (IR-B) (P = 0.01). By immunoprecipitation and Western Blot analysis both IGF-IR and IR and hybrid IR/IGF-IR could be demonstrated. Phosphorylation of the IGF-IR β-subunit was obtained by insulin 10 nM, IGF-I 0.1-10 nM and IGF-II 10 nM. IR β-subunit was activated by IGF-II 10 nM and IGF-I 1-10 nM (P < 0.05). IGF-I and IGF-II at a concentration of 10-100 nM significantly stimulated ³H-thymidine incorporation (P < 0.05), whereas insulin did not. Glucose accumulation was stimulated by IGF-I 10-100 nM, IGF-II 10-100 nM, and by insulin 100 nM (P < 0.05).

Conclusion: Both IGF-I and IGF-II activated the IGF-IR and stimulated glucose metabolism and DNA synthesis in HASMC, whereas insulin had little effect. The lack of insulin effect could partly be due to the presence of hybrid IR/IGF-IR.

Metacholine-induced vasodilation differentially modulates the vascular and the metabolic responses in skeletal muscle of insulin-sensitive and insulin-resistant obese individualsG. Murdolo¹, M. Sjostrand², L. Strindberg³, S. Gudbjornsdottir⁴, L. Lind⁵, P. Lonnroth³, P.-A. Jansson³;¹Department of Internal Medicine, Perugia University, Italy,²Astra Zeneca Research, Gothenburg University, Molndal, Sweden,³Department of Molecular and Clinical Medicine, Gothenburg University, Sweden, ⁴Department of Internal Medicine, Gothenburg University, Sweden,⁵Department of Medicine, Uppsala University, Sweden.

Background and Aims: The impairment of insulin-mediated capillary recruitment in skeletal muscle has been indicated as an important contributor to the obesity-linked metabolic resistance to glucose uptake. The main aim of this study was to test whether a sustained vasodilation induced by intra-brachial metacholine infusion (Mch, 2 µg·min⁻¹ for 60 min) improves muscle capillary recruitment and forearm glucose uptake during hyperinsulinemia.

Materials and Methods: Fifteen uncomplicated obese individuals (M/F: 14/1; age: 45.5±2.4 yrs) were divided into a group of insulin-sensitive (IS, n=8; HOMA-IR <2.5; BMI: 32.6±1.2 kg/m²) and insulin-resistant (IR, n=7; HOMA-IR ≥ 2.5; BMI: 31±0.9 kg/m²) subjects. The double forearm technique (ie, infused vs control forearm) was combined with the intramuscular microdialysis during an oral glucose tolerance test (OGTT).

Results: In the infused forearm, Mch significantly increased (p<0.0001 vs baseline) the forearm blood flow (FBF), the capillary permeability-surface area product (PS) for glucose (capillary recruitment) and the forearm glucose uptake (FGU). In the control forearm, FBF remained stable throughout the OGTT, whereas PS and FGU significantly rose over-time (p<0.001). By design, FBF changes above the baseline were larger in the infused as compared with the control forearm (p<0.0001), whereas comparable PS and FGU responses were seen between the two forearms. Moreover, in the control forearm, the IR subjects exhibited similar FBF, but lower PS and FGU changes (p<0.01), as compared with the IS controls. In contrast, in the infused forearm, FBF was slightly blunted in the IR individuals, but PS and FGU changes did not differ between the groups. Finally, we found a tight correlation between the FGU and the PS (R² adj. 0.74, p<0.01), but neither FGU nor PS were significantly associated with the FBF.

Conclusion: We conclude that, during an OGTT, the forearm glucose uptake may be independent of increment in total blood flow. The differential effects on the vascular and the metabolic response between IS and IR individuals, as well as the lack of association between the PS for glucose or the FGU with the FBF implicate that, in the obese state, the metabolic resistance to glucose uptake in skeletal muscle might be overcome by circumventing the dysfunctional capillary recruitment rather than by increasing the bulk blood flow. Further efforts are required to better elucidate the role of NO-tone modulating agents in the regulation of both vascular and metabolic responses in insulin-resistant skeletal muscle.

Impaired postprandial adipose tissue blood-flow may be an early marker of insulin resistance in type 2 diabetesV. Lambadiari¹, G. Dimitriadis¹, P. Mitrou¹, E. Boutati¹, I. Maratou², D. Panagiotakos³, T. Economopoulos¹, S. A. Raptis^{1,2};¹2nd Department of Internal Medicine and Research Institute, Athens University Medical School,²Hellenic National Diabetes Center, Attikon University Hospital,³Department of Statistics, Harokopion University, Athens, Greece.

Background and Aims: It is increasingly recognized that impairment of endothelial and vascular function is an integral part of the insulin resistance syndrome. In subcutaneous adipose tissue (AT), blood flow plays a decisive role in its metabolic and endocrine function, and normally increases after meal ingestion. In insulin resistant states, like obesity and overt type 2 diabetes (DM2), this response is blunted. The study was undertaken to investigate the existence of de novo impairment in AT endothelial function, in the various stages of type 2 diabetes.

Materials and Methods: A standard mixed meal was given to five groups of subjects, whose features are shown in the Table 1. Blood samples were drawn from the radial artery (A) at 30–60min intervals for 6h for the measurement of glucose, insulin and adiponectin. Simultaneous measurements of blood flow in AT were done with ¹³³Xe.

Results: (a) The pre-prandial values of glucose were lower in controls vs all other groups, (b) HOMA Index in controls was lower vs all other groups, (c) adiponectin was higher in controls and relatives vs other groups, (d) AT blood flow (AUC 0–360min) was higher in controls vs all other groups (Table1).

Conclusions: After meal ingestion, no response of insulin-stimulated AT blood flow was detected in the subcutaneous AT of relatives and patients with IGT, DM2-A, DM2-B. This defect could represent another facet of insulin resistance that precedes the development of overt glucose intolerance.

RELATIVES: 1st degree relatives of diabetic patients with a normal glucose tolerance test, **IGT:** subjects with impaired glucose tolerance, **DM2-A:** subjects with mild type 2 diabetes, with normal fasting plasma glucose and postprandial hyperglycemia, **DM2-B:** subjects with overt type 2 diabetes. **PPG:** Fasting Plasma Glucose

Leptin activates 5'-AMP-activated protein kinase and shifts insulin-mediated vasoreactivity to vasodilatation in muscle resistance arteriesE. C. Eringa¹, I. Korstjens¹, G. P. van Nieuw Amerongen¹,C. D. A. Stehouwer², W. Bakker¹, P. Sipkema¹;¹Laboratory for Physiology, VU University Medical Centre, Amsterdam,²Internal Medicine, Academic Hospital Maastricht, The Netherlands.

Resistance to the metabolic effects of leptin is associated with insulin resistance and hypertension. Effects of leptin on the muscle microcirculation may mechanistically explain these associations. 5'-AMP-activated protein kinase (AMPK) has been hypothesized to mediate the physiological effects of leptin.

Objective: To study the effects of leptin on vascular tone, insulin-mediated vasoreactivity and insulin-mediated cell signaling in muscle resistance arteries and the role of AMPK in these effects.

Methods/Results: Resistance arteries from the rat cremaster muscle were stimulated in vitro with leptin (10 nM) alone or in combination with insulin

Tab. 1

Table of Contents	CONTROLS N=10	RELATIVES N=11	IGT N=6	DM2-A N=6	DM2-B N=13
Age (yrs)	36±3	41±3	43,5±3	53±4	56±2
BMI (kg/m ²)	23,5±1	25±1	26±1,5	24,5±1,5	26±0,7
FPG (mM)	4,7±0,1	5±0,1*	5,7±0,4*	5,8±0,2*	8±0,2*
HOMA Index	0,98±0,1	1,43±0,1*	1,7±0,1*	1,8±0,2*	2,2±0,2*

* p<0,05 vs controls. Data are means ± SEM.

(0.01–1 nM). Vascular diameter was not significantly altered by leptin alone (10±7 percent, $P=0.3$) and insulin alone (0–2 percent, $P=0.9$). In contrast, insulin induced a dose-dependent vasodilatation in the presence of leptin (19±4 percent, $P<0.01$ vs. insulin alone). Western blotting of muscle resistance arteries revealed that the leptin-induced shift in vasoreactivity to insulin was associated with potentiation of insulin-mediated phosphorylation of Akt, which mediates insulin-stimulated NO production. Further examination of pAkt in the arteriolar wall by three-dimensional microscopy showed that phosphorylated Akt was predominantly located in the microvascular endothelium. Furthermore, leptin activated 5'AMP-activated protein kinase (AMPK) in endothelium of muscle resistance arteries, which was shown by increased phosphorylation of AMPK at its Threonine 172 residue. Finally, direct activation of AMPK with the AMPK agonist 5 amino-4-imidazolecarboxamide riboside (AICAR; 2 mM) was sufficient to mimic the effect of leptin on insulin-mediated vasoreactivity. In the presence of AICAR, insulin induced NO-dependent vasodilatation in the presence of AICAR (+20±5 percent at 1 nM, $P<0.05$ vs. insulin; +3±1 percent during NOS inhibition).

Conclusions: Leptin shifts insulin-mediated vasoreactivity of muscle resistance arteries towards vasodilatation by enhancing insulin-mediated activation of Akt and activation of AMPK. These findings provide a new mechanism for the association of leptin resistance with hypertension and insulin resistance.

Fatty liver is strongly associated with a qualitative change in the serum HDL cholesterol sub-fractions

N. Stefan¹, K. Kantartzis¹, A. Cegan¹, K. Rittig¹, C. Thamer¹, J. Machann², B. Balletshofer¹, A. Fritsche¹, E. Schleicher¹, H.-U. Häring¹;

¹Department of Internal Medicine,

²Section of Experimental Radiology, University of Tübingen, Germany.

Background and Aims: Fatty liver is strongly associated with atherosclerosis. Mechanisms explaining this relationship include a quantitative change in serum levels of triglycerides (TG), high-density lipoprotein cholesterol (HDL-c) and an increase in small dense LDL particles. So far it is unknown whether a qualitative change in serum lipids links fatty liver and atherosclerosis. As particularly a high HDL2-c level was found to be protective of atherosclerosis, and the HDL2-c and HDL3-c serum levels are regulated by the liver, we investigated whether fatty liver is associated with different HDL2/3-c levels in humans.

Materials and Methods: Thirty-seven subjects were studied. Liver fat was measured by 1H magnetic resonance spectroscopy and insulin sensitivity was determined by the euglycemic hyperinsulinemic clamp. The HDL2/3-c levels were quantified after separation by ultracentrifugation.

Results: Subjects with fatty liver ($n=16$, liver fat > 5.5 %) had lower HDL2-c levels and a lower HDL2/3-c ratio compared to controls ($n=21$, $p=0.001$ and $p=0.0001$). As expected, liver fat was negatively correlated with total HDL-c ($r=-0.47$, $p=0.003$). Of note, stronger negative correlations with HDL2-c ($r=-0.56$, $p=0.0003$) and the HDL2/3-c ratio ($r=-0.61$, $p<0.0001$) were observed. After adjustment for gender, age and body fat, liver fat was still negatively correlated with total HDL-c ($r=-0.40$, $p=0.02$), albeit weaker, and the correlation of liver fat with the HDL2/3-c ratio continued to be strong ($r=-0.54$, $p=0.001$). While additional adjustment for insulin sensitivity rendered the correlation of liver fat with total HDL-c non-significant ($p=0.25$), the correlation of liver fat with the HDL2/3-c ratio remained strong ($r=-0.43$, $p=0.02$).

Conclusion: We provide novel data showing that fatty liver is not only associated with a quantitative decline in HDL-c, but also with a qualitative change in the HDL-c composition. This may represent a new pathophysiological link between fatty liver and atherosclerosis.

Plasma adipocytokines in patients with metabolic syndrome and nonalcoholic fatty liver disease

L. Diaconu, V. Serban, R. Z. Timar, A. Vlad, B. Timar, C. Mazilu, V. Botea; Diabetes Clinic, University of Medicine and Pharmacy, Timisoara, Romania.

Background and Aims: Nonalcoholic fatty liver disease (NAFLD) is a major cause of liver-related morbidity with possible progression to cirrhosis. NAFLD often represents a component of the metabolic syndrome (MS) characterized by obesity, hyperinsulinemia, peripheral insulin resistance, diabetes, hypertriglyceridemia and hypertension. Insulin resistance states are characterized by elevated production of several adipocytokines (leptin, resistin, TNF α , IL-6, TGF β , PAI-1). Adiponectin is the only known adipocytokine which produces antiinflammatory and antiatherogenic effects. Low plasma adiponectin is considered a key factor in the development of the insulin resistance underlying MS. The aims of our study was to evaluate the prevalence of NAFLD in patients with MS, to assess plasma levels of adiponectin and proinflammatory state in patients with MS with and without NAFLD.

Materials and Methods: The study enrolled 224 subjects with MS. The diagnosis of MS was established according to IDF criteria. The diagnosis of NAFLD was based on detection of fatty liver by ultrasonography with or without chronically elevated aminotransferase levels (ALT>1.5 times the upper normal values for 6 months or more). All subjects had negative hepatitis B and C viral markers, negative history of alcohol intake, absence of autoimmune hepatitis, Celiac disease, no evidence of genetic, drug-induced or cholestatic liver disease.

Results: The prevalence of NAFLD in patients with MS was 87%. NAFLD with aminotransferase levels was present in 44 (19.64%) patients while NAFLD with normal liver enzymes was present in 151 (67.41%) patients with MS. Plasma levels of adiponectin were significantly lower in patients with NAFLD with elevated aminotransferase levels than in those with normal liver enzymes and than in subjects without NAFLD. Plasma levels of adiponectin were significantly lower in patients with NAFLD with elevated aminotransferase levels than in those with normal liver enzymes and than in subjects without NAFLD. Plasma levels of TNF- α , IL-6, leptin were significantly higher in patients with NAFLD and elevated aminotransferase levels than in patients with NAFLD and normal liver enzymes and than in subjects without hepatic injury. HOMA-IR was higher in patients with low levels of adiponectin. (Tab. 1)

Conclusion: The prevalence of NAFLD is higher in patients with MS than in general population. Although insulin resistance is present in all patients with MS, those with NAFLD present higher insulin resistance than those without NAFLD. Plasma levels of adiponectin are lower while proinflammatory adipocytokines and leptin are higher in patients with MS and NAFLD than in those without liver injury, suggesting a possible contribution of these abnormalities in the pathogenesis of NAFLD.

0716

Hepatic and systemic inflammation markers in patients with type 2 diabetes and NASH: decreased hepatic levels of TNF- α and IL-8 as increased severity of NASH

G. Kocabay¹, I. Satman¹, A. Telci², Y. Tütüncü¹, S. Ozel³, U. Cevikbaş⁴, B. Tiryaki⁵, A. Ökten⁶,

¹Endocrinology&Metabolism, ²Biochemistry, ³Statistics&Public Health, ⁴Pathology, ⁵Radiology, ⁶Hepatology, Istanbul Faculty of Medicine, Turkey.

Objective: Nonalcoholic liver steatosis (NASH) is commonly accompanied with type 2 diabetes, and is considered as a proinflammatory state linked to insulin resistance (IR). It is unclear whether serum levels of inflammatory markers reflect intrahepatic pathology. We investigated the relationships between hepatic and systemic markers of inflammation and IR in NASH cases.

Methods: The study composed of 52 type 2 diabetes cases with NASH (male 58%, mean age 53.2 \pm 7.3 years, duration of diabetes 7.4 \pm 4.7 years and BMI 31.9 \pm 4.2 kg/m²). Diagnosis of NASH was based on biochemical markers and ultrasound scans. Cases were classified according to the Brunt Criteria. Hs-CRP, ferritin, leptin and adiponectin (ADPN), glucose, lipids, liver enzymes and HOMA-IR were investigated in the serum. TNF- α and IL-8 levels were measured in biopsy specimens.

Results: Based on histopathological evaluation, 63.5% of cases had macrovesicular steatosis and the remaining had mixed type. Steatosis was mild 57.3%, moderate in 30.8%, and severe in 11.6% of cases. We did not find any infiltration in the majority, however 15.4% had mild and 5.8% had moderate infiltration. Fibrosis was mild in 50% and moderate in 7.7% cases. When the study group was stratified as mild-to-moderate (57.7%) and severe

steatosis (42.3%) based on ultrasound evaluation and compared, in severe steatosis group serum levels of hs-CRP (p=0.007), C-peptide (p=0.006), ALP (p=0.043) and GGT (p=0.034) were significantly higher than in the mild-to-moderate group. Hepatic TNF- α levels in mild steatosis group was significantly higher than in the moderate and severe groups (mild vs. moderate and severe 10.78 \pm 8.76 vs. 4.84 \pm 5.21 and 6.83 \pm 8.63 pg/mg, p=0.044). Similarly hepatic IL-8 levels tended to be higher in mild steatosis than in the moderate and severe groups (mild vs. moderate and severe 5.08 \pm 3.39 vs. 3.06 \pm 2.11 and 3.98 \pm 2.17 pg/mg, p=0.09). In the group with inflammation serum levels of ADPN was lower than the non-inflammation group (p=0.006). Based on fibrosis, serum triglyceride (p=0.03) and ferritin (p=0.015) were lower, and ALP was higher (p=0.02) in the cases with fibrosis group compared with the non-fibrosis group. After controlling for age and duration of diabetes, we found a highly significant correlation between hepatic levels of TNF- α and IL-8 (r=0.85, p=0.0001). TNF- α negatively correlated with A1C, total iron binding capacity and AST whereas IL-8 negatively correlated with ferritin and hs-CRP.

Conclusion: To our knowledge for the first time in the literature, we quantitatively measured TNF- α and IL-8 levels in the liver tissue of NASH cases. Hepatic levels of these cytokines were related to IR and glucose metabolism. But limited relations were found between tissue cytokines and systemic inflammation markers. In contrast to our expectation, we found that as the liver pathology progressed, these cytokines tended to be decreased in the liver. In order to further clarify this topic, large prospective studies should be conducted in the future.

Impaired insulin-mediated non-esterified fatty acid suppression in patients with hepatic steatosis quantified using proton magnetic resonance spectroscopy

S. R. Mehta¹, N. Barton¹, I. F. Godsland¹, S. Robinson¹, J. D. Bell², E. L. Thomas², N. Patel², J. Fitzpatrick², G. Durighel², D. Pavitt¹, S. D. Taylor-Robinson³, D. G. Johnston¹;

¹Endocrinology & Metabolic Medicine, ²Imaging Sciences, ³Hepatology, Imperial College, London, United Kingdom.

Background and Aims: Non-alcoholic fatty liver disease (NAFLD) is a condition characterised by triglyceride accumulation within the liver. It is frequently associated with features of the metabolic syndrome, with insulin resistance the most consistent underlying abnormality. The aim of the current study was to evaluate whether insulin-mediated suppression of adipose tissue lipolysis is impaired in subjects with NAFLD compared with healthy controls, in whom intrahepatocellular lipid (IHCL) content was measured by the safe and non-invasive method of proton magnetic resonance spectroscopy.

Material and Methods: We performed a frequently sampled intravenous glucose tolerance test (FSIVGTT) and proton magnetic resonance spectroscopy on 20 European males. 13 had known NAFLD with a median IHCL content of 17.87% and interquartile range 8.81–26.14% (normal IHCL

Table 1. Characteristics of patients with MS with and without NAFLD

Parameter	A. MS without NAFLD	B. NAFLD with normal liver enzymes	C. NAFLD with elevated aminotransferase levels	A vs. B	A vs. C	B vs. C

Data are mean \pm SD. p was calculated with unpaired Student's t test.

content is <5%) and 7 were healthy controls with a median IHCL content of 0.12% (interquartile range 0.01–0.17%). Sensitivity to the glucoregulatory effects of insulin was derived by mathematical modelling of glucose and insulin concentrations during the FSIVGTT using the minimal model of glucose disappearance. The rate of decline in NEFA concentrations during the IVGTT was quantified as the slope of the regression line passing through the log NEFA concentrations between 16 and 40 minutes, during which exponential decay was occurring in all participants. Sensitivity to the antilipolytic effects of insulin was expressed as a NEFA suppression index, calculated as the NEFA decay divided by the accompanying increment in the insulin concentration.

Results: Preliminary results of this ongoing study show no difference in basal NEFA concentrations between the 2 groups (median for cases with NAFLD 0.51 mEq/L [interquartile range 0.37–0.74]; median for controls 0.63 mEq/L [0.48–0.75]). The decrement in NEFA concentration at maximum suppression as a percentage of basal was 80.95 in the cases and 92.86 in the controls (Mann-Whitney $P=0.001$) and the time to maximal suppression was 100 minutes in the cases and 80 minutes in the controls ($P=0.15$). The NEFA suppression index was substantially lower in the NAFLD group than in the control group (median $27.30 \text{ min}^{-1} \cdot \text{mU}^{-1} \cdot \text{L} \times 10^{-6}$ [15.86–31.66] versus $104.25 \text{ min}^{-1} \cdot \text{mU}^{-1} \cdot \text{L} \times 10^{-6}$ [60.92–138.72]; Mann-Whitney $P<0.001$). There was a significant positive correlation between glucoregulatory and antilipolytic effects of insulin (Spearman's $\rho=0.80$; $P<0.0001$).

Conclusion: Insulin-mediated NEFA suppression is impaired in subjects with NAFLD compared with healthy controls. The role of insulin-mediated NEFA suppression in contributing to hepatic fat accumulation requires further study.

Continuous glucose monitoring in non-diabetes, non-alcoholic fatty liver disease subjects

L. Czupryniak¹, E. Szymanska-Garbacz¹, M. Pawlowski¹, M. Saryusz-Wolska¹, M. Jablkowski², J. Bialkowska², A. Borkowska¹, A. Omulecka³, J. Loba¹;

¹Diabetology and Metabolic Diseases Dept, Medical University of Lodz, Lodz, Poland, ²Infectious Diseases Dept, ³Pathology Dept, Medical University of Lodz, Poland.

Background and Aims: Non-alcoholic fatty liver disease (NAFLD), a condition associated with insulin resistance, significantly increases the risk of development of type 2 diabetes. However, the natural history of glucose intolerance in NAFLD subjects is poorly understood. The aim of our study was to assess circadian glucose profile with the means of continuous glucose monitoring system in non-diabetes NAFLD subjects.

Materials and Methods: The study group consisted of 15 individuals with liver biopsy-confirmed NAFLD (mean age 37.5 ± 8.7 years, body mass index BMI $28.8 \pm 3.1 \text{ kg/m}^2$, plasma aspartate aminotransferase (AST) activity $60.1 \pm 34.9 \text{ IU/l}$, alanine aminotransferase (ALT) activity $104.6 \pm 64.2 \text{ IU/l}$, HbA1c $5.61 \pm 0.52 \%$, HOMA index 4.13 ± 2.49). The controls were 6 matched healthy subjects, with normal liver function tests and HOMA index <2.0 . Diabetes was excluded in all studied persons upon the results of the oral 75 g glucose tolerance test (OGTT), which was performed at the beginning of the study. Continuous glucose monitoring (CGM) with the means of CGMS® System Gold (Medtronic MiniMed, Northridge, CA, USA) was conducted in all subjects. A glucose sensor was inserted into abdominal subcutaneous tissue for three days, and a CGMS monitor calibration was performed according to the CGMS use protocol. All subjects were asked to maintain their usual physical activity and food intake.

Results: In NAFLD subjects mean duration of continuous glucose monitoring was 75.6 hours (range 70–93 hours) with mean number of glucose readings 861 (range 564–1106). In the controls CGM was conducted for 76.2 hours (72–80.5 hours) with average 872 glucose readings (range 766–1062). Mean (\pm SD) glucose for the whole monitored period was $104.5 \pm 11.3 \text{ mg/dl}$ in NAFLD group and 85.5 ± 5.9 in healthy controls ($p<0.001$). Mean lowest recorded glucose values in the study group and the controls were 68.9 ± 13.5 and $54.3 \pm 14.5 \text{ mg/dl}$ ($p<0.05$) and mean highest values were 153.1 ± 16.5 and $145.1 \pm 13.9 \text{ mg/dl}$ ($p<0.05$), respectively. Glucose variability calculated as the absolute value of measured glucose minus 99 mg/dl (5.5 mmol/l) was similar in NAFLD subjects and in the controls (14.7 ± 8.4 vs $14.8 \pm 4.9 \text{ mg/dl}$).

Conclusion: Non-diabetes subjects with NAFLD present with significantly elevated diurnal glucose as assessed with CGMS, however its stability remains similar to healthy subjects.

Glucose intolerance in non-alcoholic fatty liver disease – a possible role of impaired glucagon-like peptide-1 secretion

M. Saryusz-Wolska¹, L. Czupryniak¹, E. Szymanska-Garbacz¹, M. Pawlowski¹, M. Jablkowski², J. Bialkowska², A. Omulecka³, A. Borkowska¹, J. Loba¹;

¹Diabetology and Metabolic Diseases Department,

²Infectious Diseases Department, ³Pathology Department, Medical University of Lodz, Poland.

Background and Aims: Non-alcoholic fatty liver disease (NAFLD) is associated with insulin resistance and constitutes a significant risk factor for the development of diabetes mellitus. However, it is not clear why only a fraction of individuals with NAFLD become diabetic. The aim of the study was to identify factors predictive of glucose intolerance development in a group of NAFLD subjects.

Materials and Methods: The study group consisted of 56 otherwise healthy subjects with liver biopsy-confirmed NAFLD (42 males, 14 females, mean age 46.7 ± 13.6 years, BMI $28.8 \pm 3.7 \text{ kg/m}^2$), who were subject to oral 75 g glucose tolerance test (OGTT) with blood sampled at 0, 60, 120, 180 and 240 min following glucose ingestion for glucose, insulin and entero-insular axis (plasma glucagon-like peptide-1) assessment. Fasting plasma liver function enzymes activity as well as parameters of insulin resistance (plasma adiponectin, free fatty acids; FFA), endothelial dysfunction (adhesion molecules [VCAM, ICAM] and sE-selectin) and liver regeneration (hepatocyte growth factor; HGF) in a fasting state were also measured in all subjects.

Results: Impaired fasting glucose (IFG) or impaired glucose tolerance (IGT) were found in 21 (38%) subjects, whilst 35 (62%) subjects had normal glucose tolerance (NGT). Individuals with IFG/IGT were significantly older (57.0 ± 11.2 vs 42.0 ± 13.1 years, $p<0.01$), had lower GLP-1 levels at 0, 60, 120 and 180 min of OGTT (10.5 ± 2.3 vs $24.5 \pm 6.8 \text{ ng/ml}$; 9.7 ± 3.0 vs $19.1 \pm 12.6 \text{ ng/ml}$; 8.1 ± 2.9 vs 13.6 ± 3.5 ; 6.3 ± 2.6 vs $11.2 \pm 4.1 \text{ ng/ml}$; all $p<0.05$), greater HOMA index (5.3 ± 3.7 vs 2.9 ± 1.5 ; $p<0.01$), higher plasma FFA (1.4 ± 1.0 vs $0.5 \pm 0.2 \text{ mmol/l}$; $p<0.01$), lower plasma adiponectin (1526 ± 1034 vs $2452 \pm 1358 \text{ ng/ml}$; $p<0.05$), higher plasma VCAM (2144 ± 956 vs $1504 \pm 712 \text{ ng/ml}$, $p<0.05$), ICAM (511 ± 336 vs $363 \pm 143 \text{ ng/ml}$; $p<0.05$) and sE-selectin (85.8 ± 24.1 vs $54.1 \pm 21.3 \text{ ng/ml}$; $p<0.05$), and lower HGF (835 ± 234 vs $1279 \pm 484 \text{ pg/ml}$; $p<0.05$). Notably, no differences between IFG/IGT and NGT subjects were found in body weight, plasma insulin, lipids or liver function enzymes activity.

Conclusion: Increased risk of developing glucose intolerance in the course of NAFLD is associated not only with aging and higher insulin resistance, but also with reduced secretion of GLP-1, suggesting impaired incretin effect in NAFLD. Moreover, individuals with NAFLD and concomitant glucose intolerance present with apparent endothelial dysfunction and impaired stimulation of liver regeneration process.

Long-term orlistat treatment reduces endotoxaemia in fatty liver disease patients

N. F. da Silva¹, A. L. Harte¹, M. J. Hill¹, T. S. Bilyard¹, S. Kumar¹, C. P. Day², P. G. McTernan¹;

¹Clinical Sciences, University of Warwick,

²The Medical School, University of Newcastle, United Kingdom.

Background and Aims: Obesity-mediated diabetes is associated with insulin resistance/hyperinsulinaemia and chronic sub-clinical inflammation. Recent studies have highlighted fatty liver (steatosis) as a risk factor for diabetes. In addition, hepatic steatosis *per se* can lead to hepatic insulin resistance/hyperinsulinaemia which may contribute significantly to the development of T2DM. Previous *in vitro* studies indicate liver may initiate an innate immune response which may be due to increased gut permeability through

hyperinsulinaemia. This leads to increased bacterial absorption. Furthermore HDL has been shown to have a positive effect on endotoxin clearance. However, to date no study has confirmed whether there is a relationship between increased endotoxin levels and the progression of fatty liver disease (FLD), *in vivo*. Therefore for this study we (1) investigated the effect of disease status: FLD and T2DM compared to case controls (CC), (2) the impact of Orlistat, a lipase inhibitor, on endotoxin levels and (3) assessed inflammatory markers including soluble CD14 (an immunological receptor involved in the presentation of LPS to the TLRs), TNFR1, and the anti-inflammatory cytokine adiponectin.

Materials and Methods: Fasted human blood was collected from NAFLD and case control (CC) subjects (NAFLD: Age: 36.8±11.5yrs (mean±SD)yrs, BMI: 26.5±4.4(mean±SD)kg/m² n=80; CC: Age: 38.9±12.4yrs, BMI: 26.5±4.4 kg/m², n=35) accordingly to LERC consent. Diabetic status was also ascertained by glucose and insulin levels. Endotoxin levels were measured by LAL Assay. Inflammatory markers were assessed by ELISA.

Results: The findings from this study showed that endotoxin levels were significantly higher in all patients with fatty liver disease compared with CC (FLD:11.06±0.96EU/mL (mean±SEM); CC:5.27±0.45, p<0.01). FLD alone produced comparable endotoxin levels to T2DM (FLD: T2DM: 10.82±1.15EU/mL; non-diabetic:11.16±0.90EU/mL). In addition, Orlistat treated (1yr) FLD subjects had significantly reduced endotoxin levels compared to pre-treatment (pre:15.8±1.6EU/mL; post: 11.1±1.4EU/mL, p<0.05). Furthermore, sCD14 and resistin were both raised in FLD subjects (p<0.05) whilst adiponectin was reduced in FLD compared with CC (FLD: 11.63±0.60µg/mL vs CC: 17.06±1.74µg/mL, p=0.006).

Conclusion: In summary, our results suggest that FLD is associated with a 7 fold increase in endotoxin levels but ameliorated by Orlistat treatment. As such impaired liver metabolism may result in endotoxaemia, decreased metabolic clearance and increase susceptibility to T2DM. Therefore Orlistat, currently used in the treatment of T2DM could be implemented in FLD to reduce endotoxin and consequent inflammatory burden.

Effects of metformin and fenofibrate on hepatic steatosis in Zucker diabetic rats (ZDF)

F. Forcheron¹, P. Abdallah², A. Basset³, P. Del Carmine⁴, G. Haffar², M. Beylot^{1,3},

¹Faculté RTH Laennec, INSERM ERI 22,

²Faculté RTH Laennec, INSERM U499, ³Faculté Rockefeller, ANIPHY,

⁴Faculté Rockefeller, ANIPHY, Lyon, France.

Background and Aims: Non-alcoholic steatohepatitis (NASH) is frequent in type 2 diabetes and can result in liver fibrosis, cirrhosis and carcinoma. Besides dietary recommendations no specific treatment of NASH has been defined. Promising results have been obtained with metformin in ob/ob mice but studies in humans showed only a limited action. Therefore we tested the efficiency of metformin in an experimental model of NASH, the ZDF rats. Since ppar alpha agonists stimulate lipid oxidation and could reduce tissue TG stores, we investigated also the possible beneficial effect of a ppar alpha agonist, fenofibrate, on NASH.

Materials and Methods: ZDF (n=35) and controls (Lean, L, n=15) rats, all receiving a high fat diet, were studied at 7, 14 and 21 weeks. After the initial study at 7 weeks, 10 ZDF received no treatment, 10 received metformin and 10 fenofibrate (oral administrations) until final studies at 14 or 21 weeks. L rats received no treatment. Each study comprised measurements of plasma glucose, triacylglycerols (TAG), insulin levels, energy intake and expenditure and (5 rats of each group at 7,14 and 21 weeks) hepatic lipogenesis (deuterated water) and liver sampling (TAG content and relevant mRNA concentrations)

Results: Compared to L, ZDF were obese, hypertriglyceridemic and insulin-resistant at 7 weeks, type 2 diabetic at 14 weeks and diabetic with insulin deficiency at 21 weeks. Steatosis was present at 7 weeks (liver TAG content 11.8±0.8 vs 1.9±0.2 µmoles/g p<0.001) with a large increase in hepatic lipogenesis and FAS and SCD mRNA levels (p<0.01). Steatosis was unchanged in ZDF at 14 and 21 weeks (13.7±2.6 and 12.9±0.9 µmoles/g respectively, p<0.01 vs L) despite less important rises in hepatic lipogenesis and FAS mRNA levels. Neither metformin nor fenofibrate modified significantly the evolution of body weight, energy intake or expenditure nor the evolution of diabetes. Plasma TAG were decreased by metformin at 14 (p<0.01 vs untreated ZDF

and 21 (p<0.05) weeks, but only at 21 weeks (p<0.05) by fenofibrate. Hepatic TAG content was reduced by fenofibrate at 14 (5.6±1.4 µmoles/g p<0.05 vs untreated ZDF) and 21 weeks (9.1±1.7 µmoles/g p<0.05) but only at 21 weeks (9.6±0.5 µmoles/g p<0.05) by metformin. The contribution of lipogenesis to these hepatic TAG stores was not decreased at 14 or 21 weeks, neither by metformin nor by fenofibrate, despite a decrease in liver FAS mRNA levels at 14 weeks in ZDF receiving fenofibrate or metformin. Acyl-coA oxidase mRNA levels were increased by fenofibrate (p<0.05).

Conclusion: despite a clear lowering of plasma TAG, metformin had only a moderate beneficial effect on liver steatosis. The beneficial effect of fenofibrate was more marked but remained mild. These moderate actions on liver steatosis are not explained by decreases in hepatic lipogenesis and are probably more related to an increased in hepatic lipid oxidation rate.

Effects of metformin on leptin, obesity and nonalcoholic fatty liver disease compared with lifestyle interventions in obese patients with type 2 diabetes mellitus

A. Nar Demirer¹, O. Gedik²,

¹Endocrinology and Metabolism, Baskent University Faculty of Medicine,

²Endocrinology and Metabolism, Hacettepe University Faculty of Medicine, Ankara, Turkey.

Background and Aims: Insulin resistance is a major feature of type 2 diabetes mellitus, obesity and nonalcoholic fatty liver disease (NAFLD). The pathogenesis of NAFLD is not clear and there is no universal treatment. Metformin is an oral anti-diabetic agent which improves hepatic insulin resistance and promotes weight-loss. It has been suggested that metformin also shows promising improvements in NAFLD. The mediators in these actions of metformin are not totally known. Leptin is an adipocyte-derived hormone that acts as a major regulator for food intake and energy homeostasis. Several studies pointed out the possible role of increased leptin in NAFLD in humans. The aim of this study is to determine the effects of metformin on plasma leptin levels, obesity and NAFLD in obese patients with type 2 diabetes mellitus.

Materials and Methods: Thirty four obese patients with newly diagnosed type 2 diabetes mellitus were prospectively followed for 6 months. All patients had ultrasonographic evidence of NAFLD at baseline. Other causes of liver disease were excluded. The patients were randomised into two groups: group 1 (n=15) was followed by lifestyle changes only and group 2 (n=19) received metformin (1700 mg/day) in addition to lifestyle changes. Body mass index (BMI), waist to hip ratio (WHR), fasting blood samples for the estimation of serum concentrations of glucose, HbA1c, insulin, leptin, aminotransferases and serum lipid profile were measured and liver ultrasonography was assessed at baseline and at the end of the study. There was no statistically significant difference between the groups at the beginning of therapy regarding age, sex, BMI, WHR, HbA1c, serum insulin, leptin, aminotransferases, lipid levels, and liver densities.

Results: At the end of treatment, BMI, WHR, HbA1c, fasting glucose, leptin, alanine aminotransferase (ALT) values decreased in both groups (p < 0.05 vs. baseline for all comparisons). No significant difference in the end-points was observed between two groups. Plasma leptin levels were found to correlate with BMI, but not with biochemical variables. In only group 2, who received metformin, serum LDL-cholesterol levels decreased and HDL-cholesterol levels increased significantly. Fasting insulin and triglyceride levels did not change in either group after the treatment period. Liver echogenicity decreased and hepatomegaly reversed significantly at the end of study in both groups. The percentage of patients who no longer had evidence of NAFLD was not significantly different between the groups (20% of patients on lifestyle intervention vs. 16% of patients on metformin).

Conclusion: We conclude that, metformin and lifestyle interventions equally affected the plasma leptin levels, BMI and degree of NAFLD in obese patients with type 2 diabetes mellitus. In addition, the effects of metformin on the variables were not found to be mediated by leptin.

PS 62 Oxidative stress

Redox stress parameters in type 2 diabetes mellitus

M. Vladica¹, D. Margina², D. Gradinaru², S. Ioacara¹, R. Danculescu¹;
¹Diabetes 1, “N. Paulescu” Institute of Diabetes, ²Biochemistry, “Carol Davila” University, Faculty of Pharmacy, Bucharest 2, Romania.

Background and Aim: Hyperglycemia associated with type II diabetes mellitus determines oxidative stress that leads to important structural, functional and biochemical changes of the endothelial cells and also of the blood cells. The aim of the study was to assay the relationship between the oxidative stress and the biochemical profile of endothelial cells and also of the platelets, erythrocytes and granulocytes.

Materials and Methods: We have selected 40 patients: 20 patients with type II diabetes mellitus that do not respond properly to therapy (study group) and 20 normoglycemic patients (control group). *à jeun* venous blood samples were drawn in order to separate plasma, and (by differential centrifugation), the thrombocytes, granulocytes and erythrocytes. The following parameters were evaluated: fasting plasma glucose, superoxide dismutase activity - SOD (using the Ransod method), the susceptibility to lipid peroxidation of granulocytes and platelets (induced by a non enzymatic system with Fe²⁺ and ascorbic acid and expressed as mM malondialdehyde-MDA/g proteins), the nitrites and nitrates level -NOx (with a global method using the Griess reagent).

Results: Our results pointed out a decrease of the antioxidant SOD activity at the study group (35.18±10.89UI/g hemoglobin, vs. 53.45±6.66UI/g hemoglobin, p=0.006), associated with the increase of the susceptibility of granulocytes (12.32±3.60mM MDA/mg proteins vs. 8.43±2.58mM MDA/mg proteins, p=0.01) and platelets (20.16±4.19mM MDA/mg proteins vs. 15.21±3.30 mM MDA/mg proteins, p=0.01) to peroxidation compared to control. The type II diabetes mellitus patients are characterized by a significantly higher NOx level compared to normoglycemic subjects (43.13±3.89µmoles/l plasma vs. 37.04±5.52 µmoles/l plasma, p=0.04).

Conclusions: Poor metabolic control of fasting plasma glucose in type II diabetic patients is associated with a decreased antioxidant protection at the erythrocyte level, with oxidative changes of the blood cells and with an impairment of the endogenous NO synthesis.

0724

Insulin reduces plasma enzymatic arginase activity in patients with type 2 diabetes

S. R. Kashyap¹, A. Lara², R. Zhang³, Y. M. Park⁴, R. A. Defronzo⁵;
¹Endocrinology, Diabetes and Metabolism, Cleveland Clinic Foundation, Cleveland, ²Medicine, Cleveland Clinic Foundation, Cleveland, ³Cell Biology-Lerner Institute, Cleveland Clinic Foundation, Cleveland, ⁴Cell Biology, Cleveland Clinic Foundation, Cleveland, ⁵Diabetes, University of Texas Health Science Center, San Antonio, nited States.

Background and Aims: Nitric oxide (NO) bioactivity, critical for endothelial function, is dependent on substrate arginine bioavailability. Arginase enzyme converts L-arginine to urea and ornithine, and thereby decreases substrate availability for nitric oxide synthase to produce NO. We hypothesized that arginase activity is increased in patients with type 2 diabetes and that this is related to the severity of insulin resistance.

Materials and Methods: Therefore, we measured plasma arginase activity and arginine metabolites in 12 uncomplicated type 2 dm (D)(49 ± 2y, BMI = 31 ± 1kg/m², FPG 136 ± 13 mg/dl, FPI 16 ± 2 uU/ml, HbA1c = 6.7 ± 1%; diab dur 2y; diet/ oral sulfonylurea controlled) and 10 age/BMI matched non-diabetic subjects (C)(49 ± 3 y, 29.4 ± 1 kg/m², 89 ± 1 mg/dl, 6 ± 1uU/ml)before and following 4 hour physiologic insulin infusion during a 80mU/m²/min euglycemic hyperinsulinemic clamp study to measure insulin sensitivity. Arginine metabolites were determined by tandem mass spectroscopy. Arginase activity was determined by conversion of [¹⁴C] guanidinoarginine to [¹⁴C] urea. Liberated ¹⁴Co₂, trapped as Na₂¹⁴Co₃ was quantified by scintillation counting.

Results: Insulin-stimulated glucose disposal (Rd) in D was reduced by 50% vs. C, (5.4 ± 0.3 vs. 10.4 ± 0.5 mg/ (kg*min), P<0.01). Basal arginine to ornithine ratio, (a surrogate marker of arginase activity) was markedly decreased in D

vs. C subjects. Baseline plasma arginase activity was substantially elevated in D vs. C (0.48 ± 0.11 vs.0.32 ± 0.12 umol/ml/hr, p =0.05) and reduced significantly in D with 4 hr insulin infusion (to 0.13 ± .04 vs. basal, p<0.05). In both groups collectively, plasma arginase activity correlated linearly with fasting plasma glucose (r = .32, p = 0.05) and HbA1c (r = 35, p = 0.05), but not with insulin sensitivity (Rd) or body mass index. Circulating soluble adhesion molecule, VCAM levels correlated linearly with arginase activity (R = 0.55, P = 0.05).

Conclusion: In summary, plasma arginase activity is increased in subjects with T2DM, corresponds to the degree of hyperglycemia, and is markedly reduced by physiologic levels of insulin. Elevated arginase activity may contribute to endothelial dysfunction in type 2 diabetes and moreover, insulin may ameliorate endothelial dysfunction via reducing arginase activity. Arginase blockade may be a target for future therapy in treating diabetes.

Thrombocyte function and oxidative stress markers in blood of type 1 and type 2 diabetic patients and healthy subjects: the in vitro effects of insulin

K. Maria¹, E. Arato², G. Jancso¹, B. Cserepes¹, J. Lantos¹, S. Ferencz¹, S. Bertok¹, A. Ferencz¹, E. Roth¹;
¹Surgical Research and Technique, ²Department of Surgery, Pecs University Medical School, Hungary.

Background and Aims: Insulin is one of the most intensively studied hormones with several physiological actions beyond the regulation of carbohydrate and lipid metabolism.

The aim of the present study was to investigate thrombocyte function and oxidative stress markers in the blood of type-1 (DM1, n=10) and type-2 (DM2, n=10) diabetic patients with peripheral arterial diseases and of healthy blood donors (HBD n=11). In vitro effect of insulin on thrombocyte function and free radical production were also investigated.

Methods: Platelet aggregation was measured in platelet rich plasma (PRP) and in whole blood using ADP (5 and 10 µM) and collagen (2 µg/ml) as inductors. Prooxidant status was characterized by the oxygen free radical production (ROS), in response to phorbol-12-myristate 13-acetate (PMA), and plasma malondialdehyde (MDA) levels. Reduced glutathion (GSH) level and superoxide dismutase (SOD) activity were measured to characterise the endogenous antioxidant status. Collagen induced aggregation, and ROS production were also measured in the presence of insulin (0, 40, 80, 160 µU/ml) in whole blood.

Results: ADP and collagen induced aggregation in PRP were suppressed in both patients groups compared to HBD (27,3±4,06 % DM1; 26,7±7,1DM2; 66,87±9,6 HBD) (P<0,01 in both cases), signing the satisfactory antiplatelet therapy. In whole blood the aggregations were similar in the three groups. Preincubation of samples (3 minutes before administration of inductor), with the above doses of insulin, a U-shaped reduction in collagen induced aggregation occurred in healthy (P<0,05), and in DM1 (p<0,01) subjects, but insulin was ineffective in DM2 patient's blood. PMA induced ROS production were significantly higher in both patients groups, than in healthy subjects (DM1=194,2±61,11; DM2=61,19±9,53, HBD=10,17±3,42 ArbU). Insulin reduced ROS production in DM1 patients (p<0,01), and in healthy subjects (p<0,05), but not in DM2 patients. SOD levels were reduced in DM1 (583,1±63,6 µU/ml; p<0,01 vs. HBD) and DM2 (704,4±81,6 µU/ml; P<0,05 vs. HBD) patients compared to healthy people (1008,75±91,97µU/ml). GSH level was decreased only in DM1 (p<0,05).

Conclusions: Platelets and white blood cells of healthy subjects were sensitive to insulin, which manifested in the insulin related reduction of collagen induced aggregation, and PMA induced ROS production in whole blood. A serious imbalance in endogenous antioxidant and prooxidants was observed in both patients groups and insulin resistance developed against antiplatelet and free radical decreasing effect of insulin in DM2 patients. The sensibility to insulin action was preserved in thrombocyte and white blood cells of DM1 patients.

Effect of acute hyperinsulinaemia and acute AT-1 receptor blockade on the serum levels of oxidative stress markers in type 2 diabetes and healthy subjectsT. Neskudla¹, E. Krusínová¹, M. Kalousova², J. Kopecký jr.¹, T. Pelikanová¹;¹Diabetes Center, Institute for Clinical and Experimental Medicine,²Institute of Clinical Chemistry and Laboratory Diagnostics, First Faculty of Medicine and General University Hospital, Charles University, Prague, Czech Republic.

Background and Aims: It has been shown by recent studies that patients with cardiovascular risk or type 2 diabetes do benefit from AT-1 receptor blocker (ARB) therapy. One possible explanation might be the reduced production of reactive oxygen species (ROS). The relationship between hyperinsulinaemia and oxidative stress is still unclear. The aim of the study is to test the effect of acute hyperinsulinaemia with and without acute AT-1 receptor blockade (losartan) on the serum levels of advanced oxidation protein products (AOPP), pregnancy-associated plasma protein-A (PAPP-A), homocysteine (HCY) and total antioxidation capacity (TAC).

Material and methods: 11 type 2 diabetics (T2D) and 8 lean healthy male subjects (H) underwent: 1) 4 hours lasting hyperinsulinaemic (1 mU.kg⁻¹.min⁻¹) euglycaemic (5 mmol.l⁻¹) clamp (HIC); 2) the same protocol was performed after administration of losartan (two 100mg doses 12 hours before and in the morning of the test) (ARB-HIC). Serum concentrations of AOPP, PAPP-A, HCY and TAC were measured at 0 min, 30 min and 240 min of both clamp studies. AOPP and PAPP-A serum levels were assessed in ratio to serum albumin, to avoid the influence of haemodilution.

Results: Serum concentrations of AOPP were higher in T2D compared to H (p<0.001). During HIC a decrease of AOPP was observed in both groups (p<0.001), whereas during ARB-HIC a different trend was detected without any changes in T2D and with a decline in H (p<0.01). Serum levels of TAC were in global higher in H compared to T2D (p<0.001) and they decreased during both clamps in both groups (p<0.001). During ARB-HIC lower TAC levels compared to HIC (p<0.05) were detected in both groups. HCY levels were higher in T2D compared to H in both clamps (p<0.05). No effect of HIC on HCY was detected in either group, while during ARB-HIC serum HCY decreased significantly in H (p<0.05). Serum levels of PAPP-A showed no changes in either group or clamp.

Conclusion: Acute hyperinsulinaemia is associated with reduction of total antioxidation capacity and unexpectedly of AOPP in both T2D and healthy subjects. T2D have unfavourable oxidative stress markers profile, which is not affected by acute losartan administration. In healthy subjects losartan reduced homocystein levels. (Tab. 1)

We therefore examined the effect of Ricetrienol, which is an antioxidants complex extracted from rice-bran and obtained 3% tocotrienol, and α -tocopherol on the adipocytokine abnormalities in OLETF-rats (Otsuka Long-Evans Tokushima Fatty rat)

Materials and Methods: OLETF-rats (n = 18) were fed with 30% sugar water, as a model of type 2 diabetes mellitus with obesity. The other rats (n = 18) were fed with tap water, as a model of non-diabetes with obesity. After all rats fed with sugar water developed diabetes, the water and tap water fed rats were divided randomly into three groups. Then each group was fed with a standard chew (DM-S, OB-S group), 0.05% Ricetrienol mixed chew (DM-R, OB-R group) or 0.05% α -tocopherol mixed chew (DM- α , OB- α group), respectively. After twelve weeks' feeding, all rats were sacrificed and blood and liver tissue were collected. Body weight and blood glucose were monitored throughout the experiment. Glycohemoglobin was measured by HPLC. Plasma adiponectin, resistin and leptin concentrations were assayed by ELISA. Triglyceride contents of the liver tissue were also determined.

Results: Blood glucose and glycohemoglobin levels in sugar water fed rats were significantly higher than tap water fed rats. These parameters were not affected by Ricetrienol or α -tocopherol supplementation. Plasma adiponectin was significantly reduced in DM-S than OB-S (2.39±0.69 vs 3.43±0.42 ng/dl, p<0.01). Plasma adiponectin was significantly higher in DM-R than DM-S (3.65±0.61 vs 2.39±0.69, p<0.01). Plasma resistin was significantly increased in DM-S than OB-S (29.9±10.2 vs 16.2±5.2 ng/dl, p<0.01). Plasma resistin was significantly lower in DM- α than DM-S (19.6±11.0 vs 29.9±10.2, p<0.05). There was no significant difference in plasma leptin between all groups. Although triglyceride contents of the liver tissue in DM-S were significantly increased than OB-S, triglyceride contents were significantly lower in DM-R than DM-S.

Conclusion: Ricetrienol inhibited the reduction of plasma adiponectin and triglyceride accumulation in the liver. α -tocopherol inhibited the increase of plasma resistin. Our study shows that antioxidants supplementation may prevent the adipocytokine abnormalities and fatty liver in OLETF-diabetic rats.

PS 63 Fetal programming

0728

Is there any evidence of foetal programming on insulin detectable at birth?

J. Beltrand^{1,2}, R. Verkauskern^{1,2}, O. Sibony³, O. Claris⁴, P. Gaucherand⁵, D. Chevenne⁶, C. Lévy Marchal^{1,2},
¹U690, Inserm, Paris, ²Paris 7, Université, Paris, ³Gynécologie et obstétrique, hôpital Robert Debré, Paris, France, ⁴Neonatalogie, Hôpital Edouard Herriot, Lyon, France, ⁵Gynécologie et obstétrique, Hôpital Edouard Herriot, Lyon, France, ⁶Biochimie, Hôpital Robert Debré, Paris, France.

Background and Aims: Subjects born SGA (small for gestational age) are at increased risk of developing type 2 diabetes. Two major issues are not yet solved: Is the risk detectable at birth? Is small body size or foetal growth restriction more related to insulin metabolism? We studied the effect of body composition, foetal growth velocity (FGV) and birth weight (BW) on insulin secretion in newborns included in a prospective cohort of mothers at risk of delivering SGA babies (the CASYMIR cohort).

Materials and Methods: Foetal growth was monitored by monthly ultrasounds between 22–36 GW (gestational weeks) following a highly standardized procedure. FGV was calculated as the change in customized percentiles of the estimated fetal weight (EFW) over the same period. Insulin was measured in cord blood. Fat mass was estimated with the sum of 4 skinfold thickness (STS) at postnatal day 3.

Results: 201 newborns were included. BW was 2968g +/- 601g, gestational age 38,8 +/- 2,04 GW and STS 16,57 +/- 3,5 mm. Cord insulin was 3,65 +/- 2,8 mUI/L. In a multivariate analysis, insulin levels (log transformed) were significantly correlated to BW (β =0,0003, $p=0,048$) and FGV (β =0,09, $p=0,005$) but not by gender (β =-0,03, $p=0,58$) nor gestational age (β =-0,01, $p=0,10$). When STS was included into the model, insulin level was no longer significantly associated to BW but to FGV (β =-0,09, $p=0,007$) and STS (β =0,089, $p=0,05$).

Conclusion: Insulin secretion at birth is related to the quality of foetal growth and subsequently to birth weight. As in older subjects the degree of adiposity influences circulating levels of insulin. Insulin resistance described in children and adults born SGA cannot be detected at birth, when insulin reflects primarily foetal growth. The effect of programming on glucose metabolism is not detectable at the end of foetal life. This programming will be revealed later, under the influence of post natal nutrition and growth.

Maternal diet induced obesity programmes the development of metabolic syndrome in the offspring

P. Nivoit^{1,2}, C. Morens^{1,2}, A. Piersma³, B. Reusens¹, C. Remacle¹, F. A. Van Assche²;

¹Institute of Life Sciences, Catholic University of Louvain, Louvain-la-Neuve, Belgium, ²Department of Obstetrics and Gynaecology, KULeuven, Belgium, ³Laboratory for Toxicology, Pathology and Genetics, National Institute for Public Health and the Environment, Bilthoven, The Netherlands.

Background and Aims: Pregravid and gravid obesity is a common situation with the worldwide explosion of obesity. Epidemiological studies suggest a close link between pregnancy and pre-pregnancy maternal body mass index and increased risk of obesity in children and young adults. Since obesity is a major risk factor for developing metabolic syndrome (MS), a situation usually considered as a prediabetic state, the aim of our study was to determine, in a rodent model, whether maternal diet induced obesity (DIO) could program the development of MS (obesity and impaired glucose homeostasis) in the offspring.

Materials and Methods: We developed a model in which female Wistar rats were rendered obese by consuming, from weaning on, a diet enriched in fat and/or sucrose (OB1: 45% kcal fat, 15.5% kcal sucrose and OB2: 45% kcal fat + sweetened condensed milk). A group of females fed lab chow was also included as control (C). At 3 months, females were mated and allowed to deliver spontaneously. At 21 days of age, control, OB1 and OB2 offspring were weaned onto usual lab chow diet. Body weight (BW), food intake, plasma

parameters, oral glucose tolerance and body composition were assessed in both male and female progeny.

Results: Offspring of DIO dams had a significant increased BW at weaning compared to control (C: 56.8±1.7g; OB1: 69.9±2.4g and OB2 68.1±5.0g, $p<0.001$). BW remained significantly higher at 3 and 6 months, except for OB1 females, and was associated with an increased food intake, especially in males. At 2 months, OB1 and OB2 offspring had higher leptin levels compared to C. Significance was observed for OB1 males ($p=0.023$), OB2 males ($p<0.001$) and OB2 females ($p=0.004$) but not OB1 females ($p=0.066$). Free fatty acid circulating levels were also modified with a slight non significant increase in OB1 and OB2 females whereas a stronger increase was observed in OB1 and OB2 males reaching significance in OB2 males ($p=0.004$). Glycemia, insulinemia, triglyceridemia and total blood cholesterol remained unchanged in OB1 and OB2 offspring when compared to C. At 3 months, glucose response to the oral glucose load measured by the area under the glucose curve (AUG) was unchanged in OB1 males and females compared to C whereas OB2 males and females showed an increased AUG compared to C, reaching significance only for OB2 males ($p<0.001$). Insulin response to the oral glucose load measured by the area under the insulin curve (AUI) was slightly but not significantly increased in OB1 and OB2 males compared to C whereas OB1 and OB2 females showed a stronger but not significant increase of the AUI compared to the C ones. At 6 months, animals were killed and body composition was determined, showing that OB1 and OB2 offspring had a significant increased fat mass when compared to C, especially mesenteric (males, $p=0.014$; females, $p=0.044$) and retroperitoneal fat pads (males, $p=0.009$; females, $p=0.046$).

Conclusion: Our results show that maternal DIO induce development of obesity, altered plasma parameters and perturbations of glucose homeostasis in offspring. These results strongly support the idea that maternal DIO programs the development of MS in offspring. Experiments are running using hyperinsulinemic-euglycemic clamps in 6 months-old animals to confirm these results.

Offspring of diabetic pregnancy have reduced capacity to oxidize fat and become overweight

S. Lau^{1,2}, R. Stokes¹, C. Scott¹, M. McLean², N. Cheung², J. E. Gunton^{1,2};
¹Immunology and Inflammation, Garvan Institute of Medical Research,
²Dept Diabetes and Endocrinology, Westmead Hospital, Sydney, Australia.

Background and Aims: Offspring of diabetic pregnancy (DP) are at higher risk of developing obesity and Type 2 diabetes (T2DM) than offspring of non-DP. We used a novel animal model of DP, the β -cell specific ARNT (aryl hydrocarbon receptor nuclear translocator) knockout (β -ARNT) mouse to elucidate the effects on male offspring with and without a genetic predisposition to diabetes.

Materials and Methods: β -ARNT and floxed control (FC) females were mated with FC and β -ARNT males respectively, giving mixed litters of ~50% β -ARNT and ~50% FC mice. Male offspring were serially weighed and had glucose tolerance tests (GTT) and insulin tolerance tests (ITT) at 8, 16 and 31 weeks. Food consumption was measured at 24 weeks. At 28 weeks metabolic rate was measured using indirect calorimetry and DEXA was performed to measure fat mass.

Results: Non-pregnant β -ARNT females are mildly glucose intolerant owing to a defect in insulin secretion. In late pregnancy, β -ARNT but not FC dams show marked worsening of GTT with mean peak glucose of 21.8 vs 14.4mmol/L ($p<0.01$). Dams were systemically well. Litter size and birthweights did not differ from non-DP. Both groups of DP offspring gained more weight from weaning to 18 weeks of age (20.3 and 20.6g versus 16.9 and 16.4g respectively, $p=0.05$ and $p=0.027$). By 20 weeks of age β -ARNT offspring of DP were ~10% heavier than β -ARNT non-DP offspring ($p=0.008$) despite consuming less food, and had a trend to lower energy expenditure. Floxed-control DP offspring were 1.2g lighter at weaning ($p=0.013$) but weighed ~1g more by 18 weeks of age than non-DP floxed-control offspring despite greater energy expenditure. Area under the curve (AUC) of the maternal late pregnancy GTT was significantly correlated with offspring weight ($r=0.53$, $p=0.001$ at 15 wks). Overall, DP offspring were more insulin resistant than those from non-DP ($p=0.023$ by ANOVA for repeated measures). For both FC and β -ARNT offspring, there was a trend to a higher respiratory exchange ratio (RER) during light hours in DP offspring. AUC of maternal GTT was significantly correlated with offspring RER ($r=0.46$, $p=0.01$).

Conclusion: The data suggest that DP is associated with a reduced capacity to oxidize fat compared to glucose both in offspring that do and do not have a genetic predisposition to diabetes. DP was only associated with a significantly higher weight in β -ARNT offspring, perhaps because it is also associated with lower energy expenditure. The correlation between maternal GTT and offspring RER may explain why human offspring of DP are at greater risk of developing obesity and T2DM than others who were exposed to a normal intrauterine environment.

Taurine prevented the changes of glucose metabolism and mitochondrial structure in the fetal protein-malnourished rat

Y. Y. Lee¹, S. H. Park², K. H. Yi¹, S. S. Lee³, K. S. Park⁴, H. K. Lee⁴;

¹Internal Medicine, Korea Cancer Center Hospital, ²Pathology, Seoul National University, ³Pathology, Korea Cancer Center Hospital, ⁴Internal Medicine, Seoul National University, Republic of Korea.

Intrauterine growth retardation has been linked to the development of type 2 diabetes in later life. The mechanisms underlying this phenomenon are unknown. Taurine, an amino acid, which is necessary for normal development, is implicated in this process. Also in the offspring of the protein-malnourished rats, decreased mitochondrial DNA levels in the pancreas accompanied by reduced insulin secretory responses to glucose load were reported. This study was aimed to investigate the pathogenic role of mitochondria as a link between poor nutrition in early life and type 2 diabetes in later life, and the possible preventive role of taurine of these mitochondrial changes. Male offspring of Wistar rats fed a control diet (20% casein, C group), or low-protein diet (8% casein, LP group), or a low protein diet supplemented with 2.5% taurine in the drinking water (LP-T group) during pregnancy and lactation were weaned onto the control diet. In each group, functional studies to measure insulin secretion and in vivo insulin action, and ultrastructural analysis of the pancreas were aimed at. Fetal protein-malnourished rats showed reduced insulin secretory responses to glucose load. Plasma glucose concentrations after intravenous glucose administration tended to be lower in LP and LP-T group than C group. The plasma insulin concentrations at 2 min, 6 min, and 50 min were significantly lower in LP group than C group ($p < 0.05$). Taurine supplementation tended to restore insulin response to glucose challenge, and this difference was statistically significant at 6 min ($p < 0.05$) (C 3.73 ± 0.68 , LP 1.67 ± 0.43 , LP-T 2.27 ± 0.43 ng/ml at 2 min, C 2.05 ± 0.44 , LP 0.89 ± 0.22 , LP-T 1.48 ± 0.29 ng/ml at 6 min, C 2.02 ± 0.04 , LP 0.85 ± 0.11 , LP-T 0.96 ± 0.26 ng/ml at 50 min, respectively). There were no significant differences in glucose infusion rate during hyperinsulinemic clamp studies (C 14.52 ± 0.69 , LP 19.15 ± 0.55 , LP-T 20.05 ± 0.28 mg/kg/min) among three groups. In the electron microscopic examination of beta cells, the immature secretory granules were increased in L group than C group. In L group, mitochondria were slender elongated appearance with indistinct cristae. Taurine supplementation to the low protein diet restored all these changes. These findings indicate that long-lasting mitochondrial changes caused by fetal protein malnutrition may contribute to the development of type 2 diabetes in later life, and lack of taurine may be a key causative factor for these mitochondrial changes.

Gender differences of insulin resistance development in offspring of gestational diabetic mothers

Z. Leshchenko, V. Poltorak, N. Krasova, A. Gladkih;

Laboratory for Pathophysiology and Medical Genetics, Institute of Endocrine Pathology Problems, Kharkiv, Ukraine.

Background and Aims: Previous studies have indicated that gestational streptozotocin diabetes (GD) induce insulin resistance and strengthened beta-cells dysfunction in Wistar rats adult offspring. But up to now it is unknown whether dysglycemia gender differences would exist in these offspring. The aim of the study was to compare the influence of maternal gestational streptozotocin diabetes on insulin resistance formation in male and female Wistar rats offspring of the first generation (F_1) at puberty.

Materials and Methods: The maternal cohort consisted of 25 pregnant rats exposed to GD and controls (C). GD was rendered by a single streptozotocin injection (45 mg/kg body weight, i.p.) on the second day of pregnancy. An i.p. glucose tolerance test (GTT, 3g glucose/kg body weight; 0, 30, 60, 120 min) was performed after an overnight fast in male and female F_1 groups (12 animals each) at 45 days of age. Fasting blood samples were used for glycemia, plasma insulin (IRI) and non-etherified fatty acids (NEFA) levels determination. Glycogen contents and glucose-6-phosphatase (G-6Pase) activity were measured in liver homogenates. Insulin resistance (IR) state was estimated using Homeostasis Model Assessment (HOMA).

Results: Decrease in glucose tolerance was observed in all GD offspring compared to corresponding C F_1 (AUC/2h over GTT in male: 938.53 ± 14.66 vs 690.55 ± 16.70 mmol/l/min, $p < 0.05$; in female: 1020.70 ± 55.40 vs 711.00 ± 8.58 mmol/l/min, $p < 0.05$). The reliable gender differences of above-mentioned data were absent. NEFA levels were enhanced in both GD-male F_1 and GD-female F_1 in comparison with corresponding C F_1 (male: 0.91 ± 0.04 vs 0.39 ± 0.02 mmol/l, $p < 0.001$; female: 0.77 ± 0.05 vs 0.36 ± 0.03 mmol/l, $p < 0.001$), but more pronounced in GD-male F_1 ($p < 0.05$). Plasma IRI and HOMA-IR index were significantly increased in GD-male F_1 only (IRI: 230.29 ± 4.26 vs 71.40 ± 0.02 pmol/l in C F_1 , $p < 0.001$; HOMA-IR: 7.63 ± 0.30 vs 1.99 ± 0.13 in C F_1 , $p < 0.001$). Liver glycogen content was lower compared to control group in GD-male F_1 (18.77 ± 1.07 vs 31.41 ± 0.93 mg glucose/kg, $p < 0.05$). Maternal GD does not influence on G-6Pase activity in offspring at puberty as male as female.

Conclusion: Thus, the first generation rat offspring from gestational diabetic mothers demonstrate the gender differences of insulin resistance development at puberty, exactly more marked insulin resistance manifestation in male.

Lower nocturnal respiratory quotient in young healthy men who had low birth weight

S. K. Lilleøre^{1,2}, C. Brønns^{1,2}, C. B. Jensen¹, S. Toubro², A. Vaag¹, A. V. Astrup²;

¹Steno Diabetes Center, Gentofte, Denmark,

²Department of Human Nutrition, University of Copenhagen, The Faculty of Life Sciences, Frederiksberg, Denmark.

Background and Aims: Low birth weight (LBW) is associated with obesity, insulin resistance and development of type 2 diabetes (T2D) later in life. We have previously shown increased abdominal fat accumulation and elevated fasting plasma glucose levels in healthy young lean men with LBW. Catch-up growth, which often accompanies LBW, has been associated with reduced energy expenditure (EE) and increased fat mass. The aim of this study was to determine whether LBW was associated with changes in energy expenditure and/or whole-body substrate utilization.

Materials and Methods: Forty-six healthy men, mean age: 24.43 years, were included in the study, 20 subjects with LBW (BW $\leq 10^{\text{th}}$ percentile, BMI: 24.69 ± 3.73 kg/m², lean mass (DEXA): 58.3 ± 4.82 kg, fat mass (DEXA): 16.74 ± 9.24 kg (mean \pm SD)), and 26 matched controls with normal birth weight (NBW) ($50^{\text{th}} \geq \text{BW} \leq 90^{\text{th}}$ percentile, BMI: 23.36 ± 2.59 kg/m², lean mass (DEXA): 61.12 ± 6.57 kg, fat mass (DEXA): 14.30 ± 9.24 kg (mean \pm SD)). Basal metabolic rate (BMR), 24-hr energy expenditure (EE), spontaneous physical activity (SPA), respiratory quotient (RQ), and substrate oxidation rates were assessed using respiratory chambers. Subjects were fed a weight maintenance diet (15 E% protein, 35 E% fat and 50 E% carbohydrate) during the 24-hr chamber measurements, following a 5-day standardized diet and physical activity schedule. Individual energy requirements were estimated according to FAO/WHO recommendations. Fasting plasma glucose levels were significantly elevated in the LBW subjects (4.96 ± 0.47 mmol/l vs. 4.59 ± 0.57 mmol/l (mean \pm SD), $P = 0.01$).

Results: No difference in energy balance was observed between groups. Neither BMR, nor mean 24-hr EE, SPA, RQ or substrate oxidation were different between LBW and NBW groups. This remained true after adjustment for lean mass, fat mass, SPA and energy balance. Interestingly, when the 24-hr period was broken down in intervals, the LBW subjects exhibited significantly lower mean RQ during night time, defined as 1:00 am – 6:00 am, as compared to NBW controls (Fig. 1A: 0.817 ± 0.03 vs. 0.844 ± 0.05 (mean \pm SD), $P = 0.03$). EE was not different between groups during that period (Fig 1B). As a consequence, the relative contribution of lipid and glucose oxidation to EE was shifted in LBW, with significantly higher lipid oxidation (48.54 ± 7.78 vs. 42.61 ± 10.97 % (mean \pm SD), $P = 0.05$) as compared to NBW.

Conclusion: Healthy young lean LBW men had normal 24-hr EE when fed a weight maintenance diet. Interestingly, LBW subjects exhibited a significantly lower nocturnal RQ and, as a consequence, a higher contribution of lipid as compared to glucose oxidation to EE during the night. Reduced nocturnal glucose oxidation may via the glucose-fatty acid cycle, and possibly enhanced hepatic gluconeogenesis, contribute to the elevated fasting plasma glucose levels observed in LBW subjects.

The European Foundation for the Study of Diabetes, The Danish Diabetes Foundation, Aase and Ejnar Danielsen Foundation

Conclusion: Over a 11-yr period, adults born SGA show a more rapid deterioration of glucose tolerance and insulin sensitivity due in part but not only to accretion of more adiposity. This observation suggests that foetal programming affects both body composition and glucose metabolism independently.

Supported by INSERM

0734

An 11-year prospective study on the deterioration of glucose metabolism in adults born SGA

T. Meas^{1,2}, D. Chevenne³, S. Deghmoun¹, D. Collin⁴, C. Lévy-Marchal^{1,5};
¹U690, INSERM, FRANCE, Paris, ²UMR 690, Université Paris 7, FRANCE, Paris, ³Hormonology, Hopital R Debré, Paris, ⁴Maternity, Haguenuau City Hospital, Haguenuau, ⁵UMR 690, Université, Paris 7, France.

Background and Aims: Insulin resistance observed in adults born SGA (small for gestational age) may result either from changes in body composition induced as early as during the catch-up period or from “programming” of peripheral tissues inducing IR, which would be more severe and more rapidly progressive in SGA-born subjects than in adults born AGA (adapted for gestational age).

Materials and Methods: These hypotheses were tested by prospectively observing two groups of young adults selected on birth data from a population-based Maternity registry: 88 subjects (43 women and 45 men) born full-term SGA (BW < 10th percentile) have been compared to 133 (70 women and 63 men) AGA controls (25th < AGA < 75th percentile) at 21 and 32 years of age (T1 and T2). All subjects underwent OGTT and IR was assessed by QUICKI (derived from glucose and insulin fasting concentrations).

Results:

	SGA	AGA	<i>p</i>
n	78	110	
Age (yr) at first observation	21.9 +/- 2.1	21.2 +/- 2.0	0.05
BMI (kg/m ²) first observation	22.4 +/- 3.9	23.0 +/- 4.2	0.3
Glucose 120 min (mmol/l) first observation	5.3 +/- 1.1	5.2 +/- 1.0	0.3
QUICKI 1st observation	0.17 +/- 0.01	0.17 +/- 0.01	0.2
Age (yr) at second observation	31.9 +/- 1.2	32.4 +/- 1.3	0.4
BMI (kg/m ²) at second observation	24.9 +/- 5.8	24.7 +/- 5.0	0.8
Fat mass (%) at second observation	24.06 +/- 8.3	23.4 +/- 7.3	0.5
Glucose 120 min (mmol/l) 2nd observation	5.9 +/- 1.6	5.4 +/- 1.4	0.05
QUICKI at second observation	0.16 +/- 0.01	0.17 +/- 0.01	0.07
Diff BMI T2-T1 (kg/m ²)	2.6 +/- 3.2	1.7 +/- 3.2	0.06
Diff QUICKI T2-T1	-0.007 +/- 0.002	-0.005 +/- 0.001	0.06*

*: In a multivariate analysis, the progression of QUICKI over time was not significantly affected by gender and fat mass but was significantly associated with the change in BMI (*p* = 0.01) and marginally different between SGA and AGA (*p* = 0.1).

Hypothalamic nitric oxide synthase: a key component of lipid-induced deregulation of glucose homeostasis

N. Marsollier, N. Kassis, C. Magnan, C. Cruciani-Guglielmacci; Laboratoire de Physiopathologie de la Nutrition (LPPN), CNRS UMR 7059, Paris, France.

Background and Aims: Metabolic syndrome is a constellation of physiopathologic disorders often associated with a lipid rich diet. Recently the central nervous system, and particularly the hypothalamus, arises as a key player in etiology of type 2 diabetes (T2D). Indeed the hypothalamus integrates circulating signals of satiety and hunger, and is also a nutrient sensing device that monitors and exerts a control of glucose and lipid metabolism via the autonomic nervous system. We have previously shown that 24 hour infusion of triglyceride emulsion in carotid artery toward the brain, at a rate that does not modify plasma free fatty acid and triglyceride levels, results in a hepatic insulin resistance and enhances Glucose Induced Insulin Secretion (GIIS). These mechanisms could be an early step in the development of T2D.

Nitric Oxide (NO) acts as a neurotransmitter and is linked to mitochondrial metabolism, therefore we hypothesized that NO production by Nitric Oxide Synthase (NOS) could mediate central lipid sensing in the hypothalamus, and, at least in part, relay the perturbation of glucose homeostasis induced by central lipid infusion. To characterize the relevance of NO signalling in the effect of central lipid infusion on glucose homeostasis, we used different pharmacological approaches such as local injection of NOS inhibitors, or NO donors.

Materials and Methods: 2 groups of Wistar rats were infused 24h at 2 μ L/min into carotid, one with saline and heparin (C), and the other with triglycerides emulsion (Intralipide®) and heparin (IL). We have assayed NOS activity by measuring conversion of [3H]-L-Arginine into [3H]-L-Citrulline in both groups. We also performed Intravenous Glucose Tolerance Tests (IVGTT) and measurement of glucose turnover rate (euglycemic-hyperinsulinemic clamp), with or without pharmacologic modulators of NO pathway (L-NMMA as inhibitor of the 3 NOS isoforms, 7-Nitro-Indazole as specific inhibitor of neuronal NOS, 1400W as specific inhibitor of inducible NOS, L-Arginine as substrate of NOS, and Sodium Nitro Prusside, SNP, as pharmacologic NO donor). We also determined NOS activities with these different agents. At last inflammatory cytokines (IL-1 β , IL-6, TNF- α , IFN- γ) mRNA expression were determined.

Results: Plasma triglycerides and free fatty acids are not augmented after central lipid infusion. Total NOS activities are significantly increased after 24h of lipid infusion, with a greater augmentation of constitutive NOS (iNOS: +56%, cNOS: +90%). NOS activities were normalized after carotid injection of L-NMMA and 7-Ni. L-NMMA injected before glucose challenge normalizes insulin secretion in IL group, as well as hepatic glucose production, with no effect in C group. Treatments with specific 7-Nitro-Indazole (7-Ni) also restore normal insulin secretion and glucose production. Injection of L-Arginine before IVGTT increases insulin secretion to IL level in control rats. SNP treatments lead to increased GIIS and provoke glucose intolerance, indicating a state of insulin resistance in both groups. Inflammatory cytokine expressions were not modified after 24h of lipid infusion.

Conclusion: We concluded that central NO production, and more particularly via neuronal NOS isoform, is implicated in hypothalamic lipid sensing and plays a key role in brain control of glucose homeostasis. This work could provide new molecular clues as potential target for designing anti-diabetic drugs.

Induction of abnormalities in neuronal NO synthase and its protein inhibitor PIN in rat pancreatic β cells and skeletal muscle after a high-sucrose diet

K. Mezghenna, S. Péraldi-Roux, G. Dubois, M. Manteghetti, M. Tournier, F. Castex, B. Nguyen, J. Boyer, R. Gross, A.-D. Lajoix; UMR 5232, CNRS, Montpellier, France.

Background and Aims: In our previous studies, we have shown that an isoform of neuronal NO synthase (nNOS) and its protein inhibitor PIN are

expressed and control insulin secretion in rat pancreatic β -cells. Skeletal muscle is also known to express a variant of neuronal nitric oxide synthase, nNOS μ , which modulates contractile force and glucose utilization. If a defect in the NOS pathway seems to be responsible for pancreatic β -cell dysfunction and insulin resistance in type 2 diabetes, the reasons for this remain to be determined. Our aim is thus to identify the nNOS and PIN abnormalities present in pancreatic β -cells and skeletal muscle of the high-sucrose diet fed rat, a nutritional model of insulin resistance. We therefore studied nNOS expression at the mRNA and proteic levels, its dimerization state as well as PIN expression in the pancreatic islets and the gastrocnemius skeletal muscle of rats fed a high-sucrose diet.

Materials and Methods: Male Wistar rats received sucrose (7% in drinking water) during 8 weeks. nNOS and PIN expression has been analyzed by quantitative RT-PCR as well as by Western blotting using specific monoclonal antibodies. Dimerization of nNOS has been studied by low temperature SDS-PAGE without boiling the samples, followed by a Western blotting. Subcellular localization of both proteins was determined by immunofluorescence.

Results: After 8 weeks of sucrose feeding, rats displayed a prediabetic state with a moderated hyperinsulinemia of 4.38 ng/ml versus 3.08 ng/ml in the control group ($P < 0.01$), associated with a slight significant increase in glycemia (1.30 versus 1.20 g/l in the control group, $P < 0.05$). In pancreatic β -cells, we found an increased amount of nNOS dimers that correlates with the appearance of hyperinsulinemia in prediabetic rats. We also recorded a decrease in PIN expression which agrees with the enhanced nNOS dimerization state. In addition, we observed both increased nNOS mRNA and protein levels together with a stronger colocalization with insulin after immunofluorescence staining. Conversely, in skeletal muscle, nNOS expression was decreased in insulin resistant rats whereas PIN expression remained unchanged.

Conclusion: Abnormalities in the levels of both nNOS and PIN but also in dimer/monomer equilibrium of the enzyme in pancreatic β -cells and skeletal muscle are associated with the β -cell dysfunction and insulin resistance observed in the high-sucrose fed rat model.

Hepatic iNOS and ST6GalII inflammatory markers are increased in obese diabetic but not in nondiabetic obese rat models

R. T. Ribeiro¹, A. B. Fernandes¹, R. A. Afonso^{1,2}, P. A. Videira³, M. Correia³, M. P. Macedo^{1,4};

¹Physiology, Faculty Medical Sciences, ²Biochemistry, Faculty of Medical Sciences, ³Immunology, Faculty Medical Sciences,

⁴Apdp, Portuguese Diabetes Association, Lisbon, Portugal.

Background and Aims: Several inflammatory markers have been related to obesity, insulin resistance and type 2 diabetes mellitus. The liver has been shown to be paramount in the regulation of whole body insulin-stimulated glucose uptake, by a mechanism that involves hepatic nitric oxide. The liver is also the prime site of the production of acute-phase proteins, which include an increased α -2,6 sialylation of glycoproteins and may play a role in the development of type 2 diabetes mellitus. Thus, we studied the expression of hepatic inflammatory markers related with these processes – inducible nitric oxide synthase (iNOS) and β -galactoside α -2,6 sialyltransferase (ST6GalII) – in lean, obese and obese diabetic animals. Additionally, we measured whole body insulin sensitivity. In this study, we tested the hypothesis that hepatic iNOS and ST6GalII are increased in obesity and aggravated in type 2 diabetes mellitus.

Materials and Methods: We used male 9 weeks-old Zucker lean (LZR), obese fa/fa (OZR) and obese diabetic (ZDF) rats. Hepatic iNOS and ST6GalII expression were determined by Real Time-PCR, using the relative quantification method $-2^{\Delta\Delta Ct}$. Insulin sensitivity was determined, after an overnight fast and 1h refeeding, by a transient euglycemic clamp performed after the administration of a bolus of insulin (50 mU/kg).

Results: In relation to the lean LZR controls (n=8), iNOS expression was barely altered in the obese animals (OZR: 1.8 \pm 0.2 times more expressed than LZR, n=7) but increased in the obese diabetic animals (ZDF: 532.1 \pm 123.4 times more expressed than LZR, n=6, $p < 0.001$). Similarly, ST6GalII expression, whose basal level is particularly high in liver, was also only increased in the diabetic state (OZR: 1.3 \pm 0.1 and ZDF: 2.0 \pm 0.3 times more expressed than LZR, $p < 0.05$). However, post-prandial insulin sensitivity decreased similarly in both obese and obese diabetic rats in relation to their lean littermates (OZR: 73.7 \pm 14.2, and ZDF: 92.1 \pm 3.8 vs LZR: 289.2 \pm 24.7 mg glucose/kg bw,

$p < 0.001$ for both). Observed basal glycemia, as expected, were only raised in diabetic rats (LZR: 108.7 ± 5.0 and OZR: 117.3 ± 5.7 vs ZDF: 186.8 ± 14.4 mg/dl, $p < 0.001$ for both).

Conclusion: Although we observed an increase in both inflammatory markers only with declared diabetes, insulin sensitivity was decreased in both obese and obese diabetic Zucker rats. We conclude that the hepatic inflammatory markers iNOS and ST6GalI are associated not with insulin resistance, but with the hyperglycemia shown in type 2 diabetes mellitus.

Hepatic nitric oxide synthase activity and expression related to insulin resistance in an ageing obesity animal model

A. B. Fernandes¹, P. Videira², M. P. Guarino^{1,3}, R. Ribeiro¹, R. A. Afonso^{1,4}, M. P. Macedo^{1,5};

¹Physiology, Faculty of Medical Sciences-UNL, ²Imunology, Faculty of Medical Sciences-UNL, ³Pathophysiology, Faculty of Medical Sciences-UNL, ⁴Biochemistry, Faculty of Medical Sciences-UNL, ⁵Associação Protectora dos Diabeticos de Portugal, APDP, Lisbon, Portugal.

Background and Aims: A number of studies indicate a central role of the liver in whole-body glucose disposal where a humoral factor, the Hepatic Insulin Sensitizing Substance – HISS – is released from the liver to potentiate glucose uptake in skeletal muscle. HISS synthesis is dependent of hepatic nitric oxide (NO) levels. Obesity and ageing are associated with insulin resistance. Our group described that a decrease of HISS release ($80.4 \pm 0.08\%$) is the major contributor to the insulin resistance associated with ageing. We also reported that insulin resistance presented in an animal model of obesity, the Zucker rat, is partly due to a decrease of HISS action ($40.1 \pm 6.5\%$). In this study we hypothesized that both obese and aged animals show a decrease in hepatic nitric oxide synthase (NOS) activity and expression, which correlates with decreased HISS action.

Material and Methods: The Zucker fa/fa rat (OZR) and its lean littermate, the Zucker fa/+ rat (LZR) were used. The animals were fasted for 18h and refed for 1h. In the first group of experiments, male 9 weeks-old OZR and LZR rats were used. In a second group, male 52 weeks-old OZR and LZR animals were used. Hepatic NOS activity was determined by counting the radioactivity of the ³H-citruline formed by the biochemical conversion from ³H-arginine. Hepatic expression of NOS isoforms (eNOS, nNOS and iNOS) was determined by RT-PCR, using the relative quantification method $-2^{\Delta\Delta Ct}$.

Results: The 9 weeks-old obese rats showed an impaired hepatic NOS activity (3.26 ± 0.30 pmol⁻¹ mg protein min⁻¹, n=8) when compared with lean animals (7.53 ± 0.52 pmol⁻¹ mg protein min⁻¹, n=10; $P < 0.001$). At 52 weeks of age, the hepatic NOS activity of the OZR (3.95 ± 0.32 pmol⁻¹ mg protein min⁻¹, n=5) was also impaired when compared with the LZR (5.61 ± 0.20 pmol⁻¹ mg protein min⁻¹, n=14, $p < 0.05$). Moreover, ageing induced a significant decrease in NOS activity in the LZR but not in the OZR animals. The eNOS and nNOS expression were not altered by obesity or/and age. iNOS expression was significantly altered in the 52 weeks-old LZR animals (183.60 ± 70.41 times more expressed, n = 10, $p < 0.05$) when compared to the 9 weeks-old LZR animals.

Conclusion: OZR showed an impairment of hepatic NOS activity when compared with LZR animals, independently of their age. There was no alteration in eNOS and nNOS expression, indicating that the impairment observed in NOS activity is a post-transcriptional modification. The iNOS expression was only altered in the 52 weeks-old LZR animals, suggesting an association between ageing and inflammatory process. In obese animals ageing does not aggravate the impairment in hepatic NOS activity, already observed at 9 weeks-old. In contrast, we observed that LZR animals showed a decrease of hepatic NOS activity with ageing which correlates with the age-dependent inhibition of HISS action.

Ethanol acutely stimulates islet blood flow, amplifies insulin secretion, and induces hypoglycaemia through a NO-dependent mechanism

Z. Huang, Å. Sjöholm;

Internal Medicine, Karolinska Institutet, Stockholm, Sweden.

Background and Aims: Alcohol-induced hypoglycemia is a well known problem in diabetic patients, but the underlying mechanisms have largely remained elusive. Since insulin secretion *in vivo* can be rapidly tuned by changes in pancreatic microcirculation, we evaluated the influence of acute alcohol administration on pancreatic islet blood flow and dynamic changes in insulin secretion and glycemia in the rat.

Materials and Methods: Ethanol (10 %) was injected as a bolus into a catheter located in the left ventricle of the heart in Wistar rats, yielding serum ethanol levels of ~ 8 mmol/l. Measurements of pancreatic blood flow were performed by a microsphere technique in combination with a freeze-thawing technique after 10 minutes of injection.

Results: Ethanol preferentially and significantly increased pancreatic islet blood flow approx four-fold (Fig. 1A-B),

1A

1B

Fig. 1A-B

while not influencing whole pancreatic blood flow. The nitric oxide synthase inhibitor *N*-ω-nitro-L-arginine methyl ester completely prevented the increased pancreatic islet blood flow evoked by ethanol, while atropine caused a partial prevention. The alcohol also augmented late phase insulin secretion (Fig. 2A) and induced late hypoglycemia (Fig. 2B) upon intraperitoneal glucose tolerance tests.

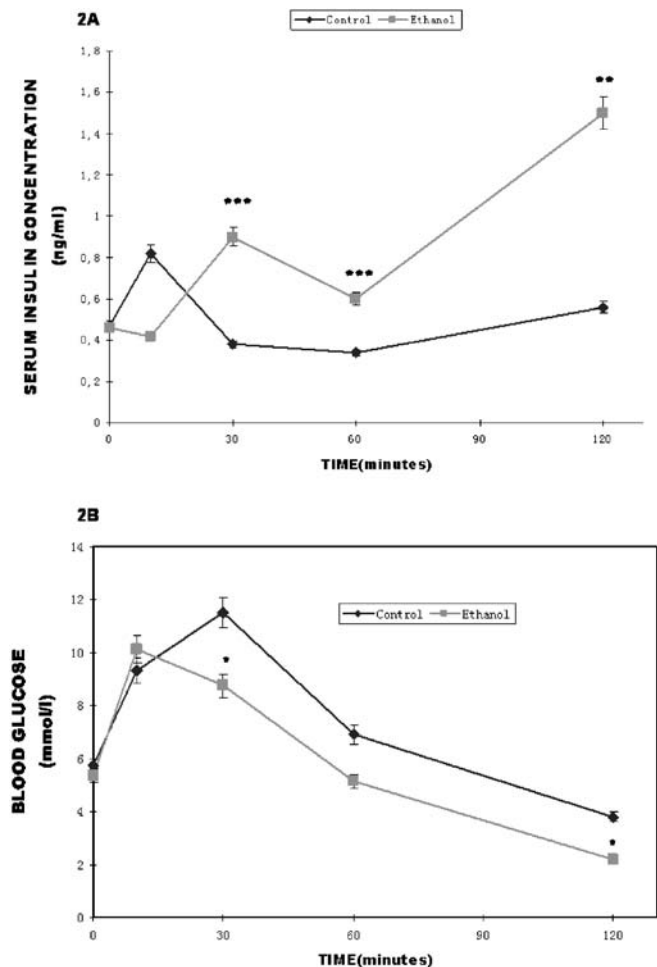

Fig. 2A-B

Conclusion: Ethanol acutely evokes a massive redistribution of pancreatic blood flow into islets via mechanisms mediated by nitric oxide and partly by vagal stimuli, augmenting late phase insulin secretion, and thereby evoking hypoglycemia. This effect may in part underlie the well known hypoglycemic properties of alcohol in diabetic patients or in alcoholics with hepatic failure. *Financial support was provided by the Alcohol Research Council of the Swedish Alcohol Retailing Monopoly*

The nitric oxide-donating derivative of acetyl-salicylic acid NCX 4016 increases glucose transport through translocation of glucose transporters to the plasma membrane in adipocytes

M. Cormont¹, V. Kaddai¹, T. Gonzalez¹, M. Bolla², Y. Le Marchand-Brustel¹; ¹Unit 568, INSERM, Nice, France, ²Research department, NicOx SA, Sophia-Antipolis, France.

Background and Aims: NCX 4016 is a nitric oxide (NO)-donating derivative of acetylsalicylic acid. NO and salicylate, which are in vivo metabolites of NCX 4016, are known to regulate glucose homeostasis. We have evaluated the activity of NCX 4016 on glucose transport in cultured adipocytes in basal conditions and following stimulation with insulin.

Materials and Methods: 3T3-L1 adipocytes were treated with NCX 4016, a reference NO-donor, or acetylsalicylic acid in presence of insulin or not. Effect of NCX 4016 on glucose uptake was measured using 2-deoxyglucose. To further characterize the NCX 4016 effect on adipocytes at molecular level we have assessed the amount of glucose transporters translocation at the plasma membrane by immunodetection, and studied the effect on different molecules of the insulin-signalling pathway.

Results: Following stimulation of 3T3-L1 adipocytes with 200 micromol/L NCX 4016 for 3 and 24 hours, glucose uptake was increased by 2 and 3 fold,

respectively. In parallel, the translocation of the glucose transporters GLUT1 and GLUT4 to the plasma membrane was increased 2.5 fold without any change in the total expression levels of either protein. Importantly, NCX 4016 enhanced the effect of a physiological (0.5 nmol/L) concentration of insulin. In this specific model it seems that NO moiety is mostly major responsible for the effect on glucose uptake, considering that acetylsalicylic acid had no effect and that a NO scavenger (cPTIO) greatly reduced it. NCX 4016-stimulated glucose transport did not require the activation of the soluble cGMP cyclase/protein kinase G pathway. It did not stimulate the insulin receptor, IRS, AS160 phosphorylation or PKB and ERK activity.

Conclusion: NCX 4016 induced a significant increase in glucose uptake in adipocytes. The effect of NCX 4016 and insulin was additive. Equimolar doses of acetylsalicylate did not have the same effect. Because NCX 4016 effectively promoted the translocation of both glucose transporters to the plasma membrane, it apparently acts on the endosomal compartment and not on the GLUT4-specific compartment. NCX 4016 may therefore represent a novel agent for treatment of hyperglycemia in patients suffering from type 2 diabetes.

nNOS is necessary for normal increases in glucose uptake during contraction of skeletal muscle

G. K. McConell, K. C. Linden, J. G. Ryall, C. Van der Poel, J. D. Schertzer, G. S. Lynch; Department of Physiology, The University of Melbourne, Parkville, Australia.

Background and Aims: People with type 2 diabetes have reduced skeletal muscle glucose uptake in response to insulin, but glucose uptake during

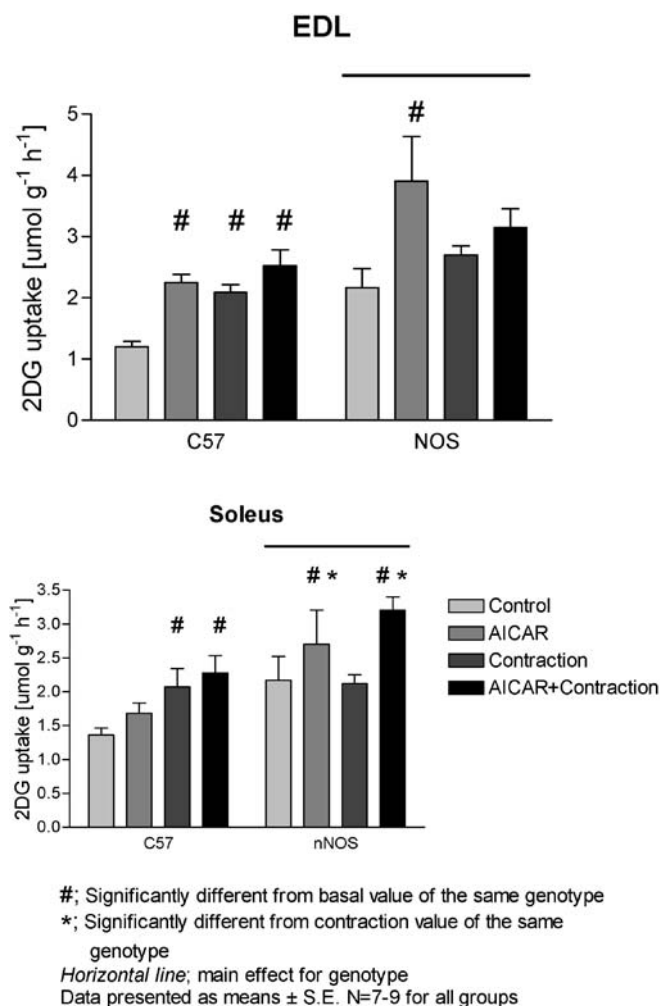

Fig. 1

exercise is normal. The factors regulating skeletal muscle glucose uptake during exercise are unclear. We have evidence that nitric oxide (NO) plays a role in humans, but evidence in rodents is conflicting. We examined glucose uptake in response to contraction and in response to the AMP-activated protein kinase (AMPK) activator AICAR in C57Bl/6 and nNOS null mice (nNOS^{-/-}). It has been shown that there is no increase in cGMP content in response to contraction in nNOS^{-/-} mice.

Materials and Methods: 2-Deoxy-D-glucose (2DG) uptake was examined during contraction in extensor digitorum longus (EDL) and soleus muscles from adult C57Bl/6 and nNOS^{-/-} mice (n= 7–9/group). Following a 40 minute incubation, muscles were stimulated to contract for either 10 minutes (EDL, 60 Hz, 600 ms, train rate 0.167) or 15 minutes (soleus, 60 Hz, 350 ms, train rate 0.167).

Results: Basal 2DG was elevated in the nNOS^{-/-} (P<0.05), however no increase in 2DG was observed during contraction in either the EDL (P>0.05), or soleus (P>0.05), while contraction mediated 2DG was ~ 1.5 fold above basal in the C57Bl/6 (P<0.05). nNOS^{-/-} mice have a normal increase (P<0.05) in glucose uptake with AICAR, and this increase is attenuated with contraction.

Conclusion: These results indicate that skeletal muscle nNOS is required for normal increases in glucose uptake in response to contraction, but not in response to AICAR. They suggest that NO is a critical regulator of skeletal muscle glucose uptake during exercise. (Fig. 1)

glycogen and increased oxidation to C¹⁴O₂ and ³H₂O. siRNA Akt2 reduced mtNOS activity and glycogen synthesis by 70%.

Conclusions: p-AKT2 activated by Insulin-PI3K in mitochondria from skeletal muscle increases the mtNOS activity by phosphorylation in allosteric fashion. This effect reduces O₂ uptake and promotes biosynthetic metabolic pathways, as glycogen synthesis. It is surmised that insulin deals out glucose utilization for energy production or glycogen store by modulating electron transfer rate through matrix NO.

We acknowledge to Dennis Stuehr for giving us cloned nNOS, to Daniel De Seta for insuline glargine and to Natalia Riobó and Juan C. Gagliardino for helpful comments. This work was supported with research grants of Agencia Nacional

0742

Insulin signaling induces p-AKT2 translocation and nNOS activation in muscle mitochondria: the NO-pathway to distribute glucose for oxidation or for glycogen synthesis

P. V. Finocchietto, F. Barreiro, S. Holod, J. G. Peralta, M. C. Franco, D. P. Converso, M. C. Carreras, J. J. Poderoso;
University of Buenos Aires, Clinical Hospital, Argentina.

Post translational modifications as N- terminal acylation and Serine 1412 phosphorylation are associated to neuronal nitric oxide synthase translocation to mitochondria in different tissues (mtNOS). mtNOS synthesizes nitric oxide (NO) vectorially directed to the mitochondrial matrix and NO steady-state concentration modulates the electron transfer, O₂ uptake and reactive oxygen species production.

Considering that Serine 1412 of NOS is in an AKT-dependent domain, we analyzed insulin/Akt effects on mitochondrial Nitric Oxide Synthase (mtNOS) from rat skeletal muscle.

Materials and Methods: Wistar rats (200–250g) were subcutaneously inoculated with 0.1U/Kg insulin glargine or ClNa 0.9% and afterwards extensoris digitorum and gastrocnemius muscles were surgically excised at 3, 12 and 24 hours. Purified muscle mitochondria from treated animals were obtained by differential centrifugation and tissue slices were incubated with insulin and LY294002 (PI3K specific inhibitor) as well. mtNOS activity was determined by conversion of [³H] L-arginine to [³H] L-citrulline. The expression of mtNOS, p-AKT, AKT 1, AKT 2 and GSK 3 α / β were analysed by Western Blot and p-AKT activity by formation of p-GSK-3 α / β . The mitochondrial p-AKT and NO were determined by flow cytometry. nNOS phosphorylation was evaluated in pure recombinant protein and mitochondria with ³²PATP. Mitochondrial and muscular tissue oxygen uptake were determined polarographically. siRNA (nNOS and Akt2) was injected into left gastrocnemius in rat under slight anaesthesia and electric pulses of 120 V, 1 Hz were applied. Metabolic activity was determined in electroporated muscles with deoxy-D glucose 2 [1,2 ³H(N)], glucose D-[¹⁴C(U)] and glucose D-[5-³H(N)]. Data were expressed as means \pm s.em and analyzed by ANOVA and Dunnet's test. Statistical significance was accepted at p< 0.05.

Results: 1) Insulin increased the mtNOS activity at 12 and 24h by 10-15 fold (C: 30 \pm 1; 3h: 35 \pm 3; 12h: 291 \pm 9; 24h: 145 \pm 3 pmoles/min/ mg prot) without changes in its expression. This activity was inhibited by LY294002 in muscle homogenates 2) AKT2 protein levels were increased in cytosol and mitochondria at 3 and 12 h but the AKT 1 expression was unaltered 3) Mitochondrial NO production rate was increased at 12 and 24h; and mitochondrial oxygen uptake was lower at 12 and 24h respect to controls and 3 h 4) p-AKT translocated to mitochondria increased at 3– 12 h respect to controls but further decreased at 24 h 5) AKT activity was higher at 3 and 12 h in mitochondria and cytosol respect to controls and 24 h 6) mtNOS was phosphorylated by p-AKT *in vivo* 7) Administration of siRNA nNOS to gastrocnemius muscle decreased by half C¹⁴-glucose (U) incorporation to

Protein array analysis reveals changes in the subcutaneous adipose tissue adipokines expression associated with the growth hormone deficiency

J. Ukropec¹, A. Penesová², M. Škopková¹, M. Pura³, M. Vlček², Ž. Rádiková², R. Imrich², V. Belan⁴, P. Vaňuga³, J. Payer⁵, J. Eckel⁶, I. Klimesš¹, D. Gašperiková¹;

¹Diabetes Laboratory, Institute of Experimental Endocrinology, Bratislava, Slovakia, ²Laboratory of Clinical Endocrinology, Institute of Experimental Endocrinology, Bratislava, Slovakia, ³Department of Endocrinology, National Institute for Endocrinology and Diabetes, Lubochňa, Slovakia, ⁴Radiodiagnostic clinic, Comenius University Hospital, Bratislava, Slovakia, ⁵5th Department of Internal Medicine, Comenius University Hospital, Bratislava, Slovakia, ⁶Inst. of Clinical Biochemistry and Pathobiochemistry, German Diabetes Center, Duesseldorf, Germany.

Background and Aims: Adipokines and inflammatory cytokines from adipose tissue contribute to the regulation of metabolic processes. However, their specific role in pathogenesis of metabolic derangements related to the growth hormone deficiency (GHD) is not fully understood. This prompted us to investigate the protein expression of 120 adipokines in the subcutaneous adipose tissue of adult patients with untreated GHD.

Patients and Methods: Sixteen (10/6, M/F) young (30±2 years), growth hormone deficient (ITT verified) individuals with BMI (27.0±1.0 kg/m²) and 16 age, gender and BMI matched healthy control subjects were investigated. Subcutaneous adipose tissue biopsy was carried out between 8:00–10:00 AM. Protein expression was determined in the tissue lysates with aid of the “RayBio” Human Cytokine Antibody Array C Series 1000”.

Results: GHD individuals had a higher waist circumference, elevated circulating hsCRP and 45% of them showed impaired glucose tolerance. Adipose tissue of the GHD patients showed elevated protein expression of **IGFBP-1** (+53%, p=0.05), and lowered expression of **BDNF** (-29.5%, p=0.015), **NT-3** (-37.3%, p=0.027) a **SDF-1** (-25%, P=0.045). Adipokine expression was significantly affected by minor changes in the obese phenotype. Multiple regression analysis using IGF-1 (GH deficiency) and BMI (obesity) as independent variables revealed some adipokines to be regulated by growth hormone deficiency, which was independent on obesity /BMI/ (**IGFBP1**, p=0.004; **Interferon γ**, p=0.014; **MCP4**, p=0.04; **IGF-1**, p=0.05). Interestingly, some of the adipokines negatively associated with GH deficiency (**GHD**) were positively related to obesity (**O**) (**TIMP2**, **GHD**: p=0.02 **O**: p=0.05; **HGF**, **GHD**: p=0.03 **O**: p=0.05; **Leptin**, **GHD**: p=0.05 **O**: p=0.001) and, conversely, some adipokines positively associated with **GHD** were negatively related to obesity (**b-NGF**, **GHD**: p=0.005 **O**: p=0.05; **IGFBP3**, **GHD**: p=0.04 **O**: p=0.05).

Conclusions: According to our knowledge this is the first data on adipokine protein expression in adipose tissue of adult GH deficient individuals, which indicates specific changes in regulation of the adipose tissue growth and differentiation as well as in tissue inflammation. We hypothesize that this phenomenon could be related to early changes of the metabolic phenotype in young adults with yet untreated growth hormone deficiency.

A role of lipin in depot specificity of peroxisome proliferator-activated receptor γ action on adipose tissue metabolism in a diabetic animal model

S. Park¹, J. Lee², E. Park², E. Kang¹, C. Ahn¹, H. Lee¹, B. Cha¹;

¹Department of internal medicine, ²Brain Korea 21 Project for Medical Science, Yonsei University college of medicine, Seoul, Republic of Korea.

Background and Aims: Treatment with rosiglitazone, a potent peroxisome proliferator-activated receptor (PPAR)- γ agonist, results in lipid storage coupled with reduced release of free fatty acids into the circulation. Many studies reported that PPAR- γ agonism brings about redistribution of fat toward subcutaneous depots and away from visceral fat. Lipin, gene product of *LPIN1*, is associated with increased adiposity in mature adipose tissue as well as differentiating adipocytes. Transgenic mice with enhanced lipin expression in adipose tissue become obese, but remain insulin

sensitive, likely due to a redistribution of lipids from ectopic sites. Herein, we hypothesized that the depot-specific regulation of lipin by rosiglitazone may be associated with the fat-redistribution and insulin-sensitizing effects of rosiglitazone.

Materials and Methods: After 4 weeks of rosiglitazone treatment in Otusuka Long-Evans Tokushima Fatty rats, an animal model of type 2 diabetes mellitus, we measured changes in adiposity, adipocyte morphology, and lipin messenger RNA and protein expression in adipose tissue.

Results: Rosiglitazone increased subcutaneous adiposity, decreased plasma free fatty acids, decreased the cell diameters of adipocyte, and improved insulin resistance. Lipin messenger RNA expression increased in subcutaneous fat, but decreased in visceral fat by rosiglitazone treatment. In 3T3-L1 cell, rosiglitazone pretreatment decreased lipolysis and increased lipin mRNA and protein expression.

Conclusion: These findings demonstrate that depot-specific changes of lipin expression in adipose tissue after rosiglitazone treatment is likely to be a mediator of reduced lipolysis, resulting in fat redistribution and insulin sensitization.

Expression of *KiSS-1* in rat adipose tissue and pituitary gland: regulation in diabetes and high fat diet

S. A. Imran¹, R. Brown², E. Ur¹, M. Wilkinson^{2,3};

¹Endocrinology & Metabolism, Dalhousie University,

²Physiology, Dalhousie University,

³Obstetrics and Gynecology, IWK Hospital, Halifax, Canada.

KiSS-1, originally thought to be a metastasis suppressor gene, encodes a 145 amino acid precursor peptide that is proteolytically cleaved to a family of peptides known as kisspeptins. Kisspeptins appear to be the natural ligands of the previously orphan receptor GPR54. There is compelling evidence that hypothalamic kisspeptin is a critical component in sexual maturation. The kisspeptin receptor, GPR54, is widely distributed in the brain but is also found in peripheral sites such as pituitary, placenta, ovary and adipose tissue. Kisspeptin might therefore be a circulating hormone and/or be locally expressed in specific tissue sites. It is known that hypothalamic *KiSS-1* mRNA levels are decreased by food restriction, stimulated by leptin and regulated by sex steroids. We have also provided evidence that the *KiSS-1* gene is expressed in rat adipose tissue (FAT) and pituitary gland (PIT). We therefore hypothesized that *KiSS-1* mRNA would be sensitive to changes in bodyweight and diabetic status in these tissues. Using realtime RT-PCR we detected a 56% reduction (p<0.01) in *KiSS-1* mRNA in visceral fat from weanling male rats fed a high-fat diet for 20 days, although no changes in pituitary *KiSS-1* mRNA were observed. Adipose *KiSS-1* mRNA levels in the adult, obese diabetic (fatty; fa/fa) Zucker rat were significantly reduced (50%; p<0.05) in both visceral and subcutaneous fat, whereas it was increased in PIT tissue (+60%, p<0.05), relative to expression in lean littermates. In contrast an overnight fast increased *KiSS-1* expression in FAT (4.5-fold; p<0.01) and significantly inhibited pituitary *KiSS-1* (-60%, p<0.05). We conclude that *KiSS-1* gene expression in fat tissue is sensitive to a high fat diet as well as diabetes. These novel findings suggest that adipose and pituitary kisspeptins may be implicated in the pathophysiology of diabetes.

Molecular cloning of a novel gene from human adipose tissue with its expression induced by fasting

Y. Kuroda, H. Kuriyama, K. Kishida, N. Maeda, H. Nishizawa, S. Kihara,

T. Funahashi, I. Shimomura;

Department of Metabolic Medicine, Graduate School of Medicine, Osaka

University, Japan.

Background and Aims: We made an expression profile in the human adipose tissue and we have isolated several novel adipose tissue-specific genes using the profile. “Adiponectin” and “Aquaporin adipose (AQPap)” correspond to those genes. We elucidated that Adiponectin is one of the important adipocytokines and a key molecule in the development of Metabolic syndrome and that AQPap is a glycerol channel in adipocytes and one of the important

factors of determining fasting blood glucose levels. We tried to find another novel gene abundantly expressed in white adipose tissue.

Materials and Methods: The novel gene was isolated by 3'-directed cDNA library method. The mRNA expression was examined by Northern blotting and quantitative RT-PCR in the liver and white adipose tissue of mice and 3T3-L1 adipocytes. The mRNA change in feeding condition was investigated in mice.

Results: Recently we isolated a novel gene from human white adipose tissue and its expression in that tissue and liver was induced by fasting, therefore, we named the gene "fasting induced protein (FIP)". The human FIP gene encoded 214 amino acids which showed approximately 60% homology with mouse FIP at the amino acid level. The mRNA expression of FIP was increasing during differentiation in 3T3-L1 cells. The administration of insulin dramatically suppressed FIP mRNA expression in 3T3-L1 and HepG2 cells in dose- and time-course dependent manners. Compatible with this observation, the refeeding condition which means high insulin levels reduced the FIP mRNA expression in the liver and white adipose tissue of mice.

Conclusion: We isolated a novel gene named "FIP", from human adipose tissue of which expression was induced by fasting and reduced by refeeding.

Adipocyte lipid-binding protein in subcutaneous adipose tissue in subjects with different categories of glucose intolerance

E. Krušinová¹, J. Kopecký Jr.¹, P. Mlejnek², P. Wohl¹, M. Pravenec², T. Pelikanová¹;

¹Diabetes Center, Institute for Clinical and Experimental Medicine, Prague, ²Institute of Physiology, Academy of Sciences of the Czech Republic, Prague, Czech Republic.

Background and Aims: Adipocyte lipid-binding protein (ALBP) has been shown to regulate lipid metabolism and thereby to affect insulin sensitivity. However, its regulation in human obesity has not been clarified up to now. Our aims were to measure the expressions of ALBP in subcutaneous adipose tissue in subjects with different categories of glucose intolerance and to analyze possible relationships of ALBP with selected metabolic parameters.

Materials and Methods: Eight healthy men (H), 12 subjects with impaired glucose tolerance (IGT) and 11 patients with type 2 diabetes (D) underwent 4-hour hyperinsulinaemic (1 mU.kg⁻¹.min⁻¹) euglycaemic (5 mmol.l⁻¹) clamp in order to verify their insulin sensitivity. Needle biopsy of abdominal subcutaneous fat was performed before the clamp to assess the ALBP expressions using the real-time PCR method. As a reference gene human cyclophilin was used.

Results: Insulin sensitivity, expressed as metabolic clearance rate of glucose (MCR), was significantly higher in H compared to D and IGT, whereas IGT did not differ from D: MCR (H vs. IGT vs. D: 8.68±0.55 vs. 4.47±0.66 vs. 4.88±0.49 ml.kg⁻¹.min⁻¹; p<0.001; ANOVA). Other anthropometric and metabolic parameters (fasting serum lipids, waist circumference, BMI) were comparable between IGT and D, and lower in H compared to other groups. Relative expressions of ALBP were at the lowest level in IGT compared to D and H, in H we detected the highest expression: ALBP mRNA/cyclophilin mRNA (H vs. IGT vs. D: 3498±761.7 vs. 1133±126.1 vs. 2024±194.8; p<0.001; ANOVA). Significant positive correlation was found between ALBP expression and MCR (r= +0.433; p<0.02) and negative correlations between ALBP and fasting triglycerides (r= -0.448; p<0.02) or waist circumference (r= -0.473; p<0.01).

Conclusion: Our results suggest, that ALBP expression in subcutaneous adipose tissue is positively associated with insulin sensitivity. Although having similar metabolic profile to type 2 diabetes, impaired glucose tolerance is associated with decreased expression of ALBP, which could not be explained by measured variables.

²Department of Surgery, Faculty Hospital, Kramare, ³Laboratory of Human Endocrinology, Institute of Experimental Endocrinology,

⁴Department of Surgery, Comenius University, Bratislava, Slovakia.

Localized subclinical inflammation in the adipose tissue (AT) seems to play an important role in development of the negative metabolic consequences associated with obesity. Significance of different AT depots in this process has been intensively studied. Nevertheless, regulation of adipocytokine production at the molecular level particularly in extreme obesity has not yet been completely understood. Therefore, this study is aimed to investigate the gene expression of pro-inflammatory adipocytokines in subcutaneous (Sc) AT and visceral (Vs) AT of extremely obese subjects.

Subjects and Methods: Twelve control (C) subjects (3M/9F) with BMI<25 kg/m² and fifteen individuals (4M/11F) with extreme obesity (O) (BMI ranging from 35 to 60 kg/m²) were recruited. ScAT and VsAT were obtained during laparoscopic gastric banding and/or during standard intra-abdominal surgical intervention in non-inflammatory diseases. The mRNA levels for selected adipokines and inflammatory cytokines were measured by the quantitative real-time RT-PCR.

Results: In ScAT of extremely obese patients, the mRNA levels for leptin (O: 2.7±0.3 vs. C: 0.8±0.2 AU; p<0.001), PAI-1 (O: 1.7±0.3 vs. C: 0.5±0.1 AU; p<0.05) and CD-68 (O: 1.0±0.2 vs. C: 0.5±0.2 AU; p<0.05) genes were higher as in the control group. The VisAT of the obese subjects, contained higher mRNA levels for leptin (O: 1.4±0.2 vs. C: 0.8±0.2 AU; p<0.01), NF-κB (O: 1.2±0.2 vs. C: 0.5±0.1 AU; p<0.01) and IL-6 (O: 6.4±1.4 vs. C: 1.7±0.4 AU; p<0.01) and lower mRNA amount for adiponectin (O: 0.9±0.1 vs. C: 1.2±0.1 AU; p<0.05) as compared to the controls. **Correlation analysis** showed that expression of leptin in ScAT is positively associated with PAI-1 (r²=0.39, p=0.0003), IL-6 (r²=0.21, p=0.016) and CD-68 (r²=0.23, p=0.07). A possible role of inflammation for the obese VisAT phenotype was further indicated by the positive correlation between NF-κB and PAI-1 (r²=0.25, p=0.011) in the VsAT.

Conclusions: Results of this study indicates that the pro-inflammatory markers and regulators are expressed in extreme obesity mainly in the visceral adipose tissue. Moreover, different expression pattern for selected adipokines and inflammatory cytokines in the two AT depots investigated clearly advocates for distinct pathophysiological roles of the subcutaneous and visceral adipose tissue in extreme obesity.

The mechanisms of adrenaline-stimulated utilisation of glucose in rat adipose tissue

M. Cahova, H. Vavrinkova, H. Dankova, L. Kazdova;

PEM, Institute for Clinical and Experimental Medicine, Prague 4, Czech Republic.

Background and Aims: Besides its main effect, which is the stimulation of triglyceride breakdown we showed that in rat adipose tissue adrenalin also potentiates basal and insulin-stimulated utilisation of glucose in adipose tissue during *in vitro* incubation. The stimulation of β adrenergic receptors by adrenalin results in the elevation of intracellular cAMP concentration and accentuated lipolysis. PKA (protein kinase A) has been considered as the main downstream target of cAMP but recently another PKA independent binding protein for cAMP called EPAC has been described. In muscle, adrenalin potentiates insulin-stimulated PKB activation via cAMP and EPAC but the role of EPAC in adipose tissue has not been elucidated yet. Our study was designed to assess the mechanism(s) of adrenalin stimulated glucose utilisation in adipose tissue. The adipose tissue was incubated in the presence of insulin, adrenalin and cAMP derivatives that stimulate selectively EPAC or PKA and the effects of these compounds on lipolysis and glucose utilisation was determined. The possible involvement of PKB in adrenalin stimulated glucose utilisation was also addressed.

Materials and Methods: The epididymal adipose tissue of fasting male Wistar rats (300 ± 20g) fed for two weeks by high sucrose diet (70 cal% as sucrose) was incubated either in basal KRB medium or in medium supplemented with adrenaline (5.10⁻⁶M), insulin (250 μU/ml), EPAC activator (8-pCPT-2-O-Me-cAMP; 5.10⁻⁴ M) or PKA activator (6-Bnz-cAMP; 1,7.10⁻³ M). The lipolysis was estimated according to the glycerol release, the utilisation of glucose was determined by incorporation ¹⁴C-glucose into Tg. The PKB phosphorylation was determined by immunodetection using specific anti phosphoAkt (Ser 473) antibody.

Results: The lipolysis in adipose tissue was comparably increased by adrenaline, EPAC activator and PKA activator. Adrenaline increased the glucose incorporation into Tg and had no effect on lactate production. In contrast to this, EPAC had no effect on glucose metabolism and PKA activator the utilisation of glucose significantly decreased. The results are shown in the table; data are expressed ± SEM, in μmol/g w.v. The PKB phosphorylation on Ser⁴⁷³ after adrenalin stimulation in vitro increased by 60% over basal, insulin under the same condition stimulated the PKB phosphorylation by 130%.

Conclusion: In adipose tissue, adrenalin concomitantly activates two opposite processes: lipolysis resulting in increased NEFA production and incorporation of glucose into glycerol of triglycerides (reesterification) that render part of the released NEFA in the tissue. Adrenaline, EPAC and PKA activators had similar positive effect on lipolysis but synthetic cAMP analogs in contrast to adrenaline did not stimulate glucose incorporation into Tg. Our experiments proved the stimulatory effect of adrenaline on PKB phosphorylation. This finding suggests the existence of possible cross talk between insulin receptor and β-adrenergic receptor signalling pathways in adipose tissue. (Tab. 1)

Supported by IGA MH CR NR/8495-3

specific CD28 antigen was upregulated >11-fold (p<0.001) and chemokine ligand 13, involved in leukocyte accumulation in inflammation, was induced >7.5-fold (p<0.00001) in FCHL. Alpha 2 glycoprotein 1, a known lipolytic factor in cancer cachexia, was also downregulated in FCHL subjects (>4.5-fold, p<0.001). In addition to individual genes, differential regulation was also observed in gene sets encoding biological pathways. The most significant changes were observed in pathways related to humoral response, antigen presentation and fatty acid metabolism (p<1E-12 for each pathway). A majority of genes related to tricarboxylic acid cycle, glycolysis and pyruvate metabolism were also found to be downregulated in FCHL subjects based on visual analysis.

Conclusion: Initial analysis of whole genome transcript profiling point to a net inflammatory state in FCHL adipose tissue mediated by upregulation of pro-inflammatory and downregulation of anti-inflammatory genes. Genes related to fatty acid and cholesterol biosynthesis are repressed, possibly due to substrate feedback. The observed data offer a possible explanation for mechanisms underlying clinical observations in FCHL and insulin resistance.

Whole-genome mRNA profiling in adipocytes from insulin-resistant subjects with familial combined hyperlipidaemia

C. J. H. van der Kallen¹, S. Ghosh², S. Meex¹, M. van Greevenbroek¹, C. Stehouwer¹, D. Noel², T. de Bruin²;

¹Department of Medicine, University of Maastricht, The Netherlands,

²GlaxoSmithKline, Research Triangle Park, United States.

Background and Aims: Insulin resistance is an underlying trigger for metabolic syndrome and is often associated with visceral adiposity, hypertension, hyperglycemia and dyslipidemia. The molecular mechanisms underlying insulin resistance are incompletely understood. We used whole-genome mRNA profiling to investigate transcriptional changes in adipocytes from insulin resistant subjects with Familial Combined Hyperlipidemia (FCHL) compared to controls. FCHL is the most common form of genetically determined dyslipidemia, present in 1–2% of the general population. FCHL patients share features of insulin resistance such as abdominal obesity, impaired glucose tolerance and hyperinsulinemia and is further characterized by familial aggregation of multiple dyslipidemic profiles in association with early-onset coronary artery disease. Our results shed light on the molecular mechanisms operative in the insulin resistant, FCHL adipocyte.

Materials and Methods: Adipocytes were isolated from periumbilical liposuction biopsies and purified by collagenase treatment and flotation after centrifugation. RNA was isolated using the Trizol reagent. RNA from 9 fasted controls and 21 fasted FCHL patients were hybridized to Affymetrix HG_U133 Plus 2.0 microarrays. Gene signals were computed and normalized by GCRMA. Identification and interpretation of statistically significant differences in genes and pathways was accomplished by bioinformatic and statistical tools including Spotfire, Ermine J and JMP.

Results: Key genes related to fatty acid and cholesterol biosynthesis were downregulated in FCHL compared to controls (e.g. fatty acid synthase repressed >2.5-fold, p<0.02; lanosterol synthase repressed >3.5-fold, p<0.0004). Phospholipase A2, a proinflammatory gene, was induced (>6.5-fold, p<0.02) and leukotriene B4 12-hydroxydehydrogenase, an anti-inflammatory gene, was repressed in FCHL (>2.5-fold, p<0.001). The T-cell

RBP4 in glucose metabolism during fasting in lean healthy humans

M. R. Soeters¹, H. P. Sauerwein¹, M. T. Ackermans², E. Fliers¹, M. J. Serlie¹;
¹Endocrinology and Metabolism, ²Clinical Chemistry, Laboratory of Endocrinology, Academic Medical Center, Amsterdam, The Netherlands.

Background and Aims: Plasma retinol binding protein 4 (RBP4) has been proposed as an adipokine involved in obesity-induced insulin resistance. Other reports suggested that the higher plasma RBP4 levels in insulin resistant subjects relate to the lower glucose influx in insulin resistant adipocytes. To test this hypothesis, we studied plasma RBP4 concentrations and glucose metabolism during fasting, since fasting is characterized by lower glucose uptake in adipocytes and insulin resistance.

Materials and Methods: We measured glucose metabolism and plasma RBP4 levels in the basal state and during a hyperinsulinemic euglycemic clamp after short term fasting. Data from 26 lean healthy volunteers were included. Six men were studied after 14 and 62 h of fasting (protocol 1), and 10 males and 10 females after 38 hours only (protocol 2).

Statistics: Data presentation median [min–max]. Differences: Wilcoxon-signed rank test (protocol 1) and Mann-Whitney U test (protocol 2). Correlations: Spearman's rank correlation coefficient (ρ).

Results: RBP4 levels were 32% lower after 62 h compared to 14 h of fasting: 27.1 $\mu\text{g/ml}$ [25.0–38.7] and 20.7 $\mu\text{g/ml}$ [12.3–21.7] respectively, ($P = 0.046$). Plasma RBP4 levels in women were 18% lower than in men: 18.4 $\mu\text{g/ml}$ [13.0–20.7] and 21.0 $\mu\text{g/ml}$ [18.1–26.1] respectively, ($P = 0.005$). The endogenous glucose production tended to be lower in women ($P = 0.074$). There was no statistically significant difference in peripheral insulin-mediated glucose uptake between women and men. Plasma RBP4 did not correlate with endogenous glucose production or insulin-mediated glucose uptake after fasting ($\rho = 0.2$, $p = 0.3$ and $\rho = 0.2$, $p = 0.4$ respectively).

Conclusion: Plasma RBP4 levels decrease during fasting in lean healthy humans. Women have lower plasma RBP4 levels than men despite comparable glucose metabolism. Plasma RBP4 is not correlated to endogenous glucose production or peripheral glucose uptake. These findings contradict a role for RBP4 as an important regulator in glucose metabolism during fasting in lean healthy humans.

0752

Serum retinol binding protein 4 levels are decreased in insulin treated type 1 diabetic patients

M. Jourdan¹, A. Jaleel¹, J. P. McConnell², M. Bigelow¹, H. Karakelides¹, K. S. Nair¹;

¹Endocrine Research Unit,

²Immunochemical Core Lab., Mayo Clinic, Rochester, United States.

Background and Aims: Retinol binding protein 4 (RBP-4) has been reported to be elevated in insulin resistant states such as in type 2 diabetes, as well as in obese and elderly people. In type 2 diabetic subjects, RBP-4 is negatively correlated to insulin sensitivity and insulin-sensitizing agents normalize RBP-4 levels. RBP-4 has therefore been proposed as an adipocyte-derived “signal” that may contribute to the pathogenesis of type 2 diabetes. No informations are available on RBP-4 levels in T1D patients or whether insulin *per se* has any effect on RBP-4 levels. Thus, the purpose of this study was to determine whether serum RBP-4 levels are altered in type 1 diabetic subjects (T1D) and whether insulin treatment has an effect in serum RBP-4 levels in T1D.

Materials and Methods: We measured serum RBP-4, plasma glucose and insulin levels in 7 T1D subjects (age= 27.1 \pm 2.5 yr, BMI=24.8 \pm 0.79 kg/m²) during insulin treatment (I+) (to maintain euglycemia) and following 8.6 \pm 0.6 hours of insulin deprivation (I-). T1D were compared with 7 nondiabetic subjects (ND) matched for their BMI (age=29.7 \pm 2.9 yr, BMI=24.9 \pm 1.1 kg/m²). RBP-4 was measured immunoturbidimetrically on the Hitachi 912 Chemistry analyzer using reagents from The Binding Site Inc.(Birmingham, UK).

Results: Insulin deprivation (I-) resulted in higher plasma glucose levels than the normal glycemia observed during insulin treatment (I+) (16.5 \pm 0.7 mmol/l in I- vs. 5.3 \pm 0.1 in I+, $p < 0.01$). Plasma insulin levels in T1D subjects during I+ were higher than in ND subjects (29.8 \pm 5.2 pmol/l in ND vs 75.8 \pm 16.4 in

I+, $p < 0.05$). During I+, RBP-4 levels in T1D subjects were lower than in ND (35.9 \pm 2.6 mg/l in ND vs. in 26.2 \pm 1.8 I+, $p < 0.01$). However, during I-, RBP-4 levels were not different in T1D than in ND subjects (35.9 \pm 2.6 mg/l in ND vs in 30.1 \pm 3.2 in I-).

Conclusions: We demonstrated that unlike in T2D patients, RBP-4 levels are not elevated in T1D patients during poor glycemic control. Moreover, insulin treatment caused a decline in RBP-4 levels clearly indicating that increased insulin action *per se* decreases RBP-4 levels.

Resistin reveals a separate evolution in placental mammals

I. Nagaev;

Internal Medicine, Goteborg University, Sweden.

Background and Aims: To explain why homologous human and mouse resistins diverged radically, as specific immune and adipose cytokines, respectively.

Materials and Methods: Phylogenetic analysis in all major mammalian groups was corroborated by experimental data from NCBI and Ensembl. Gene and protein sequences were aligned using BLAST to reconstruct an evolutionary tree based on a protein homology.

Results: Resistin and resistin like beta genes have orthologs in all general mammalian taxa: Prototheria or egg-laying mammals, Metatheria or marsupials and Eutheria or placentals. But homologous chromosomal loci in chicken outgroup void both genes, also missing in other eukaryotes. Thus, resistin gene family is a mammal-specific trait and its evolution can confer the speciation of mammals. Comparison of resistin and resistin like beta among all species revealed that these genes derived at once and deviated rapidly. However, they build identical topology, a branching pattern of phylogenetic tree, which mainly agrees with a current taxonomy. Human resistin has 72–98% identity with homologs in placentals except mouse and rat that show 55%, like Prototheria and Metatheria outgroups. Also resistin like beta has 63–98% homology among placentals but least 59% to mouse with rat and Metatheria. The partition of mouse and rat from major mammalian groups was obvious here and consistent with other studies. Thus, mouse and rat constitute a monophyletic clade or separate branch in placentals. Descendants in all branches have ancestor's similarities but new parities developed separately in respond to similar challenges. Also common ancestor traits diverged adaptively; as murine and rat adipose-specific resistin holds energy balance, the resistin in man, pig, cow and dog has immune-intrinsic roles. Resistin like beta, that usually tagged to innate immunity of intestine in placentals, was copied in dog but vanished in cow and guinea pig. In mouse and rat, paralogous resistin like gamma and alpha genes derived in that order. They have immune qualities, albeit resistin like alpha is largely expressed in adipocytes. Resistin like gamma evolved as a full analog of human resistin and so proving the divergent-parallel-convergent evolution in Eutheria. Natural roles of resistin family suggest that adipose-immune or energy-defense development was critical to mammals and proper molecular ‘fossils’ must exist. Indeed, mast cell-expressed membrane protein 1 gene is not found in chickens, while mast cells exist in birds. Both mast and blood cells bolster inflammation by expressing resistin in man but resistin like gamma in mouse and rat. Also their interleukin 6 is really an analog of a similar human gene. Since they evolved from different ancestor genes, their proteins share only 41% identity. Both subunits of the interleukin 6 receptor are homologous in placentals, yet mouse and rat show the least similarity. Oncostatin M and its specific receptor once again confirm the root division of mouse and rat from all placental orders including Rodentia.

Conclusion: Mice and rats cannot be used as a congruent model of human biology. In contrast, the comparison of our independent evolutions, when different strategies have been employed in respond to similar challenges, can disclose both biological rewards and costs, i.e. evolutionary basis of human diseases. In fact, mouse and rat developed the resistin adipose-immune traits rather evenly, because we do not have the adipose-derived resistin and resistin like alpha. Further bioinformatic inference is needed to clarify the evolutionary intricacy in placental mammals.

0754

Murine resistin induces pro-angiogenic responses in endothelial cells and aortic arch explants

S. A. Robertson, C. Rae, A. Graham;

Vascular Biology Group, Glasgow Caledonian University, United Kingdom.

Background and Aims: Angiogenesis, the formation of new blood capillaries from existing vessels, is required for physiological processes such as embryonic development, wound healing, and female reproduction, but when dysregulated can contribute to tumour growth and atherosclerosis. Endothelial cell migration and proliferation, in response to angiogenic stimuli such as hypoxia, plays an essential role in this process. The novel cysteine-rich adipokine, resistin, which causes insulin resistance in murine hepatic and peripheral tissues, is found within human and murine atherosclerotic lesions, and induces inflammatory, proliferative and angiogenic responses in vascular cells. Here, we examine the mechanisms by which murine resistin induces angiogenic responses in murine aortic arch explants, primary endothelial cells and murine b.End.5 endothelioma cell line.

Materials and Methods: Murine endothelioma cells (b.End.5) or murine thoracic aortic arch explants were treated with murine resistin (50ng ml⁻¹; 0–72h) and/or VEGF (10 ng ml⁻¹) or a combination. Migration and proliferation were then measured as indicated.

Results: Treatment with resistin (50ng ml⁻¹) increased cell growth and migration from aortic arch explants, when compared with control tissue (758±40.36µm *versus* control 322±45.99µm, n=4, p<0.01). The same concentration of resistin induced network tube formation when primary murine aortic endothelial cells, or b.End.5 cells were cultured on Matrigel matrix. Resistin (50ng ml⁻¹; 48h) significantly enhanced remodelling of an induced 'wound' or scratch in a confluent monolayer of b.End.5 endothelial cells (resistin 216µm±19.8µm *versus* control 163±10.7µm, n=6, p<0.001) compared with the control. Under hypoxic conditions, resistin (50 ng ml⁻¹) stimulated a comparable level of growth, in the same assay (158µm±13.3µm *versus* control 131±10.1µm, n=13, p<0.05), equivalent to that induced by the established angiogenic factor, murine VEGF (10ng ml⁻¹; 165±12.7µm, n=13, p<0.05); no additive response was noted when both resistin and VEGF were added together. Resistin induces a significant degree of endothelial cell migration, as judged by apical to basolateral migration (5h) across TransWell inserts (8µm pore); murine resistin and VEGF increased endothelial cell migration by 48% (44.0±2.83 *versus* control 30.0±5.45, n=6, p<0.001) and 23% (37.0±4.67, n=6, p<0.001), respectively, compared with the control incubation, and by 66% (50.0 ±5.99; p<0.01) in the presence of both resistin and VEGF. A mild increase in proliferation of b.End.5 cells was also noted in the presence of resistin (30–100ng ml⁻¹; 24h), as judged by metabolic conversion of MTT to formazan (17.5±0.7µM *versus* control 15.4±0.4µM, n=8, p<0.05). Using a real time PCR array (SuperArray, Tebu-Bio) to screen for angiogenic targets of resistin in bEnd5 cells, we have shown an increase in several factors involved in the angiogenic process: tumor necrosis factor (ligand) superfamily member 12 (TWEAK), tumor necrosis factor alpha-induced protein 2 (Tnfaip2), interleukin-6, matrix metalloproteinase 2 and VEGF-D increased after treatment with resistin (50 ng ml⁻¹; 48h), while VEGF-A and endothelial PAS domain protein-1 were down-regulated under the same condition.

Conclusion: These data suggest that murine resistin can promote angiogenesis by increasing endothelial cell proliferation and migration, and may have an important role in pathological processes such as tumorigenesis and atherosclerosis.

0755

Resistin-induced changes in fatty acid metabolism drive cholesteryl esterification and lipid accumulation in human macrophages

C. Rae, S. A. Robertson, A. Graham;

Vascular Biology Group, Glasgow Caledonian University, United Kingdom.

Background and Aims: Resistin is a novel cysteine-rich secretory adipokine, originally discovered in murine studies and proposed as a link between obesity and insulin-resistant diabetes. However, the (patho)physiological role of human resistin, secreted primarily from macrophages rather than adipocytes, is not confirmed, although it is known to exert inflammatory, angiogenic and proliferative effects in vascular cells. This study investigated the effect of resistin on lipid metabolism in macrophages, and in particular

cholesterol efflux and cholesteryl ester accumulation – key elements of atherosclerosis.

Materials and Methods: Human THP-1 monocytes were differentiated into macrophages with phorbol 12-myristate 13-acetate (PMA; 250nM): these cells do not produce or secrete endogenous resistin. Macrophages were treated with human recombinant resistin (Phoenix) and parameters of lipid metabolism determined: these included triacylglycerol and cholesteryl ester mass; fatty acid uptake ([¹⁴C] and [³H]oleate) and oxidation (¹⁴CO₂ production); [³H]cholesterol efflux and ester formation; expression of ACAT-1 (Western blotting and PCR), ATP binding cassette transporter A1 (ABCA1) and acetyl CoA carboxylase phosphorylation status (Western blotting) and apolipoprotein (apo)E protein levels (ELISA).

Results: Chronic treatment with resistin (5–100ng ml⁻¹; 24h) increased triacylglycerol accumulation in THP-1 macrophages (143% of untreated control cells, p<0.001). Resistin increased cholesteryl ester mass (control, 3.51 µg.mg protein⁻¹ *versus* resistin, 5.63 µg.mg protein⁻¹, p<0.05) and incorporation of [³H]cholesterol and [³H]oleate into the cholesteryl ester pool (to 140% and 138% of control, respectively, p<0.05). "Lipid-loading" of cells with oxidized LDL (50 µg.ml⁻¹) increased cholesteryl ester mass (5.9 µg.mg protein⁻¹, p<0.05 from control), and this effect was further enhanced by co-incubation with resistin (6.86 µg.mg protein⁻¹, p<0.001 from control). Incorporation of [³H]oleate into the cholesteryl ester pool was reduced by an ACAT inhibitor (10µM Sandoz 58–035 + resistin, 87% of control, p<0.01 from resistin). However, ACAT-1 expression was not affected by resistin. The 'anti-diabetic' agent C75, which inhibits fatty acid synthesis and promotes fatty acid oxidation, inhibited resistin-induced cholesteryl ester mass accumulation (control, 3.81 µg.mg protein⁻¹; resistin, 6.2 µg.mg protein⁻¹, p<0.05 from control; 10 µM C75 + resistin, 3.44 µg.mg protein⁻¹, p<0.05 from resistin). Neither ApoA1-dependent or independent cholesterol efflux, ApoE secretion or ABCA1 expression were affected by resistin, indicating that decreases in cholesterol efflux were not responsible for cholesteryl ester accumulation. Fatty acid uptake was, however, increased by resistin ([³H]oleate uptake increased by 29% after 5 mins, p<0.05; [¹⁴C]oleate uptake increased by 52% after 2 hours, p<0.05). Oxidation of [¹⁴C]oleate was reduced by resistin (control, 5% intracellular [¹⁴C]oleate pool; resistin, 3.6%, p<0.05); acutely, these changes were accompanied by reduced phosphorylation of acetyl CoA carboxylase.

Conclusion: The combined increase in uptake, and decrease in oxidation of fatty acids induced by resistin, enhance triacylglycerol and cholesteryl ester accumulation. This could lead to macrophage 'foam cell' formation and atherosclerosis, the principal cause of mortality in diabetic individuals.

Gene expression profiles in peripheral blood mononuclear cells reflect pathophysiology of type 2 diabetes

T. Takamura, H. Ando, A. Shimizu, H. Misu, S. Kurita, N. Matsuzawa, S. Kaneko;

Department of Disease Control and Homeostasis, Kanazawa University Graduate School of Medical Science, Kanazawa, Japan.

Background and Aims: Diagnosis and ideal treatment of diabetes require comprehensive understanding of hereditary aspects as well as habit and environmental effects as a cause of disease onset. Systemically circulating peripheral blood mononuclear cells (PBMCs) are considered to be unique tissue affected by the host condition and may reflect oxidative stress caused by high levels of glucose, insulin, free fatty acids and tissue-derived circulating bioactive mediators. To verify the hypothesis that PBMCs may change gene expression in response to diabetic circumstances, we comprehensively compared global gene expression profiles of PBMCs between people with and without type 2 diabetes, and between before and after glycaemic control by using a DNA chip technology.

Materials and Methods: PBMCs were obtained from 18 patients with type 2 diabetes and 16 young healthy volunteers. Antisense RNA from PBMC was amplified, and expression of genes was analyzed comprehensively by hybridization to an oligo-DNA chip (AceGene[®]Human Oligo Chip 30K, HitachiSoft, Japan) followed by statistical analysis for individual genes and specific gene sets for biological categories. We screened a total of 535 human gene sets defined by BioCarta, KEGG and Broad/MIT pathways. The mean centroid is the mean of the normalized gene expression levels.

Results: (1) Supervised learning methods based on the compound covariate predictor revealed that, among various clinical parameters, only the two clinical parameters, glycaemic control and the presence of diabetes significantly classified these patients. (2) The specific unique group of 48 genes coordinately altered by the existence of diabetes and by glycaemic control was involved in the c-Jun N-terminal kinase (JNK) pathway. (3) JNK mean centroid was significantly higher in people with diabetes compared with healthy subjects, and was significantly decreased after glycaemic control (Figure). (4) JNK mean centroid in the PBMCs was significantly correlated with levels of fasting plasma glucose and HbA_{1c}. (5) In contrast, the only gene set coordinately altered by the existence of diabetes, but not by glycaemic control, consists of 92 genes involved in mitochondrial oxidative phosphorylation (OXPHOS) pathway. (6) OXPHOS mean centroid was significantly down-regulated in patients with diabetes compared with healthy young subjects, whereas it was not significantly altered after glycaemic control.

Conclusion: Genes involved in JNK and OXPHOS pathways in the PBMCs may be surrogate transcriptional markers for hyperglycemia-induced oxidative stress and morbidity of type 2 diabetes, respectively. This is the first evidence that gene expression profiles of PBMCs may reflect the systemic molecular signature of diabetes, suggesting the diagnostic potential of gene expression analyses of PBMCs for hereditary aspects and environmental effects in people with type 2 diabetes.

Mitochondrial function in skeletal muscle of arm and leg of type 2 diabetic patients

R. Rabøl¹, P. V. Højberg², S. B. Haugaard³, T. Almdal³, S. Madsbad³, F. Dela¹;

¹Dept of Biomedical Sciences, Faculty of Health Sciences, University of Copenhagen, ²Dept. of Internal Medicine, Gentofte Hospital, Hellerup,

³Dept. of Endocrinology, Hvidovre Hospital, Denmark.

Background and Aims: Skeletal muscle insulin resistance is central in the pathogenesis of type 2 diabetes. Insulin resistance has been linked to decreased mitochondrial function and accumulation of intramyocellular lipid which may interfere with insulin signaling. It has been shown that insulin sensitivity in skeletal muscle is higher in arm than in leg muscle, and we have therefore measured mitochondrial function in skeletal muscle of arm (m. deltoideus) and leg (m. vastus lateralis) in patients with type 2 diabetes (T2DM) and healthy control subjects.

Materials and Methods: Ten patients with T2DM (eight male) and 10 healthy control subjects (age 52.3 (8.6) yrs (mean (SD)) and 54.3 (8.8) yrs; BMI 30.1 (3.8) kg/m² and 30.4 (3.9) kg/m², respectively) were included. Average duration of diabetes was 4.7 yrs (3.6), and patients were all treated with oral antidiabetic agents at inclusion. HbA_{1c} was on average 9.0 % (1.7) in the group of patients with T2DM and 5.4 % (0.2) in the control group (p<0.001).

Results: Mitochondrial respiration was similar in arm and leg muscle of patients with T2DM, both in state 3 respiration with substrates for complex I (malate, pyruvate and glutamate + ADP) and substrates for complex I and II (malate, pyruvate, glutamate and succinate + ADP). Compared to controls, mitochondrial respiration was significantly reduced in leg muscle of patients with T2DM while mitochondrial respiration was comparable to controls in the arm muscle. Please see table, all data are expressed as mean (SE).

O ₂ Flux pmol*sec ⁻¹ *mg ⁻¹	Arm		Leg	
	State 3, Complex I	State 3, Complex I + II	State 3, Complex I	State 3, Complex I + II
T2DM	19 (2)	46 (4)	22* (3)	50 (5)
Control	22 (2)	48 (4)	30** (3)	61 (5)

*P<0.05 compared to control leg; **P<0.05 compared to arm

Conclusion: Even though insulin sensitivity is supposedly better preserved in arm muscle than leg muscle of type 2 diabetic patients, we were not able to detect differences in mitochondrial function between these two muscle groups. However, only leg muscle mitochondrial function per muscle mass is significantly reduced in T2DM compared to age and BMI matched controls. Supported by the Danish Diabetes Association

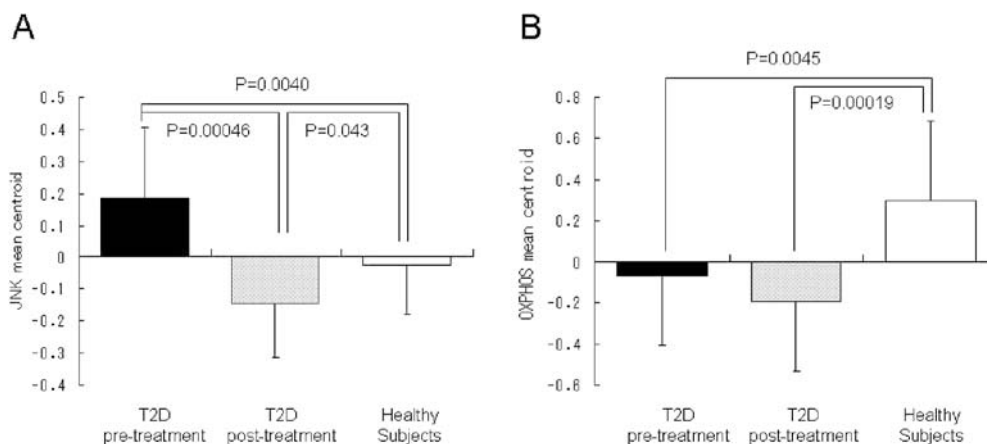

Fig. 1. Abstract 0756 JNK mean centroid (A) and OXPHOS mean centroid (B) among people with type 2 diabetes (T2D) before and after glycaemic control and healthy subjects. Values are mean ± SD.

Mitochondrial dysfunction and differentially expressed proteins in skeletal muscle of high-fat diet-fed mice

C. Bonnard¹, S. Peyrol², J. Garin³, H. Vidal¹, J. Rieusset¹;
¹U870, Inserm, Lyon, France, ²CeCil, IFR62, Lyon,
³ERM0201, CEA, Grenoble, France.

Mitochondrial biogenesis and function are altered in type 2 diabetes, as well as in insulin-resistant relatives of type 2 diabetic subjects. In addition, excess dietary fat has been implicated in the development of obesity and diabetes. The purpose of this study was to identify mitochondrial dysfunction and differentially expressed mitochondrial proteins in skeletal muscle of high-fat diet (HFD)-fed mice. Male mice were fed with a standard diet (SD) or a HFD (36%) for 4 or 16 weeks, and mitochondrial structure and content of gastrocnemius muscle were analysed by electron microscopy and mitochondrial proteins levels by 2D electrophoresis. Metabolic analysis of mice revealed that 4 weeks HFD-fed mice were glucose intolerant whereas 16 weeks HFD-fed mice were insulin-resistant as assessed by intra-peritoneal insulin tolerance test. Muscle mitochondrial content was decreased in the 16 weeks HFD-fed mice, but this effect was not observed after 4 weeks of diet. Moreover, cellular mitochondrial DNA was also reduced in 16 weeks HFD-fed mice. In agreement, expression of genes implicated in mtDNA replication (POLG2 and SSBP1 mRNA levels) or in mitochondrial biogenesis (PGC-1 α mRNA and protein levels) was decreased in muscle of 16 weeks HFD-fed mice compared to SD-fed mice. Also citrate synthase activity was reduced in muscle of 16 weeks HFD-fed mice. In addition, both subsarcolemmal and intermyofibrillar mitochondria were smaller and had altered internal structure membrane with disintegrated cristae and large low density vacuoles in muscle of 16 weeks HFD-fed mice. These changes were associated with an intramyocellular lipid accumulation, an increase of IRS1 Ser632 phosphorylation and a reduction in insulin-stimulated PKB activation, supporting the relation between mitochondrial defects and muscle insulin-resistant. To gain more information on the molecular mechanisms underlying the observed mitochondrial dysfunction in skeletal muscle, we have undertaken a differential proteomic analysis of mitochondria of SD-fed mice and 16 weeks HFD-fed mice. Identification by mass spectrometry of altered mitochondrial proteins in skeletal muscle in response of HFD should provide new insight in the pathogenesis of muscle insulin resistance in type 2 diabetes.

Insulin resistance in sepsis and mitochondrial dysfunction as markers for the outcome of a septic shock

P. G. Halvatsiotis¹, S. Stefanopoulou¹, A. Kotanidou², S. Orfanos²,
 C. Martinos², C. Roussos², T. Economopoulos¹, S. A. Raptis^{1,3};
¹2nd Dept of Int Med Propaedeutic, Athens University Medical School,
²1st Dept of Critical Care, Athens University Medical School,
³Molecular Biology Lab, Hellenic National Diabetes Center, Athens, Greece.

Background and Aims: The cause of mortality in critically ill patients is considered the sepsis-induced multiple organ failure. Oxidative phosphorylation in mitochondria produces energy and accounts for more than 90% of total oxygen consumption. Furthermore the profound alterations in metabolic pathways occur in sepsis lead to the development of acute insulin resistance and to a decrease in the rates of muscle mitochondrial substrate oxidation. However remains unclear whether the mitochondrial dysfunction resulting in organ failure is attributed to hypermetabolism, which is known to inhibit mitochondrial respiration *in vitro* and is produced in excess during sepsis.

Materials and Methods: We determined in vastus lateralis needle biopsy samples, using a real-time PCR technique, gene transcript levels of representative mitochondrial enzyme such as citrate synthase (CS), Cytochrome C oxidase I & III, NADH, and UCPs 2 & 3. We also measured the activity of the above enzymes by the means of a photometric assay. We studied 7 critically ill patients under irreversible septic shock (52 \pm 7 y) who finally died within 30 days (SS) and 8 age and gender matched septic patients (46 \pm 7 y) (p=0,51) who finally survived (SSV).

Results: All patients were non diabetic and SS group demonstrated lower insulin sensitivity than SSV by the means of HOMA test (11,56 \pm 3,5 vs 48,59 \pm 11,4) (p=0,011). There was no difference in the enzyme activity

of all mitochondrial enzymes measured between the 2 groups. The gene transcript of CS was significantly higher in SSV than SS (2,62 \pm 0,3 vs 1,29 \pm 0,6 AU) (p=0,011) while there was no difference in the transcripts of the other mitochondrial enzymes.

Conclusion: In conclusion, in septic patients we found an association of the severity of sepsis with the development of insulin resistance and with mitochondrial dysfunction solely attributed to the citric cycle, whereas the enzymes of the electron transfer chain and the uncoupling proteins were unaffected. These data implicate the existence of a bioenergetic failure, which contributes to the pathophysiological mechanism underlying the multiorgan dysfunction.

The effect of HIV status and the impact of ARV therapy on mitochondrial metabolism in human adipose tissue

M. J. Hill¹, K. C. McGee¹, M. Boothby², P. Higgins¹, C. M. Kusminski¹,
 A. L. Harte¹, G. Tripathi¹, L. L. Gathercole³, S. Kumar¹, M. Shahmanesh²,
 P. G. McTernan¹;

¹Clinical Sciences Research Institute, University of Warwick Medical School, Coventry, ²HIV Medicine, University Hospital Birmingham,

³Division of Medical Sciences, University of Birmingham, United Kingdom.

Background and Aims: Emerging evidence suggests there is an association between mitochondrial dysfunction and the progression of the metabolic syndrome. However the mechanisms by which mitochondrial function becomes dysregulated, leading to defects in energy homeostasis and regulation of metabolism, have yet to be fully elucidated. We have previously demonstrated mitochondrial dysregulation in human adipose tissue (AT), in both centrally obese and diabetic patients. HIV infection is associated with lipodystrophy and accumulation of central AT. Therefore, we investigated the effect of HIV status, in addition to antiretroviral therapy (ARV), in a number of mitochondrial and nuclear encoded genes involved in mitochondrial metabolism and energy homeostasis.

Materials and Methods: Subcutaneous fat biopsy samples were obtained from 10 controls and 18 HIV subjects (HIV: BMI: 24.3 (mean \pm SD) \pm 3.2kg/m²; Age: 37.5 \pm 10.2yrs; Control: BMI: 26.7 \pm 4.5kg/m²; Age: 35.5 \pm 11.4yrs) pre- and post- 6 month ARV therapy. Total RNA was extracted, reverse transcribed, and underwent Quantitative Real-Time PCR analysis assessing the following genes: PPAR γ co-activator 1 (PGC-1 α), UCP2, UCP3, COX4, ND1 & 4 (NADH dehydrogenase subunits 1 & 4), hCS, NRF-1 (nuclear respiratory factor-1), and TFAM (mitochondrial transcription factor A). All reactions were multiplexed with the housekeeping gene 18S, and statistical analysis was carried out by student t-test.

Results: Our findings determined that in human adipose tissue, following ARV treatment, there was a significant increase in expression of COX4 (Control: Δ Ct 9.58 \pm (SEM)0.14; Post 6 months ARV: Δ Ct 8.32 \pm 0.22, p=0.0001), NRF-1 (Control: Δ Ct 18.56 \pm 0.11; Post 6 months ARV: Δ Ct 17.95 \pm 0.13, p=0.0015), PGC-1 α (Control: Δ Ct 20.43 \pm 0.24; Post 6 months ARV: Δ Ct 19.75 \pm 0.19, p=0.04), TFAM (Control: Δ Ct 16.30 \pm 0.10; Post 6 months ARV: Δ Ct 15.58 \pm 0.12, p=0.00011), and human citrate synthase (Δ Ct 14.98 \pm 0.16; Post 6 months ARV: Δ Ct 13.96 \pm 0.18, p=0.0003). ND4 was increased in HIV naive patients compared with non HIV controls, (Control Δ Ct 18.19 \pm 0.16; Time 0 ARV: Δ Ct 17.24 \pm 0.26, p=0.008), and increased further following treatment (Post 6 months ARV: Δ Ct 15.17 \pm 0.33, p<0.0001). Additionally, HIV naive patients compared with post 6 month treatment showed a significant increase in TFAM (p=0.009), UCP2 (p=0.03), hCS (p=0.01), however no effect was observed with either ND1 or UCP-3 between controls and HIV naive or treated patients.

Conclusion: In summary, this study highlights that antiretroviral therapy significantly upregulates expression of genes involved in mitochondrial metabolism and regulation of energy homeostasis, and therefore improves overall mitochondrial function in HIV patients. This class of antiretroviral therapy may, therefore, have additional benefits to the HIV patient by improving oxidative phosphorylation, leading to increased sensitivity and lipid metabolism.

Supplementation with complex from mussels ameliorated oxidative processes in streptozotocin-induced diabetic rat's liver mitochondria

V. V. Poltorak¹, A. Shumeyko², T. Ovsyannikova², N. Krasova¹, A. Gladkih¹, O. Bityutka³, M. Gorshunskaya⁴;

¹Experimental Endocrinology Department, Institute of Endocrine Pathology Problems, Kharkiv, ²Department of Biological and Medical Physics, Karazin Kharkiv National University, Kharkiv, ³Biology Department, South Institute of Marine Fishing and Oceanography, Kerch, ⁴Chair of Endocrinology, Kharkiv Postgraduate Medical Academy, Kharkiv, Ukraine.

Background and Aims: The transport of glucose from the blood into the liver is insulin-independent process and there are not obvious causes for the decrease of oxidative phosphorylation in liver under streptozotocin-induced diabetes. Mitochondria play not only a crucial role in cellular energy production, but also participate in reactive oxygen species (ROS) generation. Oxidative stress has been implicated in the etiology of diabetes mellitus and diabetic complications. We recently demonstrated antioxidant and hepatoprotective activities of extract from mussels, which include 20 amino acids, aminosaccharides, sialic acids, mucopolysaccharides, and micronutrients. The aim of the study was to investigate the effects of mussels extract supplementation on oxidative phosphorylation and glutathione peroxidase activity in liver mitochondria of the rat with streptozotocin-induced diabetes.

Materials and Methods: 21 Wistar rats were randomized into 3 groups (7 animals each). Diabetes was induced by a single injection of streptozotocin (STZ, 45 mg/kg b.w. i.p.) – the 1st and the 2nd group. Rats of the 2nd group received mussel extract (0,4 mg/kg b.w. per os) within 2nd–25th day of the experiment. Rats of the 1st and the 3rd group (controls) received placebo. Mitochondria were isolated from liver homogenates; there were measured state 3 and 4 of the respiration rates (substrates: malate+glutamate and succinate), respiratory control ratio, glutathione peroxidase (GSH-Px) activity.

Results: GSH-Px activity was significantly increased in mitochondria of the diabetics rats (1st group: 91.94±5.42 vs 50.40±6.07 nmol NADPH/mg protein/min, p<0.01) as compared to controls. The supplementation with mussel extract resulted in decrease of GSH-Px in diabetic rats (63.80±4.55, p<0.05). State 3 of the respiration rate (with malate as substrate) was increased in the 1st group as compared to controls and the 2nd group (42.25±4.13 vs 61.07±5.95 and 74.54±1.58 nanoatom O/mg protein/min, respectively, p<0.05). There were not significant changes in the state 3 and 4 of the respiration rates in all studied groups when succinate was used as substrate. The respiratory control ratio was enhanced in the 2nd group when malate was used as substrate.

Conclusion: Our data suggest that ROS production was activated in STZ-diabetic rats, and that resulting in GSH-Px activity elevation. NADH-oxidize complex (I) was more vulnerable in STZ-diabetic rats, than the other complexes of the respiratory chain. The oral administration of mussel extract to diabetic rats resulted in normalizing of respiratory chain and antioxidative defense activity. It could associate with mussel extract composition – the large amount of amino acids that are precursors of the ubiquinone and glutathione.

dysfunction is also involved in common insulin resistance, but secondary metabolic events may be confounding the metabolic picture in overt type 2 diabetes. Acromegaly is associated with alterations of energy expenditure and insulin action and might serve as a model to investigate the role of mitochondrial function. Thus, we examined glucose metabolism, intracellular fat deposition and mitochondrial function in patients with a history of acromegaly (AM).

Materials and Methods: Six AM (4f/2m, age: 49±10 years, body mass index, BMI: 27±3 kg/m²) with an at least 7-years history of successful treatment and age-/BMI-matched healthy volunteers (CON: 3f/3m, 43±12 years, 26±4 kg/m²) were studied. Insulin sensitivity (OGIS) and first-phase insulin secretion were assessed from the frequently sampled OGTT (insulinogenic index, ISEC). Fasting mitochondrial function was assessed from ATP synthetic flux (fATP) using ³¹P magnetic resonance spectroscopy (MRS) of calf muscle. Intracellular lipid contents of tibialis anterior (IMCLt) and soleus muscles (IMCLs) as well as liver (HCL) were measured with ¹H MRS.

Results: IGF-1 did not differ between groups (AM: 177±88 ng/ml; CON: 145±51 ng/l). Fasting plasma glucose was ~16% higher in AM than in CON (99±8 vs. 85±6 mg/dl, p<0.05), OGIS was comparable (395±74, CON: 415±14 (ml.min⁻¹.m⁻²), whereas ISEC was ~87% lower in AM (0.9±0.9, CON: 6.7±4.3 pmol/mmol, p<0.05). fATP was ~22% lower in AM (10.1±1.5 vs. 12.9±2.4 mmol.l⁻¹.min⁻¹, p<0.05) and related positively to ISEC (r=0.687, p<0.01). IMCLt, IMCLs and HCL were not different between groups. IMCLs related negatively to insulin sensitivity (r=-0.745, p=0.005).

Conclusion: Patients with a history of acromegaly exhibit reduced β cell and muscle mitochondrial function despite normal insulin sensitivity. Previous long-term exposure to high growth hormone and IGF concentrations and/or chronic increases in plasma glucose concentrations could lead to similar abnormalities in both tissues.

Dapagliflozin (BMS-512148), a selective SGLT2 inhibitor, inhibits glucose resorption and reduces fasting glucose in patients with type 2 diabetes mellitus

B. Komoroski, E. Brenner, L. Li;
Bristol-Myers Squibb, Princeton, United States.

Background and Aims: The sodium-glucose reuptake cotransporter-2 (SGLT2), located in the proximal tubule, is a major pathway for renal glucose reabsorption. Dapagliflozin (BMS-512148), characterized by a stable C-aryl glucoside structure, is a rationally designed, potent, and selective inhibitor of SGLT2 that is being developed as an oral agent for the treatment of type 2 diabetes and represents a novel therapeutic approach for the treatment of hyperglycemia. This double-blind, placebo (PBO)-controlled, randomized, parallel-group, multiple-dose study assessed the safety, tolerability, pharmacodynamics, and pharmacokinetics of dapagliflozin in 47 patients with T2DM who were drug naive or on a stable dose of metformin for at least 4 weeks.

Materials and Methods: Patients were randomized to receive daily (QD): PBO (n = 8), dapagliflozin 5 mg (n = 11), 25 mg (n = 12), or 100 mg (n = 16) for 14 days. The amount of glucose excreted in urine was measured over 4h intervals following dosing, as well as 24h totals. The amount of renally-filtered glucose over the 0–4h postdose interval and the amount of glucose excreted in the urine during the same interval were used to calculate the percentage inhibition of renal glucose reabsorption.

Results: Daily doses of 5, 25, or 100 mg dapagliflozin administered alone or with metformin for 14 days appeared to be well tolerated. Exposure to dapagliflozin increased proportionally to the increment in dose. The mean amount of glucose eliminated in the urine (0–24h) after the first dose of 5, 25, and 100 mg dapagliflozin was 45.2, 75.3, and 81.3 g, respectively. Daily glucose excretion was consistent over the 14-day study. There were no apparent changes in body weight, urine volume, or urinary sodium excretion. A total of 56 adverse events (AEs) were reported in 27 patients: 37 in 20/39 (51.3%) who received dapagliflozin, and 19 in 7/8 (87.5%) who received placebo. Most AEs were mild to moderate in intensity, although 1 severe case each of constipation and flank pain were reported, both in patients receiving metformin.

Dosing of dapagliflozin over a 14-day period inhibited glucose reabsorption to a somewhat greater extent than a single dose. Over a 14-day period, dapagliflozin at doses \geq 25 mg reduced renal glucose reabsorption by approximately 40% (Table 1). Similarly, dapagliflozin decreased fasting serum glucose (FSG) after 14 days of dosing.

Table 1.

	Mean % Inhibition of Renal Glucose Reabsorption (0–4h)			FSG (mg/dL) (% change from Day -2)		
	Day -1	Day 1	Day 14	Day -2	Day 2	Day 13
PBO	0.09	0.06	0.88	151	151 (+1.3)	142 (+6.3)
5 mg	0.09	19.49	19.77	149	154 (+3.1)	127 (–14.5)*
25 mg	0.05	33.56	40.88	167	151 (–9.3)	138 (–17.3)*
100 mg	0.09	36.15	44.01	168	151 (–9.8) [†]	131 (–21.9) [†]

No stats were done on these values *P < 0.05; [†]P < 0.001.

Conclusions: Dapagliflozin, in daily doses up to 100 mg, was shown to be safe when administered to T2DM patients for 14 days.

Patients who received 25 and 100 mg dapagliflozin had increased urinary excretion corresponding to approximately 40% inhibition of renal glucose reabsorption as compared with baseline.

Based on glucose reabsorption inhibition and reductions in FSG observed in this study, dapagliflozin represents a promising novel treatment for the treatment of T2DM.

Safety, pharmacokinetics, and pharmacodynamics of Dapagliflozin (BMS-512148), a selective SGLT2 inhibitor, in an ascending, placebo-controlled, single-dose study in healthy adult subjects

L. Li¹, B. Komoroski¹, D. Boulton¹, E. Brenner¹, N. Vachharajani², D. Kornhauser³;

¹Bristol-Myers Squibb, Princeton, United States, ²Dept. of Pharmaceuticals and Agrochemical Development, Advinus Therapeutics, Bangalore, India, ³ICON Clinical Research Drug Development Division, Globomax, Ellicott City, United States.

Background and Aims: In humans, the renal sodium-glucose cotransporter-2 (SGLT2) is the major pathway by which plasma glucose is almost completely reabsorbed in the proximal tubule of the kidney. Dapagliflozin (BMS-512148), characterized by a stable C-aryl glucoside structure, is a rationally designed, potent, and selective inhibitor of SGLT2 that is being developed as an oral agent for the treatment of type 2 diabetes and represents a novel therapeutic approach for the treatment of hyperglycemia. This study assessed the safety, tolerability, and pharmacokinetics/pharmacodynamics (PK/PD) of single oral doses of dapagliflozin (2.5 to 500 mg) in fasting healthy subjects and the effect of food on its PK/PD parameters.

Materials and Methods: Eight healthy subjects were assigned to each of 8 sequential treatment panels (2.5, 5, 10, 20, 50, 100, 250, or 500 mg dapagliflozin or placebo; N = 64). Each received either a single oral dose of dapagliflozin (n = 6) or placebo (n = 2) in a 3:1 ratio following an overnight fast. After each dose regimen was found to be safe and well tolerated, the next panel of 8 subjects received the next higher dose of dapagliflozin.

Following a 7-day washout interval, all subjects in the 250-mg group returned to the clinical facility and were given a high-fat breakfast approximately 5 minutes prior to an oral dose of 250 mg dapagliflozin or matched placebo. Results were then compared to those obtained following fasting.

Results: Twenty-two adverse events (AEs) occurred in 14 subjects, including 15 AEs in 10/48 (21%) who received dapagliflozin and 7 AEs in 4/16 (25%) who received placebo. Most AEs were mild to moderate in intensity. Thirty-eight subjects had 49 laboratory abnormalities, including 11 hematologic and 7 blood chemistry variations and 31 cases of elevated urinary glucose, which were expected based on drug mechanism of action.

In the fasted state, C_{max} increased slightly less, and AUC_{inf} increased slightly more than proportionally with the dapagliflozin dose.

Median T_{max} was delayed by 2.5 hours when 250 mg of dapagliflozin was taken with a high-fat meal compared to the fasted state. Geometric mean C_{max} was 39% lower, while AUC_{inf} was 7% lower when 250 mg of dapagliflozin was administered with food (Table 1).

Table 1. Summary of Dapagliflozin Pharmacokinetic Parameters for 250-mg Dose Administered to Fasted and Fed Subjects

Pharmacokinetic Parameters	n	Fasted	Fed
C_{max} (ng/mL)	5	2510 (31)	1532 (24)
Geometric mean (CV%)			
AUC_{inf} (ng·h/mL)	5	13,337 (28)	12,455 (31)
Geometric mean (CV%)			
T_{max} (h) median (min, max)	5	1.50 (1.00, 2.00)	4.00 (4.00, 4.00)
$T_{1/2}$ (h) mean (SD)	5	17.33 (19.75)	18.25 (15.94)
%UR (mean) (SD)	6	1.54 (0.40)	1.90 (0.60)
CLR (mL/min) mean (SD)	6	4.99 (0.91)	6.33 (1.19)

AUC = area under concentration-time curve; CLR = renal clearance; C_{max} = maximum observed concentration; $T_{1/2}$ = half-life; T_{max} = time to C_{max} ; %UR = urinary recovery.

Conclusions: Single doses of dapagliflozin ranging from 2.5 to 500 mg appeared to be safe and well tolerated. Giving a single 250-mg dose of dapagliflozin 5 minutes after a high-fat breakfast extended T_{max} , but did not substantially affect the AUC .

Safety, pharmacokinetics, and pharmacodynamics of Dapagliflozin (BMS-512148) in an ascending, placebo-controlled, multiple-dose study in healthy adult subjects

E. Brenner, B. Komoroski, D. Boulton, L. Li;
Bristol-Myers Squibb, Princeton, United States.

Background and Aims: Low-affinity sodium-glucose cotransporter-2 (SGLT2) plays a crucial role in glucose reabsorption in the proximal tubule of the kidney. Dapagliflozin (BMS-512148), characterized by a stable C-aryl glucoside structure, is a rationally designed, potent, selective inhibitor of SGLT2 being developed as an oral agent for the treatment of type 2 diabetes and represents a novel therapeutic approach for the treatment of hyperglycemia. This study assessed the safety and tolerability of multiple oral doses of dapagliflozin administered to healthy subjects for 14 days. The study also assessed effects on urinary calcium excretion, safety markers in urine and serum, and impact of dosage on renal glucose resorption.

Materials and Methods: Healthy subjects received a 14-day regimen of once-daily oral administration of ascending doses of dapagliflozin (2.5, 10, 20, 50, 100 mg). Each panel of 8 subjects consisted of 6 receiving drug and 2 receiving placebo (N = 40). As each dose was shown safe and well tolerated, the next panel received the next higher dose of dapagliflozin. All subjects received diets that had fixed amounts of calcium and sodium chloride during the study. Serial ECGs were obtained on days 1, 7, and 14 with QT intervals corrected for heart rate (QTc).

Twenty-four-hour urine samples were analyzed for amino acids, calcium, chloride, creatinine, magnesium, oxalate, potassium, phosphate, sodium, uric acid, NAG, and β 2-MG.

Results: A total of 24 adverse events (AEs) occurred in 16 subjects: 15 in 11/30 (36.7%) who received dapagliflozin, and 9 in 5/10 (50%) who received placebo. All events were of mild to moderate intensity. The most frequently reported AE was rash (5 subjects). There were no apparent differences in urinary excretion (absolute or corrected for creatinine) for magnesium, amino acids,

calcium, chloride, oxalate, potassium, phosphate, sodium, uric acid, NAG, and β 2-MG. Dapagliflozin exposure (AUC) increased proportional to the increase in dose. An accumulation index of approximately 1.25 was observed for dapagliflozin upon repeated daily dosing. There was no apparent effect of dapagliflozin on renal safety markers or the QTc interval. The mean daily amount of glucose eliminated in the urine was similar after the first dose and after 14 days of dapagliflozin administration (Figure 1). Cumulative 24-h urine glucose excretion following 2.5 and 10 mg dapagliflozin was approximately 50% and 70% of that excreted after doses \geq 20 mg, respectively.

Conclusions: Multiple oral doses of dapagliflozin up to 100 mg/day for 14 days were safe and generally well tolerated.

Doses of 20 to 100 mg dapagliflozin appeared to provide the maximal inhibition of renal glucose resorption. Dapagliflozin is a potent inhibitor of SGLT2 with pharmacokinetic and pharmacodynamic behavior suitable for daily administration in humans.

Gliclazide significantly increases cellular glucose transport (CGT) – studies in patients with type 2 diabetes mellitus using the lymphocyte model (PBL)

J. Taton, P. Piatkiewicz, A. Czech;
Chair and Department of Internal Medicine and Diabetology, Warsaw Medical University, Poland.

Background and Aims: The structural integration and functional efficiency of cellular glucose transport (CGT) is of great importance, as CGT constitutes one of the basic mechanisms involved in the regulation of blood glucose levels. Impairment of CGT is involved in the pathogenesis of diabetic hyperglycemia and may therefore be regarded as a target for the action of antidiabetic drugs. Studies devoted to this process may create new pharmacotherapeutic

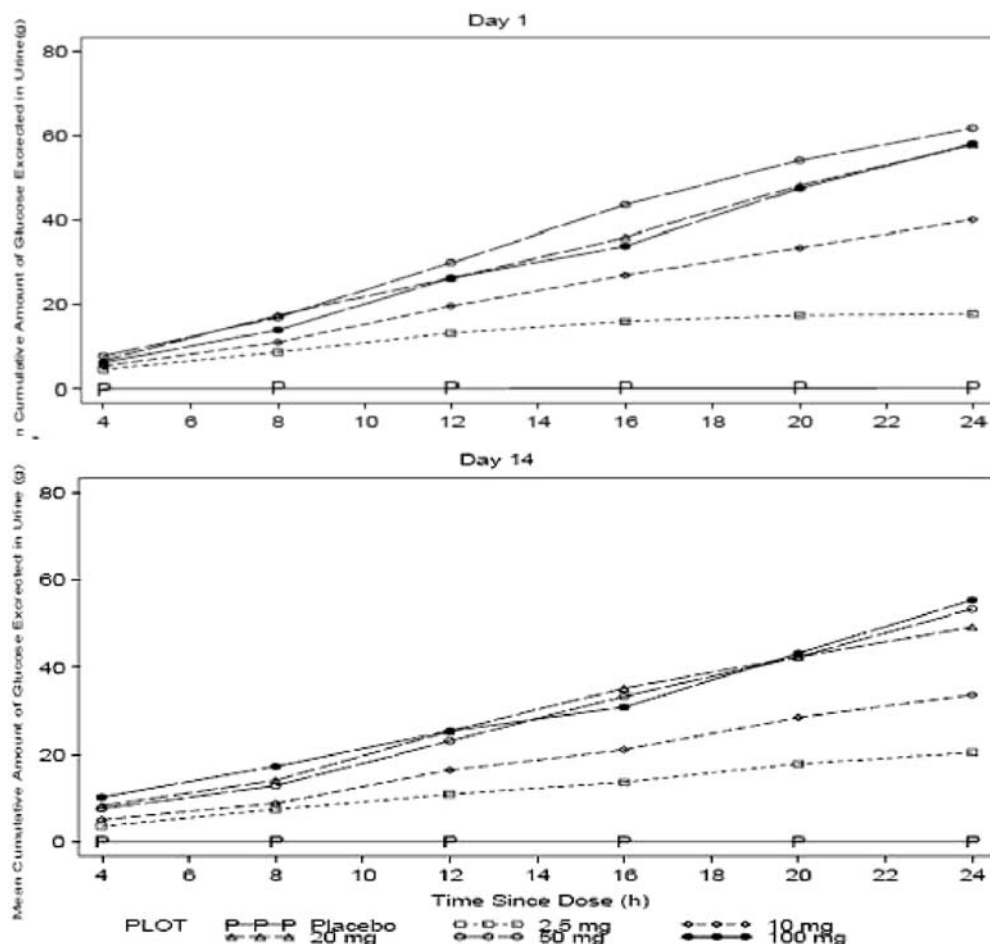

Figure 1. Mean cumulative amount of glucose excreted in urine on day 1 and day 14

possibilities and interpretations. In order to explore this hypothesis, CGT was studied before and after gliclazide therapy in a group of type 2 diabetic patients who had previously not received any pharmacotherapy, and in a group of healthy subjects.

Materials and Methods: The CGT of peripheral blood lymphocytes (PBLs) was assessed by timed incubation of cells with 2-[³H(G)] glucose in basal conditions, and after the addition of gliclazide (in substantia) or gliclazide plus insulin. Incubation tests were performed at baseline in 28 newly-diagnosed type 2 diabetics and 20 control subjects; in the diabetic patients, the tests were repeated after 3 months of therapy with gliclazide. PBLs were separated from whole blood by Ficoll-Isopaque gradient centrifugation. Incubation times were 15, 30 and 60 minutes. The scintillation of PBL lysate was measured with the Wallac 1450 MicroBeta counter.

Results: Treatment with gliclazide resulted in a statistically significant reduction in fasting plasma glucose of 1.77 mmol/L ($P<0.001$) and in HbA_{1c} of 0.69% ($P<0.001$). The magnitude of CGT in PBLs (pg/300 000 cells) in healthy subjects and in type 2 diabetics before and after 12-week therapy with gliclazide (mean dose at the end of the study, 39.6mg) is presented in the table. In all samples of PBLs, a significant increase was found in CGT as a result of treatment with gliclazide.

Table

Incubation model	Time (min)	Healthy subjects	Type 2 diabetics before therapy with gliclazide	Type 2 diabetics after 12 weeks of therapy with gliclazide
		Mean	Mean	Mean
PBL without additives	15	123.1	106.4	162.4
	30	228.7	179.4	308.1
	60	442.8	263.1	543.6
PBL with addition of gliclazide	15	203.6	113.5	210.3
	30	417.1	199.0	412.0
	60	664.1	316.2	727.2
PBL with addition of gliclazide and insulin	15	308.8	186.4	349.3
	30	647.7	293.3	689.6
	60	666.7	306.0	709.7

ALL P VALUES<0.001

Conclusions: When studied in the PBL model, CGT was found to be significantly decreased in type 2 diabetes mellitus. It was partially and significantly increased by the addition of gliclazide to the incubation probe, and it was further increased by the addition of insulin to gliclazide. Gliclazide therapy increases the CGT process, as measured in diabetic PBLs. The influence of gliclazide on the CGT process constitutes a new pleiotropic action of this drug, and underlines the importance of CGT as a target of pharmacotherapy in type 2 diabetes mellitus.

Evidence for sustained metabolic effects in Zucker diabetic fatty rats treated with GW869682, a sodium-dependent glucose transporter 2 antagonist

W. W. Harrington, N. O. Milliken, J. G. Binz, T. W. Balon, C. D. Smith; GlaxoSmithKline Research, Research Triangle Park, United States.

Background and Aims: Sustained hyperglycemia impairs insulin-stimulated glucose utilization and glycogen synthesis in human and rat skeletal muscle, a phenomenon referred to clinically as glucose toxicity. The kidneys play a major role in the regulation of plasma glucose (PG) levels via reabsorption along the convoluted segment of the proximal tubule through an active carrier-mediated transport process involving sodium-dependent glucose transporters (SGLTs). This has made SGLTs a target for the treatment of type 2 diabetes. Theoretically, inhibition of SGLTs would decrease glucose reabsorption by the kidney, decreasing PG and thus glucose toxicity. Ultimately, the reduction in glucose toxicity could lead to improvements in insulin resistance. The aim of these studies was to examine the *in vivo* efficacy of GW869682, an inhibitor of SGLT2, using Zucker Diabetic Fatty (ZDF) rats to model insulin resistance.

Material and Methods: In Study 1, 10-week old, glucose-matched animals were dosed for 8 days with vehicle or GW869682 (10, 15 or 30 mg/kg)

1–3 times/day. GW347845, a potent PPAR γ agonist, was used as a positive control. Daily blood samples were obtained 2 hours post-dose and PG levels determined. On Day 8 an OGTT was performed; a final blood sample was obtained on Day 9. In Study 2, ZDF rats or their lean counterparts were dosed with vehicle or GW869682 (30 mg/kg twice daily), and the effects on basal and insulin-stimulated skeletal muscle glucose uptake rates were determined using the perfused hindquarter. Data were analyzed by ANOVA with repeated measures model, corrected with Dunnett's and Tukey's tests. Values were considered significant when $p<0.05$.

Results: All ZDF rats were frankly diabetic when dosing began (mean PG, 470 ± 10 mg/dL). Two hours after the first dose, PG decreased in a dose-dependent fashion ($p<0.01$). After 2 days of dosing, PG of rats administered GW869682 at 30 mg/kg b.i.d. were not different from rats treated with the PPAR γ agonist. After 8 days of treatment, reductions in PG by dose were: 200 mg/dL at 10 mg/kg t.i.d.; >225 mg/dL at 15 mg/kg b.i.d. or 30 mg/kg b.i.d. and t.i.d. ($p<0.01$ vs. vehicle). HbA_{1c} levels were also decreased >1.5% at the higher doses. Rats treated with vehicle or GW869682 10 mg/kg b.i.d. were unable to dispose of a glucose load during an OGTT after 120 minutes. ZDF rats administered GW869682 15 or 30 mg/kg b.i.d. disposed of the glucose load more rapidly than rats treated with vehicle ($p<0.01$) or GW347845 ($p<0.05$). Eighteen hours after the final dose, PG had increased in a dose-related manner; however, all rats treated with GW869682 showed significantly smaller incremental increases in PG compared with vehicle ($p<0.05$). Dosing GW869682 for 7 days had no effect on basal glucose uptake or insulin responsiveness in perfused ZDF hindquarter; however, insulin-stimulated glucose uptake was enhanced ~2.5-fold vs. vehicle after 14 days of treatment ($p<0.05$).

Conclusion: Acute administration of an SGLT2 antagonist rapidly lowers PG in ZDF rats. Chronic administration may decrease glucotoxicity, resulting in long-term improvement in insulin-stimulated glucose disposal.

Lower reduction in free fatty acids in diabetic morbidly obese persons than the non-diabetic and controls during the frequently sampled intravenous glucose tolerance test

J. M. Garcia-Almeida¹, E. Garcia-Fuentes², S. Garcia-Serrano², J. Garcia-Arnes³, J. Rivas-Marin⁴, J. Gallego-Perales⁵, B. Gonzalez⁶, F. Vilches¹, B. Martinez-Alfaro¹, J. Garcia-Aleman¹, F. Tinahones¹; ¹Endocrinology, H. Virgen de la Victoria, ²Endocrinology, Ciber Fisiopatologia Obesidad y Nutricion (CB06/03), Instituto de Salud Carlos III, ³Endocrinology, H. Carlos Haya, ⁴Surgery, H. Virgen de la Victoria, ⁵Surgery, H. Carlos Haya, ⁶Psychology, H. Virgen de la Victoria, Malaga, Spain.

Background and Aims: Insulin sensitivity and free fatty acids (FFA) are increased in obese persons. The aims of this study are to assess the response of the FFA during a FSIGTT and its association with insulin sensitivity.

Materials and Methods: The study was undertaken in 38 morbidly obese persons before and seven months after undergoing bariatric surgery and in 12 healthy, non-obese persons. All persons underwent a FSIGTT and measurements of the concentration of FFA.

Results: The rate of decline of the concentration of FFA during the FSIGTT (K_{FFA1}) was significantly greater in the controls (1.83 ± 0.92) and in the morbidly obese persons with normal fasting glucose (NFG) (1.16 ± 0.41) than in the morbidly obese persons with impaired fasting glucose (IFG) (0.97 ± 0.29) or type 2 diabetes mellitus (DM) (0.47 ± 0.31) ($P<0.05$). SI and glucose tolerance index (K_G) were significantly reduced in the three groups of morbidly obese patients ($P<0.05$). The K_{FFA1} correlated significantly with glucose, insulin, SI and K_G . Of all these, K_G was the variable that was most significantly associated with K_{FFA1} before surgery ($P=0.012$). These variables improved after bariatric surgery in all the study groups. The K_{FFA1} in the morbidly obese persons was similar to that of the controls. The K_{FFA1} correlated significantly with the SI and K_G . The variables that best explained the K_{FFA1} in a multiple linear regression model were SI ($P<0.001$) and FFA ($P=0.035$).

Conclusion: During the FSIGTT, morbidly obese persons with IFG or DM experience a lower reduction in FFA than the NFG and controls, probably as a result of less inhibition of lipolysis and a reduced re-uptake of the FFA by the tissues. After bariatric surgery, the evolution of the FFA curve during the FSIGTT was similar to that of the controls.

Possible role of alpha cell insulin resistance in exaggerated glucagon responses to arginine in type 2 diabetes

A. Shimizu, N. Tsuchiyama, H. Ando, K.-I. Kato, S. Kurita, M. Sakurai, S. Kaneko, T. Takamura;

Department of Disease Control and Homeostasis, Kanazawa University Graduate School of Medical Science, Kanazawa, Japan.

Background and Aims: Diabetes is associated with increased hepatic glucose production, which is linked to fasting and postprandial hyperglycemia. This is caused by the reduced suppression of glucagon along with the impairment of insulin secretion and insulin action. Inappropriate excessive secretion of glucagon is, therefore, a novel target for the treatment of diabetes. However, a valid way of identifying responders to such therapy has not yet been established. In this study, we sought to determine the factors associated with exaggerated glucagon secretion in response to an arginine challenge in patients with type 1 and type 2 diabetes.

Materials and Methods: Changes in circulating C-peptide immunoreactivity (CPR) and immunoreactive glucagon (IRG) after an arginine challenge were investigated in 35 patients with type 1 diabetes, 130 with type 2 diabetes and 35 with normal glucose tolerance. Arginine (30 g) was administered by intravenous infusion of an L-arginine hydrochloride 10% solution over 30 min.

Results: No significant differences were found in the basal level and the area under the concentration-time curve (AUC) of IRG (AUC_{IRG}) among between type 1 and type 2 diabetic patients and non-diabetic subjects. However, as shown in Figure 1, the correlation between AUC_{IRG} and AUC of CPR (AUC_{CPR}) was inverse between type 1 ($r = -0.388$, $P = 0.023$) and type 2 diabetic patients ($r = 0.396$, $P < 0.0001$), whereas AUC_{IRG} was not correlated with AUC_{CPR} in non-diabetic subjects ($r = -0.079$, $P = 0.655$).

Fig. 1. The relationship between AUC_{IRG} and AUC_{CPR} in patients with type 1 and type 2 diabetes. AUC_{IRG} was negatively correlated with AUC_{CPR} in type 1 diabetes ($r = -0.388$, $P = 0.023$), whereas AUC_{IRG} was positively correlated with AUC_{CPR} in patients with type 2 diabetes ($r = 0.396$, $P < 0.0001$).

In type 1 diabetic patients, the AUC_{CPR} decreased and the AUC_{IRG} increased with increasing disease duration. In type 2 diabetic patients, both AUC_{IRG} and AUC_{CPR} increased with increasing levels of BMI, basal CPR level (Figure 2), and HOMA-R.

Fig. 2. The relationship between the means of AUC_{IRG} and AUC_{CPR} stratified by the class of body mass index and basal CPR level in patients with type 2 diabetes. The AUC_{IRG} and AUC_{CPR} significantly increased according to the increase of both body mass index and basal CPR level. Data are shown as mean values; error bars denote SD.

In non-diabetic subjects, AUC_{IRG} was not correlated with AUC_{CPR} .

Conclusion: Our findings suggest that the pathophysiology of the exaggerated glucagon response differs between the types of diabetes. Intra-islet insulin deficiency and alpha cell insulin resistance may be the primary contributors to this condition in type 1 and type 2 diabetes, respectively. In addition, the arginine challenge test could be useful for assessing the heterogenous nature of diabetes and may be a valid method for identifying responders to therapy targeted at glucagon and its receptor, such as GLP-1 analogs.

0770

Vascular endothelial growth factor increases during hypoglycaemia in patients with type 1 diabetes, independently of renin angiotensin system activityL. G. Bie-Olsen¹, P. L. Kristensen¹, T. Høi-Hansen¹, F. Boomsma², U. Pedersen-Bjergaard³, B. Thorsteinsson¹;¹Division of Internal Medicine I, Nordsjællands Hospital – Hillerød, Hilleroed, Denmark, ²Department of Internal Medicine, Erasmus MC, Rotterdam, The Netherlands, ³Department of Internal Medicine I, Bispebjerg Hospital, Copenhagen, Denmark.

Background and Aims: In healthy adults, levels of vascular endothelial growth factor (VEGF) rise significantly in response to hypoglycaemia. The rise is possibly positively correlated with preservation of cognitive function during hypoglycaemia. VEGF is implicated in glucose transport over the blood brain barrier, most likely due to translocation of the glucose transporter 1 (GLUT1) to the plasma membrane. High activity in the renin angiotensin system (RAS) is associated with increased risk of severe hypoglycaemia in patients with type 1 diabetes and a more pronounced deterioration of cognitive function during hypoglycaemia compared to patients with low RAS activity. RAS possibly exerts its mechanism in hypoglycaemia via VEGF. We studied the impact of mild hypoglycaemia on plasma levels of VEGF in patients with type 1 diabetes and high or low RAS activity and compared VEGF levels to cognitive functioning.

Materials and Methods: Nine patients with high and nine with low RAS activity, as classified by ACE activity, angiotensinogen concentration and genotype of the angiotensin 2 receptor subtype 2 underwent a single-blinded, placebo-controlled, cross-over study with either mild hypoglycaemia (intravenous insulin, 100% of morning dose/hour) or stable glycaemia (intravenous glucose and insulin dependent on blood glucose; control study). Cognitive function was assessed by California Cognitive Assessment Package and Alzheimer Quick Test.

Results: Nadir plasma glucose was 2.3 (0.3) mmol/l (mean (SD)) in the high RAS group and 2.5 (0.2) mmol/l in the low RAS group ($p = 0.16$). During the control study, p-VEGF did not change in either RAS-group. In high RAS group p-VEGF increased from 54 (34) pg/l to 93 (88) pg/l (42 % increment) ($p = 0.008$) and in low RAS group from 69 (26) pg/l to 104 (51) pg/l (51 % increment) ($p = 0.017$). The increase did not differ between RAS

groups ($p=0.74$). The VEGF response was not correlated with the degree of deterioration of cognitive function during hypoglycaemia.

Conclusion: Plasma VEGF levels increase during mild, short-term hypoglycaemia in patients with type 1 diabetes. The mechanism behind this phenomenon is unknown. In this study, in contrast to a study with prolonged hypoglycaemia among healthy adults, the VEGF response was not correlated to deterioration of cognitive function during hypoglycaemia. The VEGF response was equal in both RAS groups. Hence, the association between low RAS activity and better cognitive performance during hypoglycaemia, does not seem to be mediated by VEGF.

Regulation of the insulin degrading enzyme in hepatocytes in normal and high glucose conditions

O. Pivovarov^{1,2}, N. Rudovich^{1,2}, I. Goering¹, M. Osterhof¹, A. F. H. Pfeiffer^{1,2};

¹Dept. of Clinical Nutrition, German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, ²Dept. of Endocrinology and Nutrition, Campus B. Franklin, Charite University Medicine of Berlin, Germany.

Background and Aims: The liver is the main site of insulin clearance removing approximately 75% during the first portal passage. Type 2 diabetes is characterized by decreased insulin clearance. Insulin-degrading enzyme (IDE) is thought to play a key role in insulin degradation. Little is known about IDE regulation in liver, however in brain IDE was shown to be a downstream target of the insulin signaling cascade. The aim of this study was to investigate the IDE regulation by insulin in hepatocyte cell culture.

Materials and Methods: Human hepatoma HepG2 cells were incubated in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal calf serum (FCS), 10 µg/ml tavanic and either normal (5.5mM) or high (25mM) concentrations of D-glucose (insulin resistance model). For the experiment cells were maintained in DMEM containing 2% FCS for 24 h and stimulated with 0, 1, 10, 100 and 200 nM insulin for 24 h. Then total RNA or total cell lysate were prepared. The IDE mRNA level was determined by real-time PCR, the IDE protein level – by western blotting.

Results: We observed that insulin treatment of HepG2 cells maintained in normal glucose medium decreased IDE mRNA levels by ~15–20% with all insulin concentrations used in comparison to control. High glucose concentrations induced a 2-fold increase of IDE expression in the absence of insulin and altered the insulin effect: in high glucose conditions the IDE level was significantly increased after 24 h of insulin stimulation. Maximal increase (~25%) was observed with 10 nM insulin. The results of real-time PCR were confirmed by western blotting.

Conclusion: In hepatocytes insulin downregulated the IDE level. High glucose concentrations significantly increased the IDE expression and inversed the regulation of IDE by insulin. The observed changes of IDE expression may contribute in the regulation of insulin degradation and pathogenesis of type 2 diabetes.

Insulin sensitivity and beta cell function in patients with hereditary haemochromatosis

M. Hatunic¹, F. M. Finucane¹, S. Norris², G. Pacini³, J. J. Nolan¹;

¹Metabolic Research Unit, St. James's Hospital, Dublin, Ireland,

²Hepatology Department, St. James's Hospital, Dublin, Ireland,

³Metabolic Unit, ISIB-CRN, Padova, Italy.

Background and Aims: Diabetes affects 30–60% of patients with haemochromatosis. The underlying pathophysiology of diabetes in patients with haemochromatosis has not been fully elucidated. Initially thought to relate to iron induced beta cell failure, in reality many patients have features of insulin resistance. We prospectively studied the effects of iron overload on glucose metabolism in newly diagnosed patients with hereditary haemochromatosis (HH).

Materials and Methods: Fifty-three recently diagnosed HH patients had a standard 75g-OGTT. Insulin sensitivity at fasting (QUICKI) and during oral glucose tolerance test (OGIS) was evaluated. Beta cell function was assessed as C-peptide concentration during OGTT in relation to ambient to insulin sensitivity.

Results: Fifteen patients (28%) had abnormal glucose metabolism (AGM), seven (13%) had type 2 diabetes mellitus (T2DM) and eight (15%) had impaired glucose tolerance (IGT). Results are shown in the table below, with means ± standard error of the mean. (* denotes $p<0.05$.)

	Normal Glucose Metabolism	Abnormal Glucose Metabolism
n	38 (72%)	15 (28%)
Age (yrs)	46 ± 1.7	57 ± 2.3*
Male (%)	71	68
BMI (kg/m ²)	26 ± 0.8	28 ± 1.0
Waist/Hip ratio	0.92 ± 0.1	0.99 ± 0.2*
Fasting Glucose (mmol/l)	4.8 ± 0.1	6.0 ± 0.3*
HbA1c (%)	5.4 ± 0.1	6.0 ± 0.2*
Fasting C-peptide (µg/l)	2.3 ± 0.1	3.2 ± 0.3*
Fasting Insulin (µU/l)	6.5 ± 0.4	10.6 ± 0.9*
OGIS(ml/min/m ²)	451 ± 9	365 ± 13*
QUICKI	0.7 ± 0.02	0.5 ± 0.02*
Beta Cell Function Index (nmol/min/m ²)	0.7 ± 0.3	0.6 ± 0.1
Ferritin (µg/l)	735 ± 131	1266 ± 310*
Transferrin saturation (%)	78 ± 3.8	74 ± 5.2

Conclusion: Haemochromatosis patients with AGM had higher fasting insulin and C-peptide levels than normal glucose tolerant controls, with higher waist/hip ratios. Patients with AGM were more insulin resistant at fasting and with OGTT. Our results challenge the traditional view that diabetes in HH is due primarily to iron induced beta cell failure. Our cohort of HH patients with AGM in comparison with those with normal glucose metabolism were more insulin resistant, hyperinsulinemic and with visceral obesity, similar to typical T2DM.

0773

Excessive iron deposition in liver parenchyma imposes insulin resistance independent of oxidative stress pathway

C. Y. Yeung¹, A. P. S. Kong¹, C. S. Ho², W. W. M. Lam³, M. Ng⁴, R. Ozaki¹,

W. Y. So¹, C. C. Chow¹, C. W. K. Lam², C. S. Cockram¹, J. C. N. Chan¹,

P. C. Y. Tong¹;

¹Department of Medicine and Therapeutics, ²Department of Chemical

Pathology, ³Department of Diagnostic Radiology and Organ Imaging,

⁴Department of Anatomical and Cellular Pathology, The Chinese University of Hong Kong, Hong Kong.

Epidemiological studies suggest that increasing iron body stores is associated with insulin resistance, metabolic syndrome and Type 2 diabetes mellitus.

Possible mechanisms include direct effect of deposition in liver parenchyma and increase in oxidative stress associated with increase iron metabolism. We examined 50 pre-menopausal Chinese female (mean age 37.7±9.3 years) with normal glucose tolerance confirmed by oral glucose tolerance test, normal serum iron saturation and a family history of diabetes in the first degree relatives. Subjects were divided into tertiles according to the serum ferritin level. Subjects in the top tertile (Group I: serum ferritin:363.5±144.9 pmol/L), when compared with subjects with the lowest tertile (Group III: 49.2±15.2 pmol/L), had higher BMI (24.9±4.7 vs 20.6±1.9 kg/m², $p<0.01$), higher waist circumference (82.4±12.7 vs 74.5±5.3 cm, $p=0.03$), higher percentage of body fat (32.9±8.5 vs 24.7±4.6 %, $p<0.01$), higher systolic blood pressure (112.5±16.5 vs 110.0±9.1 mmHg, $p=0.01$), higher diastolic blood pressure (75.5±12.7 vs 66.3±5.3 mmHg, $p=0.02$), higher triglycerides (1.25±0.50 vs 0.74±0.4 mmol/L, $p<0.01$), higher LDL-cholesterol (2.94±0.98 vs 2.3±0.55 mmol/L, $p=0.03$), higher hsCRP (2.79±3.69 vs 0.38±0.4 mg/L, $p<0.01$) and insulin resistance (HOMA-IR:12.7±8.3 vs 6.6±2.8, $p<0.01$). Subjects in Group I had more iron deposition in liver parenchyma as reflected by elevated ALP (55.8±25.9 vs 44.4±9.0 IU/L, $p=0.045$), ALT (26.4±17.0 vs 14.8±4.8 IU/L, $p<0.01$), GGT (30.4±2.7 vs 14.1±6.7, $p=0.01$) and assessment of iron load in liver by MRI using reciprocal of T2 relaxation time (0.039±0.007 vs 0.031±0.003 s⁻¹, $p<0.01$). However, oxidative stress was not significantly different among two groups as measured by plasma isoprostanes (320.0±101.1 vs 328.6±101.1 pmol/L, $p=0.73$) and membrane isoprostane (25.5±6.8 vs 22.8±4.3 pmol/L, $p=0.18$). These results suggest that increase in iron load in the body may induce insulin resistance by effect of direct deposition in liver parenchyma without imposing significant oxidative stress.

Iron metabolism parameters and their correlation with adipocytokines in type 2 diabetic patients against the background of metabolic syndrome

N. Krasova¹, M. Gorshunskaya², Y. Karachentsev^{2,1}, E. Jansen³, A. Gladkih¹, H. Cremers³, P. Beekhof³, R. v. Loenen³, V. Poltorak¹;

Background and Aims: It is known that liver iron levels and expression of genes for iron transport are correlated with obesity in rodent models. Several studies have reported an association between serum ferritin concentration and insulin resistance or type 2 diabetes mellitus (T2DM), and it has been suggested that disturbances of iron metabolism are part of the metabolic syndrome (MS). The aim of the study was to evaluate the relationship of iron metabolism parameters with adipocytokines and inflammatory markers in obese T2DM patients.

Materials and Methods: Thirty one T2DM patients (females/males: 21/10, age 55.6±1.7 years, diabetes duration 7.8±1.2 years, BMI 31.8±0.9 kg/m², WHR 0.92±0.02, fasting blood glucose (FBG) 11.5±0.4 mmol/l, HbA_{1c} ≥7.0 %) were included. MS was diagnosed using the NCEP ATP III criteria. Seven healthy volunteers matched for age, sex and BMI served as controls. The studied subjects were assessed at the beginning and after 3 and 6 months periods. Plasma adiponectin, leptin, resistin, TNF- α , high sensitive C-reactive protein (CRP), serum iron (Fe), ferritin, transferrin (Tf), percent saturation of Tf (Fe-Tf), unsaturated iron binding capacity (UIBC), haptoglobin (Hp) and fasting insulin levels were determined. Insulin resistance (IR) was calculated using Homeostasis Model Assessment (HOMA). Statistical analysis was performed with ANOVA and the Spearman's rank order (SPSS, version 13.0).

Results: In T2DM patients, value of adiponectin was significantly reduced ($p=0.017$) whereas levels of Fe, Hp, leptin, TNF- α , CRP, ferritin, insulin and IR-HOMA were significantly enhanced ($p<0.05-0.001$) compared to the healthy subjects. Serum ferritin was negatively correlated with Tf ($r=-0.266$, $p=0.021$). Positively correlated ($r=0.356$, $p=0.002$) both ferritin and Hp were positively associated with FBG ($r=0.309$, $p=0.007$ and $r=0.503$, $p<0.0005$), IR-HOMA ($r=0.381$, $p=0.002$ and $r=0.343$, $p=0.007$) and CRP ($r=0.229$, $p=0.049$ and $r=0.334$, $p=0.003$), respectively. It is known, that ferritin synthesis is TNF- α -induced, thus ferritin concentration was strong positively correlated with TNF- α ($r=0.400$, $p<0.0005$). We found a significant negative correlation of ferritin and adiponectin ($r=-0.262$, $p=0.023$). Strong negative correlations

were revealed between leptin and such iron metabolism parameters as ferritin ($r=-0.312$, $p=0.006$), Fe ($r=-0.448$, $p<0.0005$), Fe-Tf ($r=-0.519$, $p<0.0005$), however, leptin concentrations were positively associated with Tf ($r=0.316$, $p=0.006$) and UIBC ($r=0.479$, $p<0.0005$). Finally, we report for the first time, that there was a strong negative correlation between Hp and circulating resistin ($r=-0.377$, $p=0.003$) in T2DM patients.

Conclusion: Our data support findings showing that iron metabolism parameters are strong associated not only with classical inflammatory markers, but also with adipocyte-derived hormones levels in type 2 diabetic patients with metabolic syndrome. Further work is required to establish a causative link between of iron metabolism and the development of diabetic complications against the background of obesity.

Obesity is associated with iron deficiency in men with hyperferritinaemia genetically screened for hereditary haemochromatosis

J.-M. Gonzalez-Clemente¹, N. Freixenet^{1,2}, A. Caixàs¹, O. Gimenez-Palop¹, C. Vilardell¹, F. Blanco-Vaca³, A. Remacha⁴, D. Mauricio⁵, C. Cabistañ², Y. Sánchez², J. Tarrés², V. Bach⁶, M. Baiget⁶, J. Felez²;

¹Department of Diabetes, Endocrinology and Nutrition, Hospital de Sabadell, Sabadell, ²CAP Canaletes, Institut Català de la Salut, Cerdanyola del Vallès, ³Servei de Bioquímica and Institut de Recerca, Hospital de Sant Pau, Barcelona, ⁴Hematology Department, Hospital de Sant Pau, Barcelona, ⁵Department of Diabetes, Endocrinology and Nutrition, Hospital Arnau de Vilanova, Lleida, ⁶Department of Genetics and Research Institute, Hospital de Sant Pau, Barcelona, Spain.

Background and Aims: Obesity is central in the pathogenesis of the metabolic syndrome (MS). In addition, an increase in serum ferritin (SF) concentrations has been associated with insulin resistance and the MS and, consequently, a pathogenic role of iron overload has been suggested in these conditions. Serum concentrations of the soluble transferrin receptor (sTfR) is considered a better index of body iron stores than SF, because it is not influenced by inflammatory conditions. Normally, the higher the concentrations of sTfR, the lower the body iron stores are. However, sTfR concentrations are influenced by the H63D mutation of the HFE gene of hereditary hemochromatosis (HH), with lower concentrations in subjects bearing this mutation. Our aim was to evaluate whether iron overload (measured through sTfR) is associated with the components of the MS and insulin resistance or not, in men with hyperferritinemia, taking into account the gene mutations of the HFE gene.

Materials and Methods: During 1 year-period, 150 men (age: 54.0±13.1 yrs), were genetically screened for HH (mutations of the HFE gene: C282Y, H63D, S65C) because of hyperferritinemia (SF > 200 µg/L, twice, one month apart). They were evaluated for the components of the MS (ATP III criteria), insulin resistance (HOMA-R), highly-sensitive C-reactive protein (hs-CRP), transferrin saturation index and sTfR.

Results: In the whole group, sTfR correlated positively with BMI ($r=0.173$; $p=0.046$) and waist circumference (WC) ($r=0.246$; $p=0.005$), but with no other other components of the MS, HOMA-R, hs-CRP and HFE gene mutations. Forty-seven subjects were obese (BMI > 30 kg/m²) and had significantly higher levels of triglycerides (median (interquartile range): 146 (85–118) vs 129 (66–176) mg/dl; $p=0.010$), insulin resistance (HOMA-R: 1.81(0.46–2.69) vs 1.19 (0.41–1.40); $p<0.001$) and sTfR (2.6 (1.53–3.10) vs 2.3 (1.57–2.73) mg/L; $p=0.014$) than the non-obese. Also they had lower levels of HDL cholesterol (mean±SD: 49±13 vs 53±13 mg/dL; $p=0.047$), but no differences in HFE gene mutations were found between groups. On a multiple regression analysis sTfR and WC remained positively and independently associated after adjusting for potential confounders ($r=0.290$; $p=0.001$).

Conclusion: In men with hyperferritinemia, obesity is associated with a moderate degree of iron deficiency, arguing against a role of iron overload in the pathogenesis of the MS.

C.E.R.A. twice monthly corrects anaemia and maintains stable Hb levels in patients with diabetes and CKD not on dialysisM. F. Bexon¹, F. C. Dougherty¹, D. Halimi¹, R. Beswick²;¹Hoffmann-La Roche Ltd., Basel, Switzerland,²Hoffmann-La Roche Ltd., Nutley, United States.

Background and Aims: Anaemia is more prevalent and severe in chronic kidney disease (CKD) patients with diabetes than in those without diabetes, and is also associated with progression of diabetic complications. C.E.R.A. is a continuous erythropoietin receptor activator with a prolonged half-life, which makes it suitable for treatment of anaemia at extended administration intervals. Results from the Phase III study (ARCTOS), demonstrate that subcutaneous (SC) C.E.R.A. corrects anaemia in erythropoiesis-stimulating agent (ESA)-naïve patients with CKD not on dialysis. Here we report the results from the sub-group of patients with diabetes in this study.

Materials and Methods: A total of 324 patients with CKD (≥ 18 yr) not on dialysis nor receiving treatment with ESAs were randomized (1:1) to SC C.E.R.A. twice monthly (Q2W) (0.6 mg/kg/2 wks) or SC DA once weekly (QW) (0.45 mg/kg/wk). The dose was adjusted to achieve a Hb response (≥ 1 g/dL increase and ≥ 11 g/dL) and to maintain Hb levels between 11–13 g/dL and ± 1 g/dL of the response level throughout the 28-week study.

Results: Of the 180 patients with diabetes, 86 received C.E.R.A. and 94 received DA. In those without diabetes, 76 received C.E.R.A. and 68 received DA. Mean Hb at baseline was 10.2 g/dL and 10.0 g/dL in patients with diabetes receiving C.E.R.A. and DA, respectively, and increased to 12.3 and 12.2 g/dL, respectively, during the evaluation period (wks 19–28). In patients without diabetes baseline Hb was 10.3 g/dL in both treatment groups, and increased to 12.4 and 12.1 g/dL in the C.E.R.A. and DA groups, respectively, during the evaluation period. Among patients with diabetes, 97.9% (95% CI: 92.5–99.7) responded in the C.E.R.A. group and 96.5% (90.1–99.3) in the DA group, while 94.1% (85.6–98.4) and 98.7% (92.9–100) of patients without diabetes responded to C.E.R.A. and DA, respectively. The mean (95% CI) differences in the change in Hb between C.E.R.A. and DA (from baseline to evaluation period) were 0.03 g/dL (–0.25, 0.31) in those with, and 0.38 g/dL (0.05, 0.70) in those without, diabetes. The lower limit of the 95% CI was well above the pre-specified level of –0.75 g/dL, demonstrating that C.E.R.A. Q2W is as effective as DA QW for anaemia correction in both patients with and without diabetes (both $P < 0.0001$). C.E.R.A. was generally well tolerated. Some of the more frequent adverse events, including hypertension and peripheral oedema, were slightly more frequent in patients with diabetes in both treatment groups.

Conclusions: SC C.E.R.A. administered twice monthly effectively corrects anaemia in ESA-naïve patients with CKD not on dialysis, regardless of diabetic status. This may help to simplify anaemia management in this important group of patients with diabetes.

Transgenic UCP1 in white fat protects against lipid accumulation in skeletal muscle of mice fed a high-fat diet

T. Jelenik, Z. Jilkova, K. Slamova, M. Rossmeisl, J. Kopecky;

Department of Adipose Tissue Biology, Institute of Physiology, Prague 4, Czech Republic.

Background and Aims: The development of obesity-associated insulin resistance is closely related to the accumulation of lipids in non-adipose tissues. Transgenic mice (aP2-*Ucp1* mice) with ectopic expression of mitochondrial uncoupling protein 1 (UCP1) in white adipose tissue are resistant to high-fat diet-induced obesity and glucose intolerance. Respiratory uncoupling induced by transgenic UCP1 in white fat increases fatty acid (FA) oxidation and decreases *in situ* lipogenesis, which leads to a diminished release of FA from adipose tissue upon fasting. In this study, we investigated in detail the accumulation of lipids and FA metabolism in non-adipose tissues, especially in skeletal muscle of the aP2-*Ucp1* mice fed a high-fat diet.

Materials and Methods: Male transgenic aP2-*Ucp1* mice and non-transgenic littermate controls (C57BL/6J genetic background; $n = 6 - 8$) were fed either a standard laboratory chow or high-fat diet (HF; 60% calories as fat) from 3 mo of age. After 2 mo of HF feeding, glucose tolerance (expressed as incremental AUC) was assessed in mice following i.p. injection of glucose. Plasma levels of triglycerides were measured by coupled enzyme assay (Roche). Gene expression in skeletal muscle was quantitated by quantitative real-time PCR, while lipid content in tissues was estimated by measuring glycerol release from tissue triglycerides saponified by alcoholic KOH. Oxygen consumption of skeletal muscle fragments incubated in Krebs-Ringer bicarbonate buffer (pH 7.4) at 37°C was measured using a high-resolution respirometry (Oroboros Oxygraph, Paar KG, Graz, Austria).

Results: Glucose tolerance was improved by transgenic UCP1 (AUC: transgenics, 1153 ± 126 ; controls, 1570 ± 130 mmol x 180 min; $P < 0.05$) following 2 mo of HF feeding. Only in the fasting state, plasma triglycerides were decreased by ~ 45% in the transgenics ($P < 0.001$). Accordingly, triglyceride content was significantly reduced by ~ 40% in both skeletal muscle and liver. These changes were associated with a 2.6-fold down-regulation of gene expression for stearoyl-CoA desaturase-1, while GLUT4 gene expression was increased 1.6-fold in the skeletal muscle of transgenic mice. Preliminary results using a limited number of animals ($n = 4$) suggested that oxygen consumption in skeletal muscle of transgenic mice was increased by 20–30%.

Conclusion: Respiratory uncoupling, brought about by transgenic UCP1 in white fat, limited the accumulation of triglycerides in skeletal muscle and liver, while improving glucose tolerance of mice fed a HF diet. In skeletal muscle, these changes were associated with a simultaneous inhibition of lipogenesis and induction of respiration, which could be associated with increased energy expenditure via futile cycling of fatty acids between their synthesis and oxidation. The enhancement of energy expenditure in muscle, in response to a lower release of fatty acids from white fat, may contribute to both, obesity-resistance and insulin sensitivity of the aP2-*Ucp1* transgenic mice.

The PPAR α agonist fenofibrate does not improve insulin sensitivity in type 2 diabetes in man: a randomised controlled trialN. Black¹, C. N. Ennis¹, I. S. Young², S. J. Hunter¹, B. Atkinson¹, P. M. Bell¹;¹Regional Centre for Endocrinology and Diabetes, Royal Victoria Hospital,²Nutrition and Metabolism Group, The Queen's University of Belfast, United Kingdom.

Background and Aims: Insulin resistance is a central feature of type 2 diabetes mellitus. Lipid and carbohydrate metabolism are inter-related and it is often assumed on the basis of studies in animal and human tissue models that PPAR alpha agonists can improve insulin sensitivity. However, this assumption is based mainly on surrogate measures of insulin sensitivity and the use of high-affinity PPAR alpha ligands which are not used in clinical practice. This study is designed to compare the effect on insulin sensitivity of the selective PPAR

alpha agonist fenofibrate against that of the HMG CoA reductase inhibitor atorvastatin in human subjects with type 2 diabetes mellitus.

Materials and Methods: Thirteen subjects with type 2 diabetes mellitus were studied in a double-blind crossover design with 4-week placebo run-in and washout and 12-week treatment periods. Treatment was randomised to micronised fenofibrate 267mg or atorvastatin 10mg once daily followed by the alternate drug in the second period. Insulin resistance was measured using the isoglycaemic hyperinsulinaemic clamp method with an insulin infusion rate of $2\text{mU}^{-1}\text{kg}^{-1}\text{minute}^{-1}$ with isotope dilution ($[3\text{-}^3\text{H}]\text{-glucose}$) to determine glucose disposal rate and suppression of endogenous glucose production. The plasma glucose was maintained at a constant level during hyperinsulinaemia by an infusion of isotope-labelled 20% glucose at variable rate. The glucose infusion rate during the last 30 minutes of each clamp was used as an index of insulin sensitivity. Results are described as mean \pm standard error. Analysis was by the method of Hills and Armitage for 2-period crossover studies.

Results: Mean age was 61.3 (2.5), duration of diabetes 4.4 (0.7) years and body mass index was 29.5 (0.9) kg/m^2 . Baseline fasting plasma glucose was 7.7 (0.3) mmol/L , HbA1c 7.1 (0.2) %, fasting serum insulin 11.0 (0.8) mU/L . Ten subjects had been on lipid-lowering therapy prior to the study and this was withdrawn 4 weeks prior to the placebo run-in period. The baseline lipid profile was: total cholesterol 4.97 (0.25), LDL-cholesterol 2.95 (0.22), HDL-cholesterol 1.10 (0.06) and triglycerides 2.03 (0.27) mmol/L . Weight, physical activity and other medications did not change during the study. Total cholesterol was 4.60 ± 0.21 versus 3.9 ± 0.22 $\text{mmol}/\text{L}^{-1}$ after fenofibrate and atorvastatin respectively, $p < 0.05$. LDL was 2.70 ± 0.19 versus 1.95 ± 0.23 $\text{mmol}/\text{L}^{-1}$, $p < 0.05$ and triglycerides were 1.64 ± 0.23 versus 1.84 ± 0.26 $\text{mmol}/\text{L}^{-1}$, $p < 0.05$. The glucose infusion rate required to maintain isoglycaemia was similar after each treatment (30.3 ± 1.9 versus 26.3 ± 2.4 $\text{micromol}/\text{kg}^{-1}\text{min}^{-1}$, $p = \text{NS}$). Isotopically-determined rates of insulin-stimulated whole-body glucose disposal (35.4 ± 3.1 versus 33.2 ± 3.0 $\text{micromol}/\text{kg}^{-1}\text{min}^{-1}$) and nadir endogenous glucose production (6.2 ± 1.4 versus 7.0 ± 1.1 $\text{micromol}/\text{kg}^{-1}\text{min}^{-1}$) revealed no significant differences in effects of the treatments.

Conclusion: In human subjects with type 2 diabetes mellitus there were characteristic differences in lipid profile changes but no difference in insulin sensitivity after treatment with micronised fenofibrate compared to atorvastatin. Low-affinity PPAR alpha activators at doses used in clinical practice in type 2 diabetes in man do not improve insulin action.

Fatty acid profile remodeling of epiploic and parametrial fat in long-chain polyunsaturated ω 3 fatty acid deficiency

W. J. Malaisse¹, L. Portois², C. Delporte³, A. Sener¹, Y. A. Carpentier²;

¹Laboratory of Experimental Hormonology, Brussels Free University,

²Laboratory of Experimental Surgery, Brussels Free University, ³Laboratory of Biological Chemistry and Nutrition, Brussels Free University, Belgium.

Background and Aims: A depletion of long-chain polyunsaturated ω 3 fatty acids (ω 3), as often prevailing in Western populations, may favour the development of the metabolic syndrome. Likewise, in rats, an insufficient dietary supply of ω 3 leads to hyperlipidemia, visceral obesity, liver steatosis, insulin resistance and hypertension. The present study deals with the age-related alterations of the fatty acid profile in the epiploic and parametrial adipose tissue of ω 3-depleted rats.

Materials and Methods: The fatty acid profile of epiploic and parametrial fat was assessed in 16 female control animals and 16 second generation ω 3-depleted rats (ω 3-D) of same sex and comparable age. The time course of changes in ω 3-D rats was monitored by comparing 16 young (8–9 weeks), 16 middle-aged (15–16 weeks) and 9 older (22–23 weeks) rats.

Results: In both control and ω 3-D rats, modest but significant differences were, as a rule, observed when comparing epiploic to parametrial fat. At variance with control animals, long-chain polyunsaturated ω 3 fatty acid (C18:3 ω 3, C20:5 ω 3, C22:5 ω 3, C22:6 ω 3) were below the limit of detection in ω 3-D rats. The fat content of most long-chain polyunsaturated ω 6 fatty acid (C18:2 ω 6, C20:4 ω 6, C22:4 ω 6) was also significantly lower in ω 3-D rats than control animals, this coinciding with a lower C20:4 ω 6/C18:2 ω 6 ratio in the former rats (0.020 ± 0.004) than in the latter animals (0.036 ± 0.001). On the contrary, the C12:0, C14:0, C16:0, C16:1 ω 7 and C18:1 ω 9 contents

were increased in ω 3-D rats. The C16:1 ω 7/C16:0 and C18:1 ω 9/C18:0 ratios were almost twice higher in ω 3-D rats than in control animals, whilst the C20:1 ω 9/C18:1 ω 9 ratio was lower in ω 3-D rats ($9.09 \pm 0.22 \cdot 10^{-3}$) than in control animals ($15.86 \pm 0.52 \cdot 10^{-3}$). Several of these variables underwent age-related changes in ω 3-D rats often towards accentuation of the difference between these rats and control animals.

Conclusion: The lipid fatty acid pattern of epiploic and parametrial adipose tissue in ω 3-D rats demonstrate, in addition to depletion in long-chain polyunsaturated ω 3 and ω 6 fatty acids and apparently impaired generation of C20:4 ω 6 from C18:2 ω 6, increased activity of Δ 9-desaturase and impaired generation of C20:1 ω 9, the immediate precursor of nervonic acid. Some of these features, e.g. the depletion in ω 6 fatty acids, differ from those previously documented in the liver lipids of the same rats.

Institute for Molecular Sciences, Kuopio, Finland,

²Dept. of Internal Medicine, UKSH Campus Kiel, Germany,

³Department of Physiology, Oulu University Medical School, Finland.

Background and Aims: Elevated free fatty acid levels are a central feature of metabolic syndrome which is a growing health problem in many societies. In cytosol, free fatty acids are converted to acyl-CoAs, important intermediates for many metabolic pathways. Acyl-CoA binding protein (ACBP) binds with high affinity and specificity to medium and long chain acyl-coAs and has been shown to act as a pool former and transporter. Both acyl-CoAs and ACBP have emerged as important regulators of various intracellular functions including enzymes and transcription factors involved in carbohydrate and lipid metabolism. To further characterize the effects of ACBP on regulation of lipid and glucose metabolism we have used transgenic rats overexpressing the ACBP gene and studied effect on sterol regulatory element binding protein-1 (SREBP-1) and AMP-activated protein kinase (AMPK). SREBP-1 has an important role in the regulation of lipogenic genes while AMPK is known to switching off lipogenic and switching on energy producing / catabolic pathways like β -oxidation. In addition, AMPK affects SREBP-1 expression and acyl-CoAs can regulate its function.

Materials and Methods: A rat line overexpressing ACBP was created by standard methods. Tissues were collected from adipose tissue, liver, muscle and brain and isolated hypothalamus of fed and fasted rats. Total RNA and protein was isolated and used to measure differences in either gene expression or protein levels. Gene expression analysis was performed by quantitative real-time RT-PCR using Sybr-green as fluorescent dye. Protein levels were investigated by Western blotting using specific antibodies to AMPK α , phosphorylated AMPK α , SREBP-1 and β -actin.

Results: Our results show that in fed state expression of SREBP-1 mRNA was significantly downregulated by 77% in liver and by 23% in adipose tissue of transgenic (tg) ACBP overexpressing rats when compared to wildtype (wt) litter mates. There was no significant change in mRNA levels between wt and tg rats in muscle tissue nor in the hypothalamus. These results were confirmed on the protein level in liver: tg rats had significantly reduced levels of SREBP-1 when compared to wt controls. In the fasting stage (16hrs) SREBP-1 expression was significantly downregulated in the livers of both wt and tg animals. In adipose tissue fasting reduced the SREBP-1 expression of wt rats but did not affect SREBP-1 levels in tg animals. To further characterize possible mechanisms how ACBP affects SREBP-1 we investigated protein levels of AMPK α in liver and brain. We found significantly elevated AMPK α levels in liver of the tg rats compared to wt controls. Furthermore, levels of the active, Thr172 phosphorylated form of AMPK α were also increased. On the contrary, there was no change between tg and wt animals in AMPK α protein levels in brain.

Conclusion: Our results showed that ACBP is reducing SREBP-1 levels and upregulating AMPK α levels in tissue specific manner. These results indicate that ACBP affects regulation of lipid metabolism in liver and adipose tissue either directly or through regulation of acyl-CoAs.

GLUT-4 mRNA and protein content of soleus muscle and parametrial fat in ω 3 fatty-acid-depleted ratsL. Arnés¹, P. Tornero-Esteban¹, V. Sancho¹, M. L. Villanueva-Peñacarrillo¹, W. J. Malaisse²;¹Metabolism, Nutrition and Hormones, Fundación Jiménez Díaz, Madrid, Spain, ²Laboratory of Experimental Hormonology, Brussels Free University, Belgium.

Background and Aims: Second generation long-chain polyunsaturated ω 3 fatty acid-depleted rats are currently used as an animal model for the study of the metabolic and functional consequences of an insufficient exogenous supply of these ω 3 fatty acids, as presently often prevailing in Western populations. In the light of recent findings on the perturbation of glucose metabolism in both skeletal muscle and visceral adipose tissue of ω 3-depleted rats, the GLUT-4 expression in soleus muscle and parametrial fat was now compared in these rats and control animals.

Materials and Methods: The soleus muscle and parametrial adipose tissue were obtained from 16 female ω 3-depleted (ω 3D) rats and 16 control animals of same sex and age. Eight soleus muscle samples, each from 2 rats, and 5 adipose tissue samples, each from 3–4 rats, were examined for GLUT-4 protein -by Western blot- and mRNA -by RT-PCR- content.

Results: In soleus muscle and parametrial adipose tissue from ω 3D rats, the optimal density of GLUT-4 protein, normalized to that of β -tubulin, averaged 103.2 \pm 5.2% (n = 8) and 104.1 \pm 6.1% normal (n = 5), respectively. As judged from the paired difference between the primary values (cycles) for GLUT-4 mRNA and 18S rRNA, and expressing results as a mean fold change from control data ($2^{-\Delta\Delta CT}$ values), the level of GLUT-4 mRNA in the muscle of ω 3D rats was somewhat higher (range 1.43–2.27) than in that of normal control rats (range 0.91–1.09); in the adipose tissue of ω 3D rats, the GLUT-4 gene expression was somewhat lower (range 0.49–0.73) than in that of normal group (range 0.75–1.34).

Conclusion: A defect in the expression of the GLUT-4 gene in skeletal muscle and visceral adipose tissue appears as an unlikely major determinant of the perturbation of glucose homeostasis in ω 3 fatty acid deficiency. The data here collected in soleus muscle are consistent with previous observation of an unimpaired net basal uptake of D-[U-¹⁴C]glucose by stretched soleus muscle examined *in vitro*; likewise, the present findings in adipose tissue are consistent with prior data indicating that the impairment of glucose uptake by adipocytes is not specific for the hexose, as identical results being obtained for the uptake of [1,2-¹⁴C]acetate.

Fish oil increases lipolysis and fat oxidation in healthy men with dexamethasone (D)-induced insulin-resistanceJ. Delarue¹, G. Allain¹, C. Corporeau¹, V. Le Guen¹, S. Guillerm²;
¹Laboratoire Régional de Nutrition Humaine et EA-948, ²Laboratoire Régional de Nutrition Humaine, CHU Cavale Blanche, Brest, France.

Background and Aims: Fish oil (FO) increases insulin sensitivity in healthy humans and decreases insulin response to OGTT after D treatment suggesting a partial prevention of D-induced insulin resistance (IR). The aim of this study was to assess the effects of FO on insulin sensitivity, lipolysis and fatty acid oxidation in D-induced IR in healthy males.

Materials and Methods: 16 volunteers were studied 3 times. The first two tests, made at D0 and D15, were performed to study the effect of D (D: 2 mg/d during 2 days vs placebo). The third test was performed at D36, after 3 weeks of either FO (1.5 g EPA+DHA) (n=8) or placebo (controls, n=8). The 2 groups received 2 mg/d of D at D35 and D36. Each test included of a 3-step (S) hyperinsulinaemic euglycaemic clamp (insulin rate: S1: 0.2 mU/kg/min from 0 to 90 min, S2: 0.4 mU/kg/min from 90 to 180 min and then S3: 1 mU/kg/min from 180 to 270 min). Insulin sensitivity was estimated from total plasma glucose disappearance (Rd) and hepatic glucose production (HGP) determined from infusion of 6,6-d2-glucose (hot clamp); carbohydrate (CHOox) and lipid (Lox) oxidations were determined by indirect calorimetry and lipolysis by d5-glycerol flux (Ra glycerol).

Results: (mean \pm SEM, ANOVA for repeated measures). D decreased Rd (S1: 1.92 \pm 0.12 vs 2.33 \pm 0.16; step 2: 2.33 \pm 0.17 vs 4.41 \pm 0.52; step 3: 5.66 \pm 0.43 vs

9.38 \pm 0.65 mg/kg/min; all p<0.01), reduced the inhibition of HGP by insulin (S1:1.06 \pm 0.11 vs 0.64 \pm 0.13 p<0.05; S2:0.39 \pm 0.07 vs 0.36 \pm 0.07 NS; S3:0.41 \pm 0.21 vs 0.31 \pm 0.08 mg/kg/min, NS), decreased CHOox (S1:2.26 \pm 0.12 vs 2.75 \pm 0.20; S2:2.40 \pm 0.14 vs 3.20 \pm 0.17; S3:3.29 \pm 0.15 vs 4.52 \pm 0.21 mg/kg/min; all p<0.01), increased Lox (S1:0.92 \pm 0.05 vs 0.68 \pm 0.06; S2:0.88 \pm 0.05 vs 0.53 \pm 0.07; S3:0.58 \pm 0.06 vs 0.22 \pm 0.06 mg/kg/min; all p<0.01) and increased Ra glycerol (S1:1.92 \pm 0.36 vs 1.22 \pm 0.18; S2:1.5 \pm 0.28 vs 0.87 \pm 0.11; S3:1.05 \pm 0.18 vs 0.81 \pm 0.10 μ mol/kg/min; all p<0.01). FO+D did not alter Rd vs D, increased inhibition of HGP by insulin at S3: 0.03 \pm 0.02 vs 0.67 \pm 0.37 mg/kg/min; p<0.01), increased Lox at S3: 0.71 \pm 0.08 vs 0.47 \pm 0.07 mg/kg/min; p<0.05), decreased Gox at S3: 2.66 \pm 0.38 vs 3.55 \pm 0.28 mg/kg/min; p<0.05) and increased Ra glycerol at S2: 1.4 \pm 0.34 vs 1.22 \pm 0.30 μ mol/kg/min; p<0.05)

Conclusion: D induced peripheral and liver IR and increased lipolysis and fat oxidation. FO+D enhanced the effects of D on lipolysis and Lox, did not alter peripheral IR but increased liver insulin sensitivity.

Type I Gaucher disease, a glycosphingolipid storage disorder, is associated with insulin resistanceM. J. Serlie¹, M. Langeveld¹, M. T. Ackermans², K. J. Ghauharali³, J. E. Groener³, C. E. Hollak¹, J. M. Aerts³, H. P. Sauerwein¹;
¹Endocrinology and Metabolism, Academic Medical Center, ²Clinical Chemistry, Laboratory of Endocrinology, Academic Medical Center, ³Medical Biochemistry, Academic Medical Center, Amsterdam, The Netherlands.

Background and Aims: Glycosphingolipids (especially GM3) reside within lipid rafts in cell membranes. Therefore they may influence the function of membrane-bound receptors, like the insulin receptor. Gaucher disease is a lysosomal storage disorder in which glucosylceramide and more complex glycosphingolipids accumulate in macrophages and increase whole body macrophage burden. Glycosphingolipid concentrations in plasma are also elevated in this disorder. This may influence lipid raft composition in muscle cells, adipocytes and liver cells, thereby influencing insulin sensitivity. Furthermore, cellular storage causes activation of macrophages, which may lead to increased (non-insulin mediated) glucose uptake in these cells.

Materials and Methods: We studied the influence of glycosphingolipid storage on whole body glucose metabolism, by measuring basal glucose metabolism and insulin and non-insulin-mediated glucose uptake. We studied six Gaucher patients (either naive to treatment or with considerable remaining burden of disease despite treatment) and six matched healthy control subjects, during euglycemic and hyperglycemic clamps with somatostatin (non-insulin mediated glucose uptake (NIMGU)) and during a hyperinsulinemic euglycemic clamp (insulin-mediated glucose uptake (IMGU)), using stable isotopes. We also measured plasma FFA.

Results: IMGU was significantly lower in Gaucher patients, compared to controls, while NIMGU and hepatic insulin sensitivity did not differ between patients and controls. There was a trend for a decreased suppression by insulin of plasma FFA (lipolysis) in Gaucher patients.

Conclusion: Gaucher disease, a lysosomal glycosphingolipid storage disorder, is associated with peripheral insulin resistance. This may be explained by disturbed insulin signaling via an increase in membrane glycosphingolipids.

In a placebo-controlled clinical trial a novel Chinese herb formula increased insulin sensitivity and normalised postprandial dyslipidaemia in centrally obese menC. He¹, F. Sun², B. Li¹, Y. He¹, W. Chen¹, J. Ying¹, W. Wang¹;
¹Diabetes & Endocrinology, The Institute of Chinese Integrative Medicine, Shanghai, China, ²Diabetes and Endocrinology, Postgraduate Medical School, Guildford, United Kingdom.

Background and Aims: Central obesity is a well-recognized risk factor for the development of metabolic syndrome. The degree of insulin sensitivity has also been shown to be a major determinant of postprandial lipaemic excursions following a test meal. Although postprandial dyslipidaemia has been recognized as a risk factor for cardiovascular disease, there is little

information regarding its origin in relation to metabolic syndrome and the early prevention of insulin resistance.

This study seeks to investigate the effects of a novel Chinese herb formula on a group of centrally obese subjects as described by IDF criteria in a Chinese population. Chinese herbs have historically been widely used to treat patients with various symptoms of metabolic syndrome and central obesity. Clinical effectiveness has been well demonstrated. However, the underlying mechanism of its pharmacological effect remains unknown.

Materials and Methods: A placebo-controlled clinical trial was performed in 43 centrally obese males (age 45.9±6.0y; BMI 27.3±2.5kg/m²; waist circumference 97±6.4cm) and 31 lean males (age 43.7±7.6 years; BMI 23.5±2.1kg/m²; waist circumference 81±6.9cm), who were free from any medication. The aim was to examine the effects of 10 weeks treatment of a novel Chinese herb formula (CHF) on insulin sensitivity and postprandial dyslipidaemia. Obese volunteers were randomized into a CHF treatment group or placebo group. An oral fat tolerance test (OFTT) was performed before and after treatment. Adiponectin, leptin, interleukin-6 (IL-6) and tumor necrosis factor- α (TNF- α) were also measured.

Results: At baseline, the insulin sensitivity was assessed by the homeostasis model of insulin resistance (HOMA-IR) (obese 1.6±0.6 vs 0.9±0.7 lean, P=0.0001). There were no differences in blood glucose, glucose tolerance test and fasting lipid levels between the lean and obese groups. The postprandial triglyceride (TG) response in the OFTT as determined by TG area under the curve (TG-AUC) was higher in the obese subjects (10.52±6.17mmol/L-h) than the lean (4.89±4.05mmol/L-h, P=0.0001).

After CHF treatment, there was a significant decrease in postprandial TG-AUC following the fat load with no change in the placebo group (Table 1). In addition in the CHF group there was a 34% decrease in HOMA-IR and 35.5% reduction in insulin concentration. Although there was a decrease in waist circumference in the treatment group, the change of body weight in the treatment group was small. (Table 1)

Conclusion: The Chinese herb formula significantly increased insulin sensitivity and normalized postprandial lipid excursions. Treatment also had beneficial effects on levels of adipocytokines. This treatment provides an early intervention for insulin resistance and metabolic syndrome.

Serum and glucocorticoid-inducible protein kinase (SGK)-1 protect from different apoptotic stimuli

D. Pastore, M. Lombardo, F. Ferrelli, B. Capuani, K. Basello, A. Coppola, M. Federici, P. Sbraccia, G. Donadel, D. Lauro;
Internal Medicine, University of Rome Tor Vergata, Italy.

Background: Different studies revealed that insulin resistance might be associated with the intracellular formation of ceramide. The Ceramide synthesis can be activated by different stimuli, such as TNF- α , IL-1 β , gamma irradiation, U.V. light, ischemia, serum deprivation and can induce cell necrosis and apoptosis.

Aims: It has been investigated the role of SGK-1 in modulating apoptotic stimuli induced by four different treatments: 1) serum deprivation; 2) UV treatment; 3) C2-Ceramide incubation and 4) TNF- α stimulation.

Materials and Methods: HEK-293 and COS-7 cell lines has been used as experimental models, different cell lines has been stable transfected with SGK-1 and its dominant negative construct (SGK-1 dn), apoptosis was evaluated by FACS and Western Blot analysis.

Results: Serum deprivation, can increase apoptosis process in not transfected cells, differently in SGK-1 transfected cells, stimulated or not with insulin, has been detected lower levels of apoptosis compared to not transfected cell lines. Beside, It has been found that SGK-1 overexpression can protect from U.V. light-induced apoptosis and SGK-1 transfected cells are more resistant to C2-Ceramide-induced apoptosis. This process is mediated by reduced caspase-3 and PARP cleavage and activation that is independent from insulin stimulation. C2-ceramide treatment induces a significant increase of SGK-1 protein expression (p<0.05), phosphorylation and activity compared to dihydroceramide treated cells. Interestingly, it has been found that AKT-1 was not phosphorylated and activated, in the same conditions in which SGK-1 activity and expression is induced. C2-ceramide inhibits AKT-1 kinase activation and induce apoptosis; in SGK-1 transfected cell it has been detected a reduction of apoptotic levels and an increased expression and activation of SGK-1 that is statistically significant (p<0.01) compared to mock and SGK-1dn transfected cell lines. In the present study it has been hypothesized that SGK-1 expression induced by C2-ceramide stimulation is mediated by the cAMP/PKA pathway. Western Blot analysis revealed that the induction of SGK-1 protein expression by C2-ceramide treatment is attenuated in the presence of the H-89 a cAMP/PKA inhibitor. TNF- α stimulation can rouse apoptosis process in not transfected cell lines, differently, SGK-1 transfected cells showed a higher resistance to apoptosis (p<0.001), inhibition of TNF- α signaling mediated by SGK-1 can potentially increase insulin sensibility.

Conclusions:

- 1) SGK-1 has an antiapoptotic effect after UV light, C2-ceramide and TNF- α stimuli.
- 2) C2 Ceramide and TNF- α have a different effect on SGK-1 and AKT-1:
 - a) C2 Ceramide reduce AKT-1 activity and, differently increase SGK-1 activity and expression,
 - b) TNF- α can increase SGK-1 activity and, probably, expression.
- 3) SGK-1 expression can be activated by cAMP/PKA/CREB pathway.

Comparison of the NCEP and IDF definitions of metabolic syndrome among Chinese subjects with polycystic ovary syndrome

R. C. W. Ma¹, K.-H. Liu², W.-Y. So¹, A. P. S. Kong¹, P. C. Y. Tong¹, C.-C. Chow¹, J. C. N. Chan¹;

¹Dept of Medicine & Therapeutics, ²Dept of Diagnostic Radiology and Organ Imaging, Prince of Wales Hospital, Hong Kong.

Background and Aims: Subjects with polycystic ovary syndrome (PCOS) have insulin resistance and are at increased cardiovascular risk. Carotid intima-media thickness (IMT) has been shown to predict future cardiovascular events. There has been much recent debate as to the utility of the different definitions of the metabolic syndrome (MES). We recently demonstrated that among subjects with Type 2 DM, the IDF definition of MES failed to identify a subgroup of patients who were at highest risk for CHD. In this study, we aimed to compare the frequency of metabolic syndrome among a cohort of Chinese subjects with PCOS, and to compare their metabolic profile and cardiovascular risk as quantified by carotid IMT.

Materials and Methods: Ninety-eight Chinese subjects with PCOS were evaluated. All subjects fulfilled a diagnosis of PCOS according to the revised 2003 Rotterdam ESHRE/ASRM PCOS Consensus Workshop Group diagnostic criteria. Subjects with known cardiovascular or renal disease were excluded. Anthropometric measurements and metabolic risk profile, including a standard OGTT, were assessed in all subjects. All subjects were categorized by the criteria of IDF and NCEP. All subjects underwent an ultrasound examination for measurements of thickness of mesenteric, preperitoneal, and subcutaneous fat as well as carotid intima-media thickness.

Results: The subjects had a mean age of 27.5 ± 6.2 . Mean BMI was 24.1 ± 5.1 kg/m². Fifteen (15.3%) of the subjects had metabolic syndrome according to the National Cholesterol Education Adult Treatment Panel III criteria whilst 12 subjects (12.2%) fulfilled a diagnosis of metabolic syndrome according to the IDF definition, using the Asian definition of central obesity of waist-circumference >80 cm ($p < 0.01$ by χ^2). Subjects who had metabolic syndrome by either the NCEP or IDF definition had a more adverse metabolic profile, as well as a higher ALT and creatinine. There was no significant difference in HOMA-IR among subjects with and without MES according to the IDF definition. Mesenteric fat was significantly associated with all components of the MES. IMT was increased among subjects who had metabolic syndrome by NCEP definition, but not among subjects who had MES by IDF definition alone.

Conclusion: Our preliminary data suggest that the NCEP definition identifies significantly more subjects with metabolic syndrome among subjects with PCOS. Subjects who had metabolic syndrome by NCEP definition had significantly increased carotid IMT compared to subjects without MES. Among Chinese subjects with PCOS, the NCEP definition of MES may be superior to the IDF definition in identifying subjects at increased risk of cardiovascular disease.

Rapid insulin pulsatile secretion in women with polycystic ovary syndrome

T. Grimmichova¹, J. Vrbikova¹, P. Matucha¹, K. Vondra¹, P. P. Veldhuis², M. L. Johnson²;

¹Laboratory of Functional Diagnostics, Institute of Endocrinology, Prague, Czech Republic, ²Department of Pharmacology and Internal Medicine, University of Virginia, Charlottesville, United States.

Background and Aims: Polycystic ovary syndrome (PCOS) is considered as a risk factor for impaired glucose tolerance and diabetes mellitus type 2. Hyperinsulinaemia secondary to insulin resistance, abnormal insulin secretion and decreased insulin clearance was reported in PCOS. The aim of our study was to evaluate rapid insulin pulses and insulin secretion regularity in fasting state in lean PCOS women in comparison to lean healthy controls.

Materials and Methods: PCOS women ($n=8$; age 25.1 (21.8 – 29.5) years) fulfilling the diagnostic criteria as defined by ESHRE/ASRM. Healthy controls (C ; $n=7$, age 30.2 (25.1 – 38.1) years). Blood samples for hormonal levels were performed in early follicular phase of menstrual cycle. After overnight

fast PCOS and C underwent frequent blood sampling each minute for 60 minutes assessing rapid insulin pulses. Data analysis: Deconvolution software AutoDecon evaluating insulin pulsatility. Approximate entropy (ApEn) appraised insulin concentrations time series orderliness. Statistics: All data are given as retransformed means and 95% confidence interval. Unpaired t -tests and Pearson correlation coefficients were used on transformed data ($p < 0.05$ was considered statistically significant).

Results: PCOS had higher testosterone (3.2 (2.8 – 3.6) vs 2.3 (0 – 3.3) nmol/l; $p < 0.02$), prolactin (23.8 (16.8 – 32.5) vs 13.7 (6.3 – 25.4) ng/ml; $p < 0.05$) and lower SHBG levels (46.3 (28.4 – 64.1) vs 98.1 (83.1 – 113.1) nmol/l; $p < 0.0006$) in comparison to C . PCOS had higher BMI than C (21.9 (20.2 – 23.5) vs 20.1 (18.9 – 21.2) kg/m²; $p < 0.05$). Fasting blood glucose (4.2 (4 – 4.35) vs 4.1 (4 – 4.4) mmol/l), insulin (5.1 (3.9 – 6.5) vs 4.2 (3.1 – 5.6) mIU/l), C-peptide (0.54 (0.4 – 0.71) vs 0.51 (0.23 – 0.96) nmol/l) and cortisol concentrations (564 (442 – 729) vs 449 (306 – 680) nmol/l) did not differ between PCOS and C . Deconvolution analysis results: Insulin elimination kinetics were established with individual insulin half-life of 3.3 (2.8 – 4.1) in PCOS and 3.2 (2.6 – 4.1) minutes in C . Both PCOS and C had comparable average frequency of 10 insulin pulses per 60 minutes. Insulin burst mass (2.1 (1.5 – 3) vs 1.4 (1 – 2.4) mIU/l), basal secretion (0.7 (0.4 – 1.0) vs 0.5 (0.2 – 0.8) mIU/l/min), interpulse interval (5.9 (5 – 7.2) vs 5.6 (4.6 – 7.1) min) and burst amplitude (1.1 (0.7 – 2.1) vs 1.5 (1.0 – 2.6) mIU/l/min] did not differ significantly between groups. PCOS women had a tendency to broader peaks determined by a common half-duration (2.0 (1.1 – 3.4) vs 0.9 (0.5 – 1.5) min; $p < 0.07$) (duration of an algebraically Gaussian secretory pulse at half-maximal amplitude). The common-half duration was positively correlated with prolactin and cortisol concentrations ($r=0.76$; $p < 0.008$, $r=0.64$; $p < 0.03$, respectively). Higher testosterone levels were correlated with higher burst mass ($r=0.61$; $p < 0.05$). ApEn in PCOS was not different from C (1.14 (1.09 – 1.19) and 1.08 (0.94 – 1.16), respectively; $p < 0.17$). Higher BMI and prolactin levels were correlated with more irregular insulin secretion (ApEn) ($r=0.57$; $p < 0.04$; $r=0.68$; $p < 0.03$, respectively).

Conclusion: We observed similar insulin pulsatile release and insulin secretion orderliness in lean PCOS women in comparison to healthy lean controls. Prolonged and intensive action of prolactin, androgens and cortisol could participate in alteration of insulin secretion patterns leading to glucose intolerance.

Insulin resistance and beta cell function in polycystic ovary syndrome: the influence of family history of type 2 diabetes mellitus

J. Vrbikova¹, M. Hill², B. Bendlová³, K. Vondra¹, T. Grimmichova¹, G. Pacini⁴;

¹Functional diagnostic, Institute of Endocrinology, Prague, Czech Republic, ²Steroid, Institute of Endocrinology, Prague, Czech Republic, ³Molecular Endocrinology, Institute of Endocrinology, Prague, Czech Republic, ⁴Metabolic Modeling Unit, National Research Council, Padova, Italy.

Background and Aims: Polycystic ovary syndrome (PCOS) is often considered a risk factor for type 2 diabetes mellitus (DM2). It is not known if the family history of DM2 plays a role in the overall state of PCOS. The aim was to evaluate insulin sensitivity and beta cell secretory compensation in women with PCOS with respect to their family history of DM2.

Materials and Methods: 79 PCOS women (age 27.4 ± 7.2 years, BMI 26.7 ± 7.3 kg/m²) according to NIH consensus and 94 healthy women (CT; age 26.6 ± 5.7 years, BMI 23.1 ± 5.2 kg/m²) free of family history of DM2 underwent oGTT (sampling at 0, 30, 60, 90, 120, 180 min) for blood glucose (mg/dl), C peptide (nmol/l) and insulin (mIU/l). PCOS were divided into PCOS+ with first-degree relative affected by DM2 ($n=23$; age 29.9 ± 6.5 , BMI 29.1 ± 7.8) and PCOS-, without family history of DM2 ($n=56$; age 26.8 ± 6.6 , BMI 26.1 ± 6.2). Insulin resistance was evaluated by oral glucose index (OGIS, ml/min/m²) and insulin secretion by the areas under the curve AUC_I for insulin (U/l 3h) and AUC_{Cp} for C peptide (μmol/l 3h). AUC_G for glucose (g/dl 3h) was computed. Beta cell compensatory mechanism (adaptation index, AI) was evaluated as $OGIS \times AUC_{Cp}$. All data are as mean \pm SD; BMI- and age-adjusted ANCOVA followed by least significant difference multiple comparisons ($p < 0.05$) for evaluation of between-group differences.

Results: Impaired glucose tolerance was found in 9/23 PCOS+ and in 6/56 PCOS-. Basal blood glucose was higher in PCOS+ than in PCOS- (90.5 ± 12.8 vs. 82.5 ± 11.4) or CT (83.4 ± 8.4). Basal insulin was significantly higher in PCOS+ (14.9 ± 12.7) than in PCOS- (9.6 ± 7.7) or in CT (7.3 ± 5.1).

In comparison with CT, all PCOS have significantly higher basal C-peptide (0.89 ± 0.45 vs. 0.60 ± 0.27), AUC_G (20.1 ± 5.9 vs. 16.4 ± 2.4), AUC (10.8 ± 8.3 vs. 5.7 ± 4.6) and AUC_{CR} (0.51 ± 0.22 vs. 0.36 ± 0.12). Only PCOS+ have significantly lower OGIS (439.6 ± 105.3) than CT (524.9 ± 69.8). Hepatic insulin extraction was decreased in PCOS- (64.3 ± 11.4 %) compared to CT (71.2 ± 12.4 %) while did not differ in PCOS+ (61.6 ± 17.8 %). Adaptation index was higher in PCOS- than in CT (0.24 ± 0.08 vs. 0.19 ± 0.06) and was not different between PCOS+ (0.22 ± 0.06) and CT.

Conclusion: The family history of DM2 plays an important role in the metabolic state of women with PCOS: in fact, elevated insulin resistance is present only in PCOS with first degree relative with DM2. On the other hand, insulin hypersecretion is present in PCOS irrespective of family history of DM2 and obesity. Despite this beta cell hypersecretion, PCOS women are not able to maintain similar blood glucose levels after oral glucose load as the healthy control subjects

Abnormal glucose tolerance and metabolic syndrome in the first degree relatives of women with polycystic ovary syndrome

S. Yadav, P. Kalra, V. Bhatia, E. Bhatia;
Endocrinology, SGP GIMS, Lucknow, UP, India.

Background and Aims: Polycystic ovarian syndrome (PCOS) is a common problem affecting 6–8% of reproductive females. There is a high incidence of IGT, diabetes mellitus, insulin resistance, and hyperandrogenemia in first degree relatives of PCOS patients.

Our aim was to study prevalence of abnormal glucose tolerance (impaired glucose tolerance and or diabetes mellitus) and metabolic syndrome in first degree relatives of women with PCOS as compared to controls from north Indian population.

Materials and Methods: One hundred and seventy nine family members of 75 patients with PCOS [Mothers (n=71; mean age, 45.3 yr; mean body mass index (BMI), 27.6 kg/m²), Fathers (n=70; mean age, 50.7 yr; mean BMI, 25.6 kg/m²), Sisters (n=17; mean age, 29.9 yr; mean BMI, 24.5 kg/m²), and Brothers (n=21; mean age, 22.9 yr; mean BMI, 22.5 kg/m²)] and 118 unrelated healthy control subjects without a family history of PCOS (4 age and BMI matched subgroups, i.e. Control Mothers, Control Fathers, Control Sisters, and Control Brothers) were evaluated by anthropometric measurements, OGTT, fasting and post glucose 2 hour insulin and fasting lipid profile.

Results: Prevalence of any degree of glucose intolerance (impaired glucose tolerance and or diabetes mellitus) was present in 52.9% of mothers of women with PCOS, and 27.5% of control mothers ($p < 0.05$; odd ratio 3.0); 48.5% fathers of women with PCOS and 24.5% control fathers ($p < 0.05$; odd ratio 2.9); 52.9% sisters of women with PCOS and 13.3% control sisters ($p < 0.05$; odd ratio 7.3); 19.0% brothers of women with PCOS and 14.3% control brothers ($p = NS$). Metabolic syndrome as defined by NCEP-ATP III guidelines was present in 27.5% mothers of women with PCOS and 10.3% of control mothers ($p < 0.05$); 39.1% fathers of women with PCOS and 14.6% control fathers ($p < 0.05$), 23.5% sisters of women with PCOS and 6.6% control sisters ($p = NS$), 23.8% brothers of women with PCOS and none of control brothers ($p < 0.05$). For analyzing insulin resistance, we matched the relatives of women with PCOS and healthy controls for age and BMI, till now we analyzed in 47 subjects in each group. HOMA-IR was significantly higher in relatives of PCOS subjects as compared to healthy controls ($P = 0.05$). Univariate logistic regression in first degree relatives of PCOS subjects showed that metabolic syndrome, triglyceride and all parameters of obesity significantly predicted whether a subject would have abnormal glucose tolerance. In stepwise logistic regression analysis metabolic syndrome, waist hip ratio, and age were significant predictive factors for development of abnormal glucose tolerance in relatives of PCOS subjects.

Conclusions: Our results suggest that first degree relatives of PCOS subjects are at high risk for diabetes mellitus and glucose intolerance; there is an increased prevalence of metabolic syndrome in first degree relative of PCOS women. We propose that the high risks of these impairments warrant screening in first degree relatives of women with PCOS.

0790

Elevated risk markers of atherosclerosis in polycystic ovary syndrome (PCOS) were significantly reduced during pioglitazone treatment in a randomised placebo controlled study

D. Glintborg¹, K. Højlund¹, M. Andersen¹, J. Henriksen¹, H. Beck-Nielsen¹, A. Handberg²;

¹Endocrinology, Odense University Hospital,

²Clinical Biochemical department, Aarhus University Hospital, Denmark.

Background and Aims: Recent studies found increased levels of risk markers for atherosclerosis in polycystic ovary syndrome (PCOS), but the effect of insulin sensitizing treatment on these markers remains to be established. A soluble form of CD36 (sCD36) in plasma was recently identified, and shown to be strongly related to risk factors of accelerated atherosclerosis in type 2 diabetes including insulin resistance and glycemic control. In the present study, we investigated the relation between sCD36, oxidized LDL (oxLDL), high sensitive CRP (hsCRP), and interleukin 6 (IL-6 and measures of body composition and glucose metabolism in PCOS before and during pioglitazone treatment.

Materials and Methods: Thirty PCOS patients were randomized to pioglitazone, 30 mg/day or placebo for 16 weeks. Fourteen weight-matched healthy females were included as controls. sCD36, oxLDL, hsCRP, IL-6, euglycemic hyperinsulinemic clamps, and measures of fat mass (whole body DXA-scans) were performed.

Results: PCOS patients had significantly decreased insulin-stimulated total (Rd), oxidative and non-oxidative glucose metabolism than controls, all $p < 0.05$. sCD36 (2.87 ($0.88 - 9.36$) vs. 1.67 ($0.72 - 3.89$) relative units), oxLDL (44.9 ($26.9 - 75.1$) vs. 36.1 ($23.4 - 55.5$) U/l), and hsCRP (0.26 ($0.03 - 2.41$) vs. 0.12 ($0.02 - 0.81$) mg/dl) were significantly increased in PCOS patients vs. control subjects (geometric mean (-2SD-2SD)). In PCOS patients, positive correlations were found between sCD36, hsCRP and IL-6 and abdominal fat mass ($r = 0.40 - 0.43$, $p < 0.05$) and between hsCRP, IL-6 and total fat mass ($r = 0.59$ and 0.59 , $p < 0.05$). sCD36 furthermore showed a positive correlation with lipid oxidation during insulin stimulation ($r = 0.53$, $p = 0.003$) and an inverse correlation with insulin-stimulated oxidative glucose metabolism ($r = -0.57$, $p = 0.001$). Following pioglitazone treatment, insulin sensitivity and measures of insulin-stimulated glucose metabolism significantly increased (all $p < 0.05$), whereas hsCRP (0.36 ($0.06 - 2.20$) vs. 0.24 ($0.04 - 1.58$) mg/dl) and sCD36 (3.21 ($0.71 - 13.6$) - 2.33 ($0.84 - 6.46$) relative units) significantly decreased. No significant changes were observed in oxLDL and IL6.

Conclusion: sCD36, oxLDL, hsCRP, and IL6 were correlated with abdominal and total fat mass, thus supporting the hypothesis that the high risk for the metabolic syndrome and possible future atherosclerosis is in part related to abdominal obesity in PCOS. sCD36 furthermore correlated positively with lipid oxidation and inversely with oxidative glucose metabolism. Pioglitazone treatment reduced sCD36 and hsCRP while improving insulin-stimulated glucose metabolism, thus suggesting that sCD36 may be used as a surrogate marker for insulin resistance and future risk for atherosclerosis in PCOS.

Hyperphosphorylation and low protein content of muscle glycogen synthase contribute to insulin resistance in polycystic ovary syndrome: effects of pioglitazone treatment

K. Højlund¹, D. Glintborg¹, N. R. Andersen², J. B. Birk², J. T. Treebak², H. Beck-Nielsen¹, J. F. P. Wojtaszewski²;

¹Department of Endocrinology, University of Southern Denmark, Odense,

²Department of Human Physiology, University of Copenhagen, Denmark.

Background and Aims: Insulin resistance in skeletal muscle, characterized primarily by impaired insulin-stimulation of glycogen synthesis, is a major risk factor for type 2 diabetes in women with polycystic ovary syndrome (PCOS). The molecular mechanisms underlying reduced insulin action on glycogen synthesis in skeletal muscle of patients with PCOS have not been established.

Materials and Methods: We investigated protein content and multisite phosphorylation of glycogen synthase (GS) and its major upstream inhibitor,

glycogen synthase kinase 3 (GSK3) in skeletal muscle of 24 PCOS patients and 14 matched control subjects, and examined the effects of 16 weeks treatment with pioglitazone in PCOS. Skeletal muscle biopsies from vastus lateralis were obtained before and after euglycemic-hyperinsulinemic clamp studies combined with indirect calorimetry.

Results: Reduced insulin-mediated total, oxidative and non-oxidative glucose disposal (all $p < 0.05$) was associated with impaired insulin-stimulated GS activity in women with PCOS ($37 \pm 2\%$ vs. $46 \pm 2\%$ fractional velocity (FV); $p < 0.05$) compared with controls. This was caused by a 36% lower protein content of muscle GS (70 ± 6 vs. 110 ± 10 AU; $p < 0.05$), as well as a ~2-fold increase in the phosphorylation of GS at sites 2+2a, 3a+3b and 1b after correction for GS protein (all $p < 0.05$). No significant abnormalities in protein content or phosphorylation of GSK3- α or - β were found in PCOS. Pioglitazone treatment improved insulin-stimulated glucose metabolism in PCOS, and this was paralleled by a 30% increase in insulin-stimulated GS-activity ($33 \pm 2\%$ vs. $43 \pm 2\%$ FV; $p < 0.05$). This was associated with a 40–50% reduction in the phosphorylation of GS at sites 3a and 3a+3b ($p < 0.05$), whereas protein levels of GS remained reduced.

Conclusion: Impaired insulin activation of GS in part explains insulin resistance at the molecular level in skeletal muscle in PCOS. Both reduced protein levels and hyperphosphorylation at several sites of GS may contribute to this defect. The ability of pioglitazone to enhance insulin sensitivity may involve improved insulin-mediated dephosphorylation of GS.

Effect of high-protein low-fat diet on cardiovascular disease risk factors of individuals with metabolic syndrome

E. Papakonstantinou¹, D. Panagiotakos¹, A. Koutsovasilis², A. Manolis³, A. Melidonis², A. Zampelas⁴;

¹Dietetics and nutritional science, Harokopio University, ²Diabetes Clinic, Tzanio General Hospital of Piraeus, ³Hypertension Management Clinic, Tzanio General Hospital of Piraeus, ⁴Department of Food Science and Technology, Agricultural University of Athens, Athens, Greece.

Background and Aims: When substituted for carbohydrate in an diet, dietary protein improves blood pressure, glycemic control and markers of cardiovascular disease in people with metabolic syndrome. It is unknown whether the effect is due to increased protein or reduced carbohydrate. We compared the effects of 2 isocaloric, hypoenergetic diets that differed in protein and fat content on indices of glycemic control, body composition, blood pressure, and lipids.

Materials and Methods: 17 obese volunteers, age 46 ± 3 y, with mild type 2 diabetes in a random, blind, cross-over design study followed 2 diets: (a) a high protein, low fat diet (30% protein, 50% carbohydrates, 20% fat) and (b) a low protein, high fat diet (15% protein, 50% carbohydrates, 35% fat), for 4 weeks each with 3 weeks washout period without treatment. Diets included 2 meal replacements. Blood was collected in the beginning and end of treatments. At the beginning and end of each treatment, the volunteers consumed a meal (30% protein, 50% carbohydrates, 20% fat) after 12-hour fast. Glucose and insulin were measured at fasting, 30, 60, 90, 120, 150, 180 minutes postprandially. Weight, waist circumference, blood lipids, and blood pressure were measured. Repeated measures analysis was used to test the effects of treatment, time of measurement, and their interactions on the dependent measures.

Results: High protein, low fat diet caused a significantly higher reduction in blood pressure ($p = 0.013$) and triglyceride levels ($p = 0.042$) compared to a low protein diet. High protein diet caused a significant reduction in glycated hemoglobin ($p < 0.001$), whereas the low protein diet did not. Both diets reduced glucose and insulin levels, but no significant difference was found between them. Both diets led to a significant reduction of total, LDL, and HDL cholesterol but no significant difference was found between the diets. No statistically significant difference was found between the diets concerning BMI, waist, body fat, or fat-free mass.

Conclusion: A high protein low fat diet improves more blood pressure and plasma triglyceride levels compared to a low protein high fat diet. The improvements in glycated haemoglobin, insulin resistance, weight loss and blood lipids did not differ significantly between the two diets.

The effect of a high-protein diet on parameters of glucose and lipid metabolism in patients with type 2 diabetes (T2DM) on insulin therapy

B. Tripp, B. Ludvik, K. Schindler;

Internal Medicine III, University of Vienna, Austria.

Background and Aims: The optimal macronutrient composition of a diet for T2DM remains a matter of controversy. This study investigated the metabolic effects of a high-protein diet predominantly from vegetables in type 2 diabetic patients on insulin therapy.

Materials and Methods: 44 patients with T2DM were randomly assigned either to a weight-maintaining high protein diet (PR: $n = 22$; P:CHO: F=30:40:30%, age: 61.0 ± 5.7 years, body weight: 94.1 ± 15.6 kg, insulin dose: 57.3 ± 26.6 IU/day, HbA_{1c}: $7.8 \pm 1.4\%$), or a standard diet (ST: $n = 22$, P:CHO: F=15:55:30%, age: 63.7 ± 5.2 years, body weight: 91.5 ± 20.2 kg insulin dose: 52.7 ± 28.8 IU, HbA_{1c}: $7.6 \pm 0.9\%$). Parameters of glucose- and lipid metabolism and anthropometric parameters were evaluated at baseline and after 3 months. The main outcome variables were daily insulin requirements and metabolic control.

Results: Body weight decreased in both groups after 3 months (PR: to 91.0 ± 15.7 ; ST: to 90.5 ± 19.4 kg, $p < 0.05$), albeit to a higher extent in PR ($p = 0.0042$). In PR, insulin dose was reduced ($p < 0.05$) from 57.3 ± 26.6 to

48.2±30.8IU/day, HbA_{1c} from 7.8±1.4 to 7.5±1.4%, FPG from 203.2±56.9 to 160.0±47.7mg/dl, triglycerides from 186.9±114.9 to 140.7±55.6mg/dl. Diastolic blood pressure showed a significant decrease from 83.2±7.2 to 76.9±8.7mmHg ($p<0.05$). Fat mass was reduced from 29.1±8.2 to 26.7±6.2kg ($p<0.05$). No specific changes were seen in ST except for an increase in insulin dose ($p<0.05$).

Conclusion: In this study we could demonstrate beneficial effects of a high-protein diet on glycemic parameters and insulin requirement in type 2 diabetic patients over 3 months compared to a standard diet. These changes seem to be related to the greater weight loss and require confirmation over longer observation periods.

0794

High-CHO/high-fibre diet vs. low-CHO/high-MUFA diet: which is the better approach to improve postprandial lipid abnormalities in type 2 diabetic patients?

G. Annuzzi, C. De Natale, L. Patti, L. Bozzetto, O. Ciano, P. Massaro, G. Costabile, G. Riccardi, A. A. Rivellese;
Department of Clinical and Experimental Medicine, University Federico II Naples, Italy.

Background and Aims: Postprandial lipid abnormalities may have an important role in increasing cardiovascular risk, especially in type 2 diabetes. Nonetheless, very few studies have evaluated the possibility to improve these abnormalities in type 2 diabetic patients by different dietary approaches. We compared the effects on postprandial lipaemia of the two diets generally recommended to individuals with diabetes (high-CHO/high-fibre diet and low-CHO/high-MUFA diet).

Materials and Methods: Six type 2 diabetic patients (age 58±5 years; BMI 27±7 kg/m²)(M±SD) in satisfactory blood glucose control on diet or diet+oral hypoglycaemic drugs, have been studied so far, according to a randomised cross-over design. They followed for one month a diet relatively rich in CHO (52% total energy) and fibre (28g/1000 kcal) with low glycaemic index (GI) (58%) or a diet low in CHO (45% total energy) and fibre (8g/1000 kcal) with high GI (88%), and then crossed over to the alternate diet for another month. At the end of each period a test meal of the same composition as the corresponding diet was administered and plasma samples for determination of lipids and lipoprotein fractions (separated by discontinuous density gradient ultracentrifugation) were taken before and over 6 hrs after meal.

Results: Fasting LDL cholesterol and postprandial blood glucose were lower at the end of the high-CHO/high-fibre/low-GI diet compared to the low-CHO/high-MUFA diet, as was the postprandial response of plasma triglycerides (incremental AUC 136±99 vs. 272±145 mg/dl-6hrs, $p=0.03$). At the end of the high-CHO diet, also cholesterol (Chol) and triglycerides (Tg) concentrations were significantly lower in chylomicrons (incremental AUC Chol 1.8±0.6 vs. 4.0±1.8 mg/dl-6h, $p<0.01$; Tg 55±25 vs. 93±38 mg/dl-6h, $p=0.009$) and in large VLDL (incremental AUC Chol 10±16 vs. 30±17 mg/dl-6h, $p=0.03$; Tg 108±78 vs. 214±120 mg/dl-6h, $p=0.03$).

Conclusion: Compared to a low-CHO/high-MUFA diet, a relatively high-CHO/high-fibre/low-GI diet significantly improves the postprandial response of TG-rich lipoproteins. This kind of diet, also by virtue of its beneficial postprandial effects, could be the optimal approach for treating diabetic patients to reduce their cardiovascular risk.

Glycaemic index, glycaemic load and non-alcoholic fatty liver disease in Japanese adults

J. Oya¹, T. Nakagami¹, S. Jimba¹, S. Sasaki², T. Kasahara³, T. Wasada³, Y. Iwamoto¹;

¹Diabetes Center, Tokyo Women's Medical University, Tokyo, ²Nutritional Epidemiology Program, National Institute of Health and Nutrition, Tokyo, ³Internal Medicine, Saitama-ken Saiseikai Kurihashi Hospital, Saitama-ken, Japan.

Background and Aims: We have previously reported that non-alcoholic fatty liver disease (NAFLD) existed at 20% of non-obese Japanese adults and was closely associated with hyperglycemia and dyslipidemia, independent from age and abdominal obesity (Diabetologia 49 suppl1: 448, 2006). Recently, a

study showed a favorable impact of supplementation with n-3 long-chain polyunsaturated fatty acids (n-3 PUFA) on NAFLD in Italian subjects. However, little is known about nutritional composition responsible for the development of NAFLD in Japanese living in Japan whose major resource of carbohydrate is white rice. Thus, we compared dietary habits and nutritional components between people with NAFLD and those with normal liver to establish a dietary recommendation to prevent NAFLD as one surrogate marker of the metabolic syndrome in Japan.

Subjects and Methods: The study subjects were 1282 men (51 ± 9 years) and 772 women (51 ± 9 years) in a cohort of middle-aged apparently healthy adults without medications for diabetes, hypertension or dyslipidemia. They took medical examinations including B-mode ultrasonography of the liver and measurement of waist circumference (Wc) at the height of umbilicus. We collected their dietary information of recent one month by brief-type self-administered diet history questionnaire developed by S.S and calculated nutritional intake. The diagnosis of NAFLD (147 subjects) was done on the basis of ultrasonographic findings and amount of alcohol intake less than 40 gram/week. The difference of foods and nutrition was compared between subjects with normal liver and NAFLD.

Results: The prevalence of NAFLD was 17.2 % for men and 13.6 % for women. The group with NAFLD had significantly higher intakes of grains, milk, fruits, soft drinks and lesser intake of fish for men ($p<0.05$), but no significant difference was found for women. In the group with NAFLD, intake of vegetable proteins, total fats, vegetable fats, saturated fatty acids, monounsaturated fatty acids, n-6 polyunsaturated fatty acids, dietary fiber, vitamin C, sugar was significantly higher than the group with normal liver only for men ($p<0.05$ for all). However, no difference was found for intake of magnesium, animal proteins and fats, n-3 PUFA in both sexes. The group with NAFLD had significantly lesser intakes of alcohol for both sexes ($p<0.000$). While the group with NAFLD had significantly higher intake of glycemic index (GI)(31.8 vs. 34.6 /1000 kcal; $p<0.000$) and glycemic load (GL) (85.5 vs.96.6 /1000 kcal; $p<0.000$) only for men. The logistic regression analysis showed that GI and GL were continuous and independent risk factors for NAFLD, after adjusting for age, body mass index, smoking, physical activity, dietary supplements, eating speed, total energy intake, and total dietary fiber intake in men.

Conclusion: Both GI and GL are continuous and independent risk factors for NAFLD in Japanese men whose major resource of carbohydrate is white rice.

The effect of daily consumption of b-glucan-enriched bread on serum cholesterol and plasma glucose levels of type 2 diabetic persons

P. Tsapogas¹, S. Liatis¹, C. Dimosthenopoulos¹, E. Chala², E. Kapantais², S. Grammatikou¹, K. Makrilakis¹, N. Katsilambros¹;

¹1st Dep Propaedeutic Medicine, Laiko General Hospital, ²Department of Diabetes, Obesity, and Metabolism, Metropolitan Hospital, Athens, Greece.

Background and Aims: Certain studies have shown that the water-soluble dietary fiber beta-glucan, a natural component of oat, has hypocholesterolaemic actions, at least in normal subjects. The aim of this study was to evaluate whether the enrichment of bread with b-glucan can improve serum cholesterol levels in patients with type 2 diabetes mellitus (DM) and secondarily whether it affects glycaemic control and fasting insulin levels.

Materials and Methods: A double-blind, prospective, randomised study, was performed on 54 patients with type 2 DM (31 men, 23 women, aged 62.7±9.6 years, BMI 28.55±4.53 kg/m², total cholesterol 223.17±32.12 mg/dl, LDL-C 150.16±28.58 mg/dl), who completed the study. Each subject consumed 120 g of bread daily for 3 weeks, enriched with 3 g of b-glucan from oat (Group A, n=26) or not-enriched [regular bread (Group B, n=28)]. None of them were receiving hypolipidaemic treatment and their antidiabetic regimen remained stable throughout the study.

Results: At the end of the study, both groups showed a statistically significant reduction of BMI (−0.365, $p=0.003$ and −0.163 Kg/m², $p=0.030$ for Group A and Group B respectively) and waist circumference (−1.354 $p=0.017$ and −1.036 cm, and 0.027 for Group A and Group B respectively). Group A showed a statistically significant reduction of total-Cholesterol and LDL-Cholesterol compared to Group B (decrease of total-Cholesterol by 19.62 mg/dl vs. decrease by 1.18 mg/dl, [$p=0.017$], and decrease of LDL-C by 16.85 mg/dl

vs. decrease by 0.01 mg/dl, [p=0.022] respectively). Group A also showed a greater decrease in fasting glucose and insulin levels compared to Group B (decrease of plasma glucose by 7.65 mg/dl vs. decrease by 2.82 mg/dl, and of serum insulin decrease by 2.31 μ U/ml vs. increase by 1.43 μ U/ml) but these differences did not reach statistical significance (p=0.61 and p=0.23, respectively). Both groups showed a significant reduction in HbA_{1c} (group A: 7.07% baseline vs. 6.85% at the end of study, p=0.002, and group B: 7.01% baseline vs. 6.83%, p=0.042). Mean differences in HbA_{1c} in the two groups were -0.220 (group A) and -0.188 (group B), p=0.764. The HOMA insulin resistance index was not statistically different in the 2 groups (Group A vs. Group B -1.776 vs. +0.132, p=0.29). Group A showed a significant reduction in systolic blood pressure (141.7mmHg baseline vs. 134.4mmHg at the end of study, p=0.012) while in group B there was a tendency for a lower systolic blood pressure (131.2mmHg baseline vs. 126.9mmHg at the end of study, p=0.051).

Conclusion: In persons with type 2 DM, the daily consumption of bread enriched with 3 g beta-glucan from oat leads to a significant reduction of total-Cholesterol and LDL-Cholesterol within 3 weeks.

0797

Vinegar reduces postprandial glycaemia in patients with type 2 diabetes when added to a high glycaemic index (but not a low glycaemic index) carbohydrate-rich meal

S. Liatis¹, S. Grammatikou¹, K. A. Pouliou¹, D. Perrea², N. Apostolopoulos¹, E. Diakoumopoulou¹, N. Katsilambros³;

¹First Department of Internal Medicine, Athens University Medical School Laiko Hospital, ²Laboratory of Experimental Surgery and Surgical Research, Athens University Medical School Laiko Hospital, Greece.

Background and Aims: Previous studies have shown that the addition of vinegar in a carbohydrate-rich meal lowers glucose and insulin responses in both healthy individuals and patients with type 2 diabetes. The mechanism remains virtually unknown.

Aim of the present study was to examine the effect of vinegar in relation to the type of carbohydrate (CHO) used in the meal

Materials and Methods: 16 patients with mild type 2 diabetes (treated either with diet alone or with metformin \leq 850 mg daily, mean age 59.5 \pm 9.15 years, mean HbA_{1c}: 6.2 \pm 1.05%) participated in the study and were divided into two equal groups, matched for age, sex and HbA_{1c}. Patients in the first group (group A) were given a high-glycaemic index (GI) meal (mashed potatoes plus low-fat milk: CHO 52g, proteins 13g and fat: 2g) on two different days, with and without the addition of vinegar (20ml, acidity 6%) respectively. In the second group (group B), patients were given an isocaloric meal with the same nutrient composition but a low GI (whole grain bread plus lettuce plus low-fat cheese), using the same protocol (with and without vinegar). Postprandial serum glucose and insulin values were measured every 30 minutes for a total period of 3 hours

Results: In group A (high GI meal), incremental area under the curve (iAUC) of glucose after meal ingestion was lower after the addition of vinegar (3574.75 \pm 1628.32 mg min/dL vs. 6300.25 \pm 3965.04 mg min/dL, P=0.04). iAUC of insulin was also reduced but the difference was of marginal statistical insignificance (2455.16 \pm 1097.93 μ U min/ml vs. 3573.68 \pm 2023.74 min/ml, P=0.07). In group B, the addition of vinegar did not affect the iAUC of either glucose (6594.37 \pm 1516.85mg min/dL with vinegar vs 7036.87 \pm 2103.81 mg min/dL, without vinegar, P=0.69) or insulin (with: 4680.66 \pm 1295.76 μ U min/mL vs. without: 5267.99 \pm 2202.63 μ U min/mL, P=0.38).

Tab. 1

Variable	Controls (n=10)		Flaxseed oil (n=20)		Fish oils (n=20)	
	Baseline	After 6 weeks	Baseline	After 6 weeks	Baseline	After 6 weeks
Ankle-brachial index, right	1.06 \pm 0.09	1.08 \pm 0.09	1.05 \pm 0.10	1.07 \pm 0.09	1.08 \pm 0.07	1.08 \pm 0.07
Ankle-brachial index, left	1.03 \pm 0.12	1.05 \pm 0.10	1.04 \pm 0.12	1.06 \pm 0.12	1.08 \pm 0.09	1.09 \pm 0.07
Mean arterial pressure, brachial	53.3 \pm 3.3	53.0 \pm 2.7	53.8 \pm 3.6	53.7 \pm 1.7	53.4 \pm 2.5	52.7 \pm 1.8
Mean arterial pressure, ankle	43.0 \pm 2.3	42.7 \pm 3.3	40.4 \pm 4.6	41.6 \pm 3.5	41.6 \pm 3.0	40.7 \pm 4.5
Arterial stiffness, right	42.0 \pm 15.4	39.7 \pm 11.7	47.3 \pm 20.9	47.6 \pm 17.9	44.8 \pm 23.2	41.3 \pm 14.0
Arterial stiffness, left	43.5 \pm 16.7	43.4 \pm 16.7	59.3 \pm 23.7	45.8 \pm 24.8*	47.9 \pm 25.3	43.8 \pm 13.6*
Pulse wave velocity brachial, right	1816.5 \pm 405	1767.7 \pm 272	1791.3 \pm 342	1827.5 \pm 260	1863.1 \pm 321	1817.6 \pm 225
Pulse wave velocity brachial, left	1849.8 \pm 411	1882.6 \pm 446	1918.0 \pm 375	1836.1 \pm 309	1898.2 \pm 369	1849.2 \pm 225

* P<0.05

Conclusion: We conclude that the addition of vinegar reduces postprandial glycaemia in patients with type 2 diabetes only when it is added to a high GI meal. Thus, vinegar may be useful for the reduction of postprandial hyperglycemia in patients with diabetes

0798

Lard oil compared to olive oil impaires insulin-dependent glucose uptake in skeletal muscle

J. Lee¹, S. Park², E. Park¹, J. Lee², E. Kang², C. Ahn², H. Lee², B. Cha²;
¹College of Medicine, Brain Korea 21 Project for Medical Science, ²College of Medicine, Internal Medicine, Yonsei University, Seoul, Republic of Korea.

Background and Aims: Otsuka Long Evans Tokushima fatty (OLETF) rat is an animal model of human type 2 diabetes mellitus. Resistance of skeletal muscle to insulin-dependent glucose uptake and phosphorylation is an early step in the development of type 2 diabetes. The objective of this study is to confirm the difference in insulin signaling pathway between lard oil and olive oil.

Materials and Methods: Twenty nine-weeks-old OLETF rats were divided into 3 groups (n=10/group) : normal diet (N), high fat diet with lard oil (L) and high fat diet with olive oil (O). Rats were fed a diet for 3 weeks. We confirmed messenger RNA (mRNA) levels of insulin receptor substrate 1 (IRS-1) and insulin receptor substrate 2 (IRS-2) by reverse transcriptase-polymerase chain reaction (RT-PCR) in skeletal muscle (SKM). Protein levels of phosphatidylinositol 3-kinase (PI3K), extracellular-signal-regulated protein kinase (ERK1/2) and glucose transporter 4 (GLUT4) were analysis by western-blotting in SKM.

Results: The mRNA expression of IRS-1 was significantly increased in group O as compared with group L (p<0.05). By contrast, the expression of IRS-2 was significantly increased in group L as compared with group O (p<0.05). Insulin mediated PI3K and GLUT 4 translocation were significantly increased in group O but not in group L (p<0.05). Group L showed significantly increased phosphorylation of PI3K and ERK1/2 as compared with group O (p<0.05).

Conclusion: These observations show that diets with different fatty acid composition, lard oil versus olive oil, have important differences in insulin signaling pathway. Unlike group O, which show stimulates glucose uptake of SKM via IRS-1, PI3K and GLUT4 translocation pathway, less translocation of GLUT4 was observed in group L. Interestingly, in group L, IRS-2, PI3K and ERK signaling axis were induced by lard oil. These suggest that lard oil induced insulin resistance impaired with IRS-1 dependent glucose uptake but not in olive oil in SKM.

0799

Omega-3 fatty acid supplementation and vascular functions in type 2 diabetes

A. Gupta¹, M. Matta², N. Singh², R. Gupta³;

¹Diabetes, Jaipur Diabetes Research Centre,

²Foods and Nutrition, University of Rajasthan,

³Medicine, Monilek Hospital and Research Centre, Jaipur, India.

Background: Omega-3 fats are derived from marine (fish oils) and vegetable (flaxseed oil) sources and are useful to prevent diabetes complications.

Influence of short term supplementation on vascular function in type 2 diabetes is not well studied.

Methods: In fifty patients (age 53.3 ± 7.9) with stable type 2 diabetes (HbA_{1c} 8.0 ± 1.7) we performed a randomised trial to evaluate vascular effects of supplementation of fish oil (300 mg, $n=20$) or flaxseed oil (1000mg, $n=20$) containing eicosapentanoic acid 180 mg and docosahexanoic acid 120 mg. 10 age and sex matched controls were taken for comparisons. Vascular functions were measured using Vascular Profiler-1000* and included measurements of blood pressure, ankle-brachial index, arterial stiffness, and pulse wave velocities in upper and lower limbs at baseline and after 6 weeks of supplementation.

Results: The mean body mass index (27.4 ± 4.3 kg/m²), waist (93.2 ± 11.4 cm), waist-hip ratio (0.92 ± 0.09), serum cholesterol (188.7 ± 45.3 mg/dl), triglycerides (153.0 ± 79.3 mg/dl), HDL cholesterol (45.1 ± 7.5 mg/dl) levels and dietary intake of calories (1755 ± 449 /day), total fats (79.5 ± 24.1 g/day), saturated fats (24.5 ± 8.0 g/day), monounsaturated fats (23.2 ± 8.2 g/day), polyunsaturated fats (28.5 ± 11.1 g/day), and omega-3 fats (9.4 ± 4.8 g/day) were not significantly different in the three groups. Vascular functions are shown in the table. There is a significant decline in arterial stiffness in left arm in flaxseed and fish oil supplementation groups. (Tab. 1)

Conclusions: Omega-3 fatty acids supplementation using either marine or vegetable sources causes a significant decrease in arterial stiffness in type 2 diabetes subjects.

0800

A fenugreek seed extract selectively reduces fat consumption in healthy volunteers and overweight subjects

H. Chevassus^{1,2}, A. Farret^{1,2}, N. Molinier¹, E. Renard³, P. Petit⁴, F. Galtier^{1,2},
¹Clinical Investigation Centre, CHU Montpellier, ²Cic 0001, Inserm, Montpellier, ³Maladies Endocriniennes, CHU Montpellier, ⁴UMR 5232, Université Montpellier I / CNRS, Montpellier, France.

Background and Aims: Fenugreek (*Trigonella foenum-graecum* L.) is an herbaceous Mediterranean plant, whose seeds are traditionally assumed to have nutritive properties. A number of pharmacological and clinical studies have shown blood glucose and plasma lipid lowering properties of either the seed itself, seed extracts or purified components. Several animal studies have demonstrated modifications of the feeding behavior after repeated treatment with seed extracts. However, no clinical study has previously investigated an action on eating behavior and energy intake in human.

Materials and Methods: Healthy volunteers: 12 healthy men aged 19 – 26, mean BMI 22.5 kg/m² (20.0 – 25.0), participated in a double-blind randomised placebo-controlled trial of two different doses (588 or 1176 mg/day) of a fenugreek seed extract, according to a latin square design. The three 14-day treatment periods were separated by a 14-day washout. Food intake was assessed using a 3-day record (last 3 days of each period). On the last day of each period the following evaluations were performed: weight, lipid profile, blood glucose and insulin and visual analog scales for appetite and satiety before and 30, 60, 90, 120, 150, 180, 210 and 240 min after a standardised meal. Overweight subjects: 39 overweight men aged 18 – 59, mean BMI 27.3 ± 0.2 kg/m² (24.9 – 29.4), participated in a 6-week double-blind, parallel, randomised placebo-controlled trial of 1176 mg/day of a fenugreek seed extract. Dietary intake was assessed twice (prior to treatment start and during the last week of treatment) using a 7-day record checked by a trained dietician. On the last day of treatment the following evaluations were performed: weight, bio-impedance analysis, visual analog scales for appetite and satiety before and 30, 60, 90, 120, 150, 180, 210 and 240 min after a standardised meal, and spontaneous food intake during an *ad libitum* test meal.

Results: Spontaneous fat intake was significantly decreased with fenugreek seed extract treatment, both for healthy volunteers (mean \pm SEM : 3.73 ± 0.29 vs. 4.51 ± 0.28 MJ/d, i.e. -17.3% , $p = 0,038$) and for overweight subjects (3.41 ± 0.20 vs. 3.77 ± 0.19 MJ/d, i.e. -9.5% , $p = 0,032$ for energy expenditure-adjusted fat intake). There was a trend towards a decrease in total spontaneous energy intake for healthy volunteers (9.97 ± 0.76 vs. 11.29 ± 0.75 MJ/d, i.e. -11.7% , $p = 0,1$) but not for overweight subjects (8.73 ± 0.52 vs. 9.16 ± 0.44 , NS). Basal plasma insulin/blood glucose ratio was decreased in overweight subjects treated with fenugreek seeds extract (0.891 ± 0.088 vs. 1.60 ± 0.095 mUI/mmol, $p = 0.044$). There was no difference concerning weight, body composition, appetite and satiety scores, plasma lipid profile, post prandial glucose and insulin values and spontaneous food intake during the *ad libitum* test meal.

Conclusion: These 2 clinical studies in healthy and overweight subjects yielded concordant results showing that a short-term administration of a fenugreek seeds extract modifies food consumption, with a specific reduction in fat intake. These results constitute a novel information which contrasts with the current use of fenugreek seeds and opens new perspectives for clinical applications.

The effect of dietary choice on body size and insulin resistance in children: a longitudinal study

A. N. Jeffery, B. S. Metcalf, J. Hosking, D. S. Gardner, L. D. Voss, T. J. Wilkin;

Department of Endocrinology and Metabolism, Peninsula Medical School, Plymouth, United Kingdom.

Background and Aims: Rates of childhood obesity are increasing but few longitudinal studies have examined the contribution of dietary choice. We examined the impact of dietary choice on the development of obesity and insulin resistance in healthy young children.

Materials and Methods: Participants were from The EarlyBird Diabetes Study (140 boys and 111 girls). This prospective, non-intervention, cohort study is following healthy children from age 5 to 16, assessing factors leading to insulin resistance. Annual measures from 5 to 9 years: BMI(sds), sum of 5 skinfolds (SSF), insulin resistance (HOMA-IR). Dexa % abdominal fat at 9 years. Food frequency questionnaires completed annually by a parent and three variables calculated (number of days consumed per week expressed as a percentage of maximum possible frequency): HS (composite of 6 high sugar foods and drinks including cola), HF (11 high fat foods), FV (3 foods: fruit, vegetables, salad). No food was assigned to more than one group.

Results:

1. Dietary reports were consistent year-on-year (in each food group year-on-year correlation $r=0.3$ – 0.5).
2. From 5–9 years, BMI(sds) rose (0.34 to 0.48 , $p=0.007$); SSF rose (3.98 cm to 5.62 cm, $p<0.001$) yet frequency of HF fell (25.5% to 22.1% , $p<0.001$) and HS fell (54.4% to 49.3% , $p<0.001$).
3. Frequency of FV remained unchanged (11.4% to 11.6% , $p=0.5$) and was not associated with BMI or SSF in either gender, or with HOMA-IR in boys ($r<0.1$). In girls at 5y and 6y, FV was positively associated with HOMA-IR ($r=0.21$, 0.22 , $p<0.05$).
4. Frequency of HF correlated with HS foods at each age ($r=0.2$ – 0.6 , $p<0.01$).
5. BMI at 8 and 9y was inversely related to HF in both genders ($r=-0.18$ to -0.28 , $p<0.05$).
6. BMI and SSF were inversely related to HS at every age, significantly so in girls ($r=-0.18$ to -0.29 , $p<0.05$).
7. HS at 5y predicted lower BMI, SSF, HOMA-IR and % abdominal fat at 9y in girls ($r=-0.26$, -0.30 , -0.24 , -0.26 , $p<0.05$ respectively).

Conclusion: Parental reports regarding children's dietary habits are consistent year-on-year. Body size appears unrelated to frequency of consumption of healthy foods. Unexpectedly, children whose diets are highest in fat and sugar seem to be the leanest and metabolically healthiest. This could be due to parents underestimating their child's intake of high fat and sugar foods, but it is also possible that meal size is more important than content in childhood obesity.

The effect of exercise training on lipopolysaccharide-induced cardiovascular dysfunction of type 1 diabetic rats

C. H. Hung¹, C. N. Chang¹, Y. W. Chen², J. T. Cheng³;

¹Department of Physical Therapy, National Cheng Kung University,

²Department of Medical Research, Chi-Mei Medical Center, ³Department of Pharmacology, National Cheng Kung University, Tainan, Taiwan.

Background and Aims: Diabetic patients usually develop serious infections such as sepsis which is often accompanied with severe hypotension. However, heat shock protein 72 (HSP72) overexpression could reduce the mortality rate and organ damage in septic shock and attenuate hemodynamic alterations due to lipopolysaccharide (LPS). Furthermore, through exercise training, HSP72 can be induced in various organs of normal rats. We validated the hypothesis that exercise preconditioning may induce the overexpression of HSP72 in the heart and nucleus tractus solitarius (NTS) of the brain and confer cardiovascular protection during endotoxemia in streptozotocin-induced diabetic rats.

Materials and Methods: Adult male Wistar rats were randomly assigned to one of the following groups: sedentary normal rats, sedentary diabetic rats, and diabetic rats with exercise training. The trained animals ran on a treadmill 5 days/week, 30–60 min/day with an intensity of 1.0 mile/hour over a 3-week period. After 24 hrs from the last training session, we compared the temporal profiles of mean arterial pressure, heart rate, cardiac output, stroke volume, total peripheral vascular resistance, and serum tumor necrosis factor-alpha level of urethane-anesthetized rats in all groups after injection of LPS. In addition, the HSP72 expressions in heart and NTS of the brain were determined in different groups by western blot with monoclonal anti-HSP72 antibody.

Results: The HSP72 expression in heart and NTS were significantly greater in diabetic rats with exercise training than in those without exercise training (7.5 ± 1.2 fold and 3.1 ± 0.9 fold, respectively). After administration of LPS, the survival times were significantly longer in diabetic rats with exercise training than those in sedentary diabetic rats (489.17 ± 23.47 min versus 316.40 ± 39.55 min, $P = 0.0004$). Tumor necrosis factor-alpha level in serum were significantly lower in diabetic rats with exercise preconditioning than those in diabetic rats without exercise training (78.89 ± 56.30 pg/ml versus 1080.30 ± 489.49 pg/ml, $P = 0.007$). In addition, prior exercise training could significantly diminish cardiovascular dysfunction in diabetic rats during endotoxemia.

Conclusion: Exercise preconditioning could overexpress HSP72 in the heart and NTS, confer significant protection against a high mortality rate, and improve cardiopulmonary function of streptozotocin-induced diabetic rats during endotoxemia.

Impact of diabetic status in the six-minute-walk-test

E. Marin, R. Fabregate, O. Sánchez, M. Fabregate, S. Redondo, G. Nuñez de Arenas, N. de la Torre, J. Sabán-Ruiz;

Endothelial Pathology Unit, Ramon y Cajal Hospital, Madrid, Spain.

Introduction: Modern systems allow for the evaluation of cardiac and vascular adaptations to body demands of increased tissue blood flow during exercise, particularly at the muscle.

Aims: To evaluate the haemodynamic response and recovery to a standardized exercise test in diabetic and non-diabetic patients.

Methods: N=21 patients, 40–80 years (56.10 ± 2.71), 15/6 male/female ratio, 10 hypertensives, and 5 smokers. They were distributed in two groups: Group A (non-diabetic group): n=14, aged 41–71 (59.89 ± 5.18), 8/4 male/female ratio; Group B (diabetic group): n=9, aged 40–80 (59.89 ± 5.18), 7/2 male/female ratio, 2 type 1, 7 type 2. Both groups were comparable by age, and hypertension and smoking status. Pulse Rate (PR)(beats/min), Systolic and Diastolic Blood Pressure (SBP, DBP) (mm Hg), Pulse pressure (PP=SBP-DBP). Large (C1) and small (C2) artery elasticity index (ml/mmHg \times 100), Systemic Vascular Resistance (SVR)(dyne.sec.cm⁵), Total Vascular Impedance (TVI)(dyne.sec.cm⁵). Stroke Volume (SV)(ml/beat); Stroke Volume Index (SVI)(ml/beat/

m²). Cardiac Output (CO)(L/min). Cardiac Output Index (COI)(L/min/m²). Cardiac Ejection Time (msec)(CET). HDI/PulseWave CR-2000. The Proflor test was performed at baseline and after two, five and ten minutes during recovery time. It was not possible to record data at all three different moments for all patients in the control group. Six-minute-walk (SMW) test: constant slope (7%) and marching speed were equivalent in groups A and B (4.67 ± 0.50 vs 4.78 ± 0.53 mph, respectively; not statistically significant). Statistical analysis: Kolmogorov-Smirnov, Mann-Whitney and Wilcoxon Signed Rank non-parametric tests. Independent and Paired Student's T tests.

Results: 1- After two minutes post-SMW: both groups showed an increase in PR compared to baseline (Group A: $p=0.017$)(Group B: $p=0.038$) and a decrease in SVI (A: $p=0.032$)(B: $p=0.012$); in A, but not in B, both CO and COI showed significant increases [($p=0.033$) and ($p=0.017$), respectively]. Besides, in B, blood pressure levels increased (SBP: $p=0.038$)(DBP: $p=0.012$) as well as PP levels ($p=0.05$), whereas CET decreased ($p=0.021$). 2- After five minutes: significant haemodynamic changes were present only in Group A: increase in PR ($p=0.010$), CO ($p=0.041$), and COI ($p=0.021$), and decrease in SVR ($p=0.021$) and SVI ($p=0.028$). 3- After ten minutes: in group A there was an increase in PR ($p=0.012$), and a decrease in SVR ($p=0.028$). In diabetic patients, no differences were found after ten minutes with respect to baseline.

Conclusions: 1- Two minutes after moderate exercise, only the non-diabetic group shows increases in CO and COI. On the contrary, only the diabetic group has significant increases in blood pressure and pulse pressure, and decreases in CET. 2- After five minutes, significant differences with respect to baseline were observed in the non-diabetic group compared to the diabetic group in terms of PR, SVR, CO, COI, SVI. 3- After 10 minutes of moderate exercise, the diabetic group shows different haemodynamic behaviour compared to that of the non-diabetic group, with an increase in PR and a decrease in SVR.

Relationship of oxygen consumption with beta cell function and insulin sensitivity in IGT and newly diagnosed type 2 diabetic subjects

Q. Nahar¹, M. O. Faruque², M. A. Rashid², M. H. Rahman³, K. Sultana¹, S. Kasem¹, A. K. Azad Khan⁴;

¹Dept of Human Nutrition, ²Biochemistry & Cell Biology,

³Dept of Endocrinology, ⁴Health Economics Unit, BIRDEM, Dhaka, Bangladesh.

Background and Aims: Physical fitness is a strong independent determinant of insulin sensitivity and it is determined by the measurement of oxygen consumption worldwide. The present study was planned to explore the relationship of oxygen consumption with Beta cell function and insulin sensitivity in IGT and newly diagnosed type 2 diabetic subjects.

Materials and Methods: A total number of 188 subjects were recruited of which 34 were Control, 92 were isolated IGT, 27 were combined IFG-IGT and 35 were type 2 DM. Plasma insulin was measured by chemiluminescence based immunoassay technique. Insulin secretory capacity HOMA B (%) and insulin sensitivity HOMA S (%) were calculated from fasting glucose and fasting insulin values by homeostasis model assessment (HOMA) using HOMA-CIGMA software. For the estimation of oxygen consumption subjects were requested to run on a treadmill for 6 min at their maximum speed and the burning calorie including the weight of the subjects were used in a standard formula.

Results: BMI and waist-hip ratio did not differ among the Controls, IGT, IFG-IGT and DM subjects. DM subjects had significantly ($p<0.05$) higher neck circumference compared to controls. Significantly ($p<0.05$) higher TG and cholesterol levels were found in IGT and IFG-IGT subjects compared to controls. The data showed significantly ($p<0.05$) lower HOMA B in IGT [101 (29-288)], IFG-IGT [77 (25-121)] and DM [77 (27-161)] subjects compared to Controls [(112 (34-247))]. Insulin sensitivity (HOMA S) in diabetic subjects [100 (16-306)] was significantly ($p<0.05$) lower compared to controls [122 (48-308)]. Oxygen consumption (ml/kg/min) in DM subjects [13.8(8.8-18.8)] was significantly ($p<0.05$) lower compared to Controls [17.8(8.8-33.5)]. The levels of oxygen consumption in IGT [16.2(8.2-33.5)] and IFG-IGT [16.2(9.5-28.2)] did not differ with Controls or DM subjects but a lowering tendency of oxygen consumption was observed in both IGT and IFG-IGT subjects compared to Controls. In regression analysis it was found that oxygen consumption was negatively associated ($r=-0.71$, $p=-0.08$.) with fasting serum glucose concentration in diabetic subjects. Oxygen

consumption level in IGR (IFG and IFG-IGT) subjects was negatively associated ($r=-0.29$, $p=0.01$) with HOMA B and it was positively associated ($r=0.27$, $p=0.02$) with HOMA S.

Conclusion: Diabetes mellitus is associated with decreased oxygen consumption. In hyperglycemic condition oxygen consumption is positively correlated with insulin sensitivity.

The importance of light intensity physical activity in sedentary individuals with a family history of type 2 diabetes

U. Ekelund, S. J. Griffin, N. J. Wareham;

Institute of Metabolic Sciences, MRC Epidemiology Unit, Cambridge, United Kingdom.

Background and Aims: Increasing levels of energy expenditure devoted to physical activity (PAEE) is likely to be important in the prevention of type 2 diabetes, especially in those with a family history of the disease, as the risk is further magnified by physical inactivity. It is not clear whether the variation PAEE is due to the variation in light, moderate or vigorous intensity physical activity. Identifying the sub-dimensions of activity that contributes the most to the variation in PAEE is essential when promoting physical activity and when designing interventions.

Materials and Methods: Participants ($n=258$) were selected from the ProActive trial, which is a randomised controlled trial of the efficacy of a family-based intervention to increase physical activity among individuals at high risk of diabetes. Physical activity energy expenditure was measured by individually calibrated heart rate monitoring and body movement was simultaneously measured by accelerometry. We analysed whether the time estimates (time spent sedentary, light, moderate and vigorous intensity activity) from accelerometry contributed to the explained variance in PAEE by linear regression analysis.

Results: PAEE was significantly correlated with time spent at light intensity physical activity ($r = 0.17$, $P = 0.007$) and with time spent at moderate intensity activity ($r = 0.20$, $P < 0.001$). In multiple regression analysis, sex, age and body weight explained 13.7% (adjusted R^2) of the variance in PAEE. In our multivariate model, fraction of time spent at light ($\beta = 0.015$, $P < 0.001$) and at moderate intensity physical activity ($\beta = 0.038$, $P = 0.026$), but not fraction of time spent sedentary ($\beta = 0.0002$, $P = 0.96$) or at vigorous intensity activity ($\beta = 0.05$, $P = 0.50$) contributed to the explained variance in PAEE, with a full model of 20.6% (adjusted R^2). The magnitude of association between light intensity activity and PAEE was almost twice as strong as that between moderate intensity and PAEE.

Conclusion: Time spent at light and at moderate intensity physical activity, but not vigorous intensity activity, significantly contributes to an elevated PAEE. Therefore, incorporating activities of light and moderate intensity into daily life, such as walking, bicycling and household and garden work, which contributes to an elevated PAEE, is likely to be important in the prevention of type 2 diabetes and related metabolic disorders.

Prevalence of cardiovascular risk factors and physical capacity in cardiac rehabilitation: is there a difference between diabetic and non diabetic patients?

P. R. Blanc¹, A. Boussuges², S. Chopra¹, X. Debussche³;

¹Cardiac Rehabilitation, Sainte Clotilde, Réunion,

²IMNSSA, Mediterranean University, Toulon Marseille, France,

³Diabetology, Felix Guyon Hospital, Sainte Denis, Réunion.

Background and Aims: Patients with type 2 diabetes mellitus have typically elevated risk factors and low fitness. We compared the prevalence of cardiovascular risk factors and physical capacity between diabetic patients with coronary heart disease (CHD) and non diabetic patients (NDP) with CHD admitted in a 6-week multidisciplinary cardiac rehabilitation program.

Materials and Methods: 351 type 2 diabetic patients (DP) were compared with 480 non diabetic patients (NDP). DP and NDP were not different in age

(57 vs. 57 years), sex ratio (19% vs. 16% women) and type of coronary event. Sixty two percent of DP was treated by insulin. Baseline HbA_{1c} was greater than 6.6% in 63% of cases, retinopathy and microalbuminuria were detected in respectively 30% and 36% of subjects.

Results: Compared with NDP, DP had a higher prevalence of hypertension (70% vs. 45% $-p<0.001$), hypercholesterolemia (80% vs. 66% $-p<0.001$), hypertriglyceridemia (41% vs. 32% $-p=0.01$), obesity (33% vs. 15% $-p<0.001$) and excess abdominal fatness quantified by waist circumference measurement (98.5 vs. 93.7 cm in women, 97.5 vs. 95 cm in men $-p<0.05$). Furthermore, DP had a higher score (HAD scale) for depression (6.52 vs. 5.74 $-p<0.027$) with a higher prevalence of depression (38.1% vs. 30.5% $-p<0.05$). Anxiety (HAD scale) and stresses were similar in the two groups. Patients who continue to smoke were less frequent in DP compared with NDP (9.8% vs. 16% $-p=0.007$). At baseline, DP had a lower VO₂ peak (14.4 vs. 16.7 ml/kg/min $-p<0.001$) at the cardiorespiratory exercise testing, a lower time of anaerobic threshold (1.60 vs. 1.76 min $-p<0.001$), a lower distance at the 6 min walk test (325 vs. 400 m $-p<0.05$) and a lower, but non statistically significant, hand strength at the hydraulic dynamometer (34 vs. 37 KGs for right hand 33 vs. 35 KGs for left hand), when compared with NDP. At the end of the exercise program, the entire patients achieved significant improvements in physical capacity. Improvements were statistically similar in DP and NDP: peak VO₂ (+25% vs. +27%), time of anaerobic threshold (+70% vs. +70%) and distance at the 6 min test (+32% vs. +34 %). The comparison between DP and NDP after exercise training demonstrated lowers VO₂ peak (18 vs. 21.3 ml/kg/min $-p<0.001$), time of anaerobic threshold (2.7 vs. 3 min $-p<0.001$), and distance at the 6 min walk test (429 vs. 530 m $-p<0.05$) in DP.

Conclusion: In our study, DP with CHD had a higher cardiovascular risk including hypertension, dyslipidemia, abdominal fatness and depression as well as a lower physical capacity compared with NDP. The entire patient group demonstrated improvements in exercise capacity after rehabilitation. However, in DP, physical capacity was lower at the beginning of the program and remained significantly altered after the training. This study emphasizes the need to target DP for an aggressive and multidisciplinary program of risk factor management, including exercise training and educational programs. Greater efforts to improve their outcomes are needed.

0807

Influence of combined exercise training on indices of obesity, diabetes and cardiovascular risk in diabetes type 2 patients

P. Calders¹, S. Lambers¹, K. Van Acker², C. Van Laethem¹;

¹Revalidatiewetenschappen en Kinesithérapie Gent, Arteveldehogeschool, Belgium, ²Endocrinologie, AZ Sint-Jozef, Bornem, Belgium.

Background and Aims: The influence of combined exercise training (strength and endurance training) on indices of obesity, diabetes and cardiovascular risk in type 2 diabetes patients was investigated compared to endurance training.

Materials and Methods: Forty six type 2 diabetes patients (female: 17, male: 29) were randomly assigned to three experimental groups (COM: combined exercise training ($n=17$); END: endurance training ($n=18$) and C: control ($n=11$). Patients exercised for three months three times a week for 1 hour. Before and after the training period following parameters were assessed: 6 minute walk test (6MWT), muscular strength of upper limb (sum of 1 Repetitive maximum (1RM) of m. Biceps brachii and m. Triceps brachii) and lower limb (sum of 1RM of m. Quadriceps femoris and mm. Hamstrings), sit to stand test, length, weight, body mass index, body composition (fat mass), HbA_{1c}, glycemia, triglycerides, HDL, total cholesterol and quality of life (SF36).

Results: Comparing combination training to no training, combination training had significant higher results on the sit to stand test ($P<0,05$), 6 minute walk test ($p<0,05$), strength upper limb ($p<0,001$) and strength lower limb ($p<0,05$) compared to the control group. HbA_{1c} ($p<0,05$) (figure 1) and cholesterol ($p<0,01$) showed a significant decrease in the combination group and an increase in the control group. HDL increased in the combination group and decreased in the control group ($p<0,05$) (figure 2). Comparing the endurance group to the control group, the endurance group had significantly higher results on the 6 minute walk test ($P<0,01$) compared to the control group. Comparing combination training to endurance training, the combination group had significantly higher results on strength upper ($p<0,005$) and lower limb ($P<0,05$). The evolution of SF-36 items was not significantly different between the 3 groups.

Conclusion: Combined exercise training had significant effects on indices of obesity, diabetes and cardiovascular risk in type 2 diabetic patients. Compared to endurance training, combined exercise gave a tendency towards better results.

We thank Dr. Luc Feyen, Mrs. Erna Feyen (general practice, Sas-Van-Gent, Holland), Mrs. Greet Vergauwen (AZ Sint-Jozef, Bornem, Belgium) for selecting and encouraging the participants and for their local support of this project

Educational intervention in a group of half-marathon runners with type 1 diabetes (The DIATLETIC team)

S. Murillo¹, R. Arana², M. Subirà¹, A. Novials¹;

¹Institute of Diabetes, Fundació Sardà Farriol, Barcelona,

²Fundación para la Diabetes, Madrid, Spain.

Background and Aims: Little is known about the strategies that diabetic athletes use in relation to insulin and carbohydrate dosage and theirs

glycemic fluctuations in a half-marathon competition. The aim of this study is to investigate the self-management with regard to a half-marathon race in patients with type-1 diabetes (T1DM) and the influence of an educational intervention.

Materials and Methods: 14 well controlled T1DM men (age 35.6±7.4 years, IMC 23.9±2.3kg/m²) took part in the study. They were amateur athletes belonging to the DIATLETIC diabetes team. All the participants were taking insulin in multiple bouts a day and 3 of them were using an insulin pump.

The day before the race, they completed a questionnaire about their usual insulin dosage and carbohydrate intake (in reference to those days without exercise practice). These data were collected again a few days after, in reference to the half-marathon day. Moreover, values of glycemic control were gathered by means of capillary blood analyses at the following points: start, km 5, km 10, km 15, arrival, 2 hours post-exercise (lunch), pre-dinner, 3 a.m. and pre-breakfast of the following day. All these athletes took part in the same half-marathon the following year. Again, data about insulin dosage, carbohydrate intake and glycemic control were collected, using the same protocol as in the previous year. Furthermore, the day before the competition, athletes were informed about the results obtained in the previous year in an educational session of 30 minutes duration. Results obtained in the first edition (FE) were compared with those of the second edition (SE).

Results: On average, participants realised a reduction in the total units of insulin of 14.13% in the FE and of 13.13% in the SE. This reduction was greater in the delayed action or basal insulin in the FE than in the SE (5.1±4.6 units vs. 4.63±7.9 units respectively, p<0.05). Also, the reduction of short action insulin in the breakfast before the competition was greater in the FE than in the SE (2.0±1.3 units vs. 1.07±0.47 units respectively, p<0.05). We did not find significant differences in the insulin doses used during the rest of the day. On the other hand, all runners needed to take supplements with carbohydrates to avoid hypoglycaemia during the competition. In comparison to their usual breakfast, they added 15.0±6.9g (p<0.05) in the FE and 18.0±4.9g (p<0.05) in the SE. As well, athletes needed additional carbohydrates during the course, this quantity being greater in the SE than in the FE (59.1±11.2g vs. 49.0±16.4g respectively, p<0.05). These carbohydrates were taken preferably as isotonic beverages or glucose gels. Before the competition, the mean value of blood glucose was of 254.6±121mg/dl in the FE and of 187.3±57.9mg/dl in the SE, going down to 167.7±67mg/dl in the FE and until 147.74±75.5 in the SE in the finish line. The percentage of values over 300 mg/dl was of 22.2% in the FE and of 5.0% in the SE (p<0.05) and below 100mg/dl was of 33.3% in the FE and of 15% in the SE (p<0.05).

Conclusion: Adaptations to a half-marathon competition in T1DM patients imply a reduction in the insulin doses and an increase in carbohydrate intake. However, it seems to be more successful if these carbohydrates extra are taken during the competition. Educational intervention in T1DM athletes group is an effective tool to improve glycemic control reducing glycemic fluctuations in a half-marathon competition.

Long-term brisk walking vs medical fitness in type 2 diabetes

S. F. E. Praet¹, L. S. J. van Rooij¹, L. J. M. Boonman-de Winter²,

A. P. Wijnvliet¹, T. Enneking³, L. J. C. van Loon¹;

¹Movement Sciences, Nutrition and Research Institute Maastricht,

²SHL Contract Research, Stichting Huisartsen Laboratorium, Etten-Leur,

³General Practitioner Group De Keen, Health Center De Keen, Etten-Leur, The Netherlands.

Background and Aims: Structured exercise is considered an important cornerstone to achieve good glycemic control and improve cardiovascular risk profile in type 2 diabetes (T2D). However, long-term adherence to medical fitness (MF) programs is generally poor, while costs are high. As such, brisk walking (BW) may be an attractive alternative, however, its long-term efficacy as an addendum to a primary health care based diabetes care program is unknown. Therefore, the effects of 1 yr BW versus 1 yr MF in T2D patients in a primary health care setting was studied.

Materials and Methods: 92 T2D patients (59.9±/− 0.9 yrs) were randomised to structured exercise, consisting of either 3 times a week 45-60 min BW (n=43) or MF (n=49). Changes in metabolic profile, blood pressure regulation, physical fitness and BMI were monitored 12 months after start of the exercise intervention.

Results: After 1 yr, 39.1% of the participants (BW:n=17, MF:n=19, ns) were still actively participating, while only 25% of the participants adhered to >70% of the exercise sessions. Besides motivational problems, co-morbidities, such as overuse injuries and subclinical osteoarthritis appeared an important reason for our relatively high drop out rate. Intention-to-treat analysis showed significant improvements in blood pressure regulation, HbA1c, TChol/HDL-C ratio, LDL-C and BMI, while fasting glucose tended to improve as well ($p=0.09$). Post-hoc analyses revealed that glycemic control at baseline (HbA1c_{BL}) correlates negatively with the change in HbA1c (Pearson's $R=-0.39$, $p0.05$). Table 1 shows the results of this subgroup analysis. Overall, metabolic and cardiovascular improvements in BW were not statically different from MF (ANOVA, $p>0.05$).

Conclusion: Long-term structured exercise interventions, as addendum to primary health care based diabetes care programs, improve cardiovascular risk profile, especially in patients with suboptimal glycemic control. Long-term program adherence may improve if the exercise intervention is tailored to the physical capabilities of the individual patient. (Fig. 1)

Regular use of pedometers does not enhance beneficial outcomes in a physical activity intervention study in type 2 diabetesM. R. Bjørgaas^{1,2}, J. T. Vik³, T. Stølen⁴, S. Lydersen², V. Grill^{2,1};¹Department of Internal Medicine, University Hospital of Trondheim, Trondheim, Norway, ²Department of Cancer Research and Molecular Medicine, Norwegian University of Science and Technology, ³Department of Physical Medicine and Rehabilitation, University Hospital of Trondheim, ⁴Department of Circulation and Medical Imaging, Norwegian University of Science and Technology, Trondheim, Norway.**Background and Aims:** Use of pedometer is proposed to increase walking and improve physical fitness. We investigated whether use of pedometer can enhance beneficial outcomes in a physical intervention study in type 2 diabetes (T2DM).

Tab. 1

Clinical and laboratory variables at Visit 1 in Pedometer-group, Non-Pedometer-group and Dropouts

	Pedometer group (n=23)	Non-Pedometer group (n=25)	Dropouts (n=22)
Age (years)	56.4 (11.0)	61.2 (9.7)	57.7 (14.0)
Weight (kg)	94.8 (19.3)	95.2 (16.6)	94.3 (14.3)
BMI (kg/m ²)	31.2 (5.3)	31.5 (5.6)	31.0 (4.4)
FPG (mmol/l)	8.0 (1.6)	8.7 (2.6)	7.5 (1.9)
HbA _{1c} (%)	7.4 (1.1)	7.7 (1.4)	7.3 (1.1)
Insulin C-peptide (nmol/l)	1.1(0.5)	1.1(0.6)	1.3 (0.5)
Cholesterol (mmol/l)	5.0 (1.2)	5.0 (0.8)	4.8 (1.2)
HDL-cholesterol (mmol/l)	1.28 (0.38)	1.17 (0.32)	1.12 (0.24)
Triglycerides (mmol/l)	2.0 (1.0)	2.0 (1.0)	2.2 (1.2)
VO ₂ peak (l/min)	2.70 (0.70)	2.65 (0.88)	2.19 (0.60)
VO ₂ peak (ml/kg/min)	29.6 (8.3)	28.1 (7.5)	22.4 (5.3)

Materials and Methods: Seventy persons with T2DM were randomised to a pedometer- and a non-pedometer-group (P- and Non-P-group). All participants were seen by a nurse at a baseline visit (V1), after 1 month (V2), 3 months (V3) and 6 months (V4) and were then encouraged to increase walking. Subjects in the P-group additionally registered pedometer steps 3 days twice per month for 6 months. After V1 and V4 aerobic capacity (VO₂peak) was measured and subjects reported perceived physical fitness and activity. At V4 they were also asked if they could recognise any change in physical or mental state during the study.**Results:** Twenty-two subjects did not complete the study (dropouts). VO₂peak at V1 was lower in dropouts than in subjects who completed the study (completers) ($p=0.003$). In the P-group, the number of steps/day was 7628 (3715) (mean (SD)) in month 1 and 8021(3368) in month 6 and did not increase during the study ($p=0.65$). In completers, taken together, there was a decrease in body weight ($p=0.005$), HbA_{1c} ($p=0.034$), fasting blood glucose ($p=0.033$), triglycerides ($p=0.002$) and diastolic blood pressure ($p=0.048$) and an increase in HDL-cholesterol ($p=0.38$). Perceived improvement in physical and mental state correlated with improvement in VO₂peak ($r=0.45$, $p=0.008$ and $r=0.38$, $p=0.03$, respectively, $n=34$).**Conclusion:** Participation in the study entailed favourable changes in metabolic parameters. Improvement in VO₂peak correlated with perceived improvement in health. Use of pedometer did not increase walking, nor enhance beneficial outcomes. The low VO₂peak in dropouts indicates that persons most needy of physical exercise are the least compliant in exercise programmes. (Tab. 1)

PS 74 Hypoglycaemia

0811

Continuous glucose monitoring – what can we learn about nocturnal hypoglycaemia?G. Roman¹, M. Geamanu², N. Hâncu¹, A. Morosanu¹, M. Gribovschi³;¹Clinical Center of Diabetes, Nutrition, Metabolic Diseases, "Iuliu

Hatieganu" University of Medicine & Pharmacy,

²Clinical Center of Diabetes, Nutrition, Metabolic diseases, County Hospital,³Clinical Center of Diabetes, Nutrition, Metabolic diseases, "Motilor" Medical Center, Cluj-Napoca, Romania.**Background and Aims:** Glycaemic control is a major therapeutic objective in the clinical management of diabetes: glycaemic values should be as near as possible to normal and A1c in target. First step should be to normalise fasting glycaemia without nocturnal hypoglycaemia. Optimising glucose control raises the risk of hypoglycaemia, a barrier to glycaemic control. Continuous glucose monitoring (CGM) is an ideal tool to assess glycaemic values during the night and to individualise therapeutic interventions. The aim of the study was to assess and interpret the nocturnal hypoglycaemic values in correlation with glycaemic control and therapy, in patients with type 1 and 2 diabetes who had CGM.**Materials and Methods:** In persons with type 2 diabetes, 78 Medtronic CGM have been applied: age 55.6 ± 10.3 years, mean duration of diabetes = 8.6 ± 7.3 years, 22 women and in persons with type 1 diabetes, 46 CGM: median age 24 years, 39 women. Initial therapy: 2 on diet, 29 oral therapy, 47 on insulin. Among persons with type 1 diabetes, 13 were on insulin pump. The CGMS measures glucose every five minutes, 72 hours, around 850 glucose values. For this study only nocturnal values between 00–6 am have been considered. Hypoglycaemia has been considered at a glucose value below 72mg/dl, as threshold for hormonal counter regulation. Basal glucose value has been considered at 6.00 am.**Results:** The distribution according to A1c value was 36 patients $\leq 7\%$, 35: 7.1–8%, 22: 8.1–9% and 31: $> 9\%$. In type 2 patients glucose values ≤ 72 mg/dl represented 2.6% from all the values recorded, no severe hypos. While total period analysed summarised 822 hours, glucose values ≤ 72 mg/dl lasted 21.4 hours, 2.55%. Mean fasting glucose was 141 ± 46.1 mg/dl. When A1c $\leq 7\%$, the mean basal glucose value was 116.1 ± 17.6 mg/dl compare to 142.2 ± 54.7 in patients with A1c $\geq 9\%$. In patients with A1c $\leq 7\%$, glucose values ≤ 72 mg/dl occurred in 1.5%, vs. 4.5% in patients with A1c $\geq 9\%$. In patients on oral agents, mean A1c was $7.84 \pm 1.6\%$ vs. $8.5 \pm 1.6\%$ in those insulin treated. In patients on insulin glargine, mean basal glucose value was 128.42 ± 45.4 mg/dl, mean of all glucose values was 122.4 ± 17 mg/dl, with 3.4% glucose values ≤ 72 mg/dl, compared to mean basal glucose of 157.6 ± 52 mg/dl, mean of all glucose values 142.7 ± 20.7 mg/dl and 4.1% hypos in patients on other insulin. In persons with type 1 diabetes, total period summarised 852 hours with 75.6 hours glucose values ≤ 72 mg/dl, 8.9%. Among the 13 patients with A1c $\leq 7\%$, 8 experienced glucose values ≤ 72 mg/dl, lasting 26 hours, 11% from a total of 234 hours of monitoring, while among the 7 patients with A1c $> 9\%$, one experienced glucose values ≤ 72 mg/dl with a duration of 8.2 hours/3 nights, 5.7% from a total of 144 hours.**Conclusion:** Nocturnal hypoglycaemia can occur in patients with both type 1 and type 2 diabetes. Nocturnal hypoglycaemia was more frequent in patients with type 1 diabetes well controlled and type 2 diabetes poorly controlled. In type 2 diabetes, improvements in glycaemic control can be obtained with a low risk of hypos. Patients treated with insulin glargine had a better basal glucose value and lower prevalence of hypos. Identifying hypoglycemia with CGMS can minimise the frequency of hypoglycemia and help patients attain their glycemic goals.

0812

Do high fasting glucose levels suggest nocturnal hypoglycaemia? The Somogyi effect – fact or fiction?P. Choudhary¹, C. J. Emery², S. R. Heller²;¹Department of Diabetes, King's College London,²Department of Diabetes, University of Sheffield, United Kingdom.**Background and Aims:** High fasting blood glucose levels can be a frustrating obstacle in achieving glycaemic targets. In this setting, it is common clinical

practice to ask patients to check their blood glucose at 3 am to exclude the Somogyi effect (asymptomatic nocturnal hypoglycaemia causing counterregulatory hormone release leading to fasting hyperglycaemia). Patients are often advised to reduce their overnight insulin if fasting glucose levels are high. We used continuous glucose monitoring data to establish the prevalence of this phenomenon in clinical practice in patients with insulin treated diabetes.

Materials and Methods: We obtained Continuous Glucose Monitoring data from 226 patients with insulin treated diabetes (91 type 1); mean (sd) age 56.2(12.1) yrs; mean (sd) HbA1c 7.5(1.0) %. We analysed the first complete valid night of data and identified capillary readings entered at bedtime and pre-breakfast. The lowest sensor glucose value between these two points was termed the nadir glucose. Nocturnal hypoglycaemia was defined as nadir sensor glucose <3.0mmol/l.

Results: Nocturnal hypoglycaemia occurred on 28.1% of nights in type 1 diabetes and 23% of nights in type 2 diabetes. Nocturnal hypoglycaemia was more common in those with longer duration of diabetes. 3/56 episodes of nocturnal hypoglycaemia was followed by fasting glucose > 10mmol/l, although in 2 episodes the patient had been woken up by hypoglycaemia and had consumed carbohydrate. Fasting blood glucose was significantly lower following nights with hypoglycaemia compared to nights with no hypoglycaemia 5.9(2.0) vs. 8.7(3.1) mmol/l ($p<0.001$). In 40% of episodes, fasting blood glucose was < 5mmol/l following nocturnal hypoglycaemia. There was no difference in age, HbA1c, duration of diabetes or self reported hypoglycaemia awareness between those who did or did not have nocturnal hypoglycaemia. There was a significant correlation between nadir glucose and fasting glucose ($r = 0.7$; $p<0.001$) but there was no correlation between bedtime capillary glucose and nadir glucose ($r = 0.25$; $p = 0.7$).

Conclusion: Nocturnal hypoglycaemia is common in insulin treated diabetes and is usually associated with low fasting blood glucose levels. Our data refutes the existence of the Somogyi effect.

How to classify hypoglycaemia awareness in type 1 diabetes?

T. Høi-Hansen, U. Pedersen-Bjergaard, B. Thorsteinnsson;
Medical department 1, Nordsjællands Hospital-Hillerød, Denmark.

Background and Aims: Impaired hypoglycemia awareness (IHA) is a major risk factor for severe hypoglycemia (SH) in patients with type 1 diabetes. There is no consensus on classification of hypoglycemia awareness (HA). We compared three methods for assessment of self-estimated HA in a clinical setting.

Materials and Methods: A questionnaire including all three methods was mailed to all our outpatients with type 1 diabetes. Method A is a 7-point Likert scale (7: total IHA; 1: total HA) dividing patients into HA or IHA. Method B uses 8 questions and an additive symptom score dividing patients into HA or IHA. Method C uses the question: 'can you feel when you have an hypo?', with 4 possible answers dividing patients into HA, IHA or unaware (HUA). All patients were divided into two groups with 0 or ≥ 1 episode of severe hypoglycemia the preceding year.

Results: A total of 385 (77 %) patients returned the questionnaire. In the preceding year, 289 (75%) patients had no episodes of severe hypoglycemia, and 91 have had ≥ 1 episode (5 did not provide an answer). The mean number of episodes for all patients was 0.91 per patient-year while patients with ≥ 1 episode had 3.8 episodes per patient-year.

Using method A, B and C, respectively, 100 %, 79 % and 53 % of the patients could be classified as HA or IHA/HUA (C) whilst the rest of the patients were either classified as having impaired awareness (method C: 46 %) or could not be classified (method B: 21 %). The table shows number of patients with HA and IHA/HUA, as well as positive and negative predictive values in relation to retrospectively recalled episodes of severe hypoglycemia for the three methods.

Conclusion: In conclusion, method C had higher positive and negative predictive values, and was at the same time one of the simplest methods. However, both method B and C left many patients unclassified or classified as IHA. Consensus on the method for clinical classification of hypoglycaemia awareness is warranted.

Frequency and predictive values

	Method A	Method B	Method C
HA (n)/ SH (mean)	281/ 0.56	195/ 0.34	152/ 0.14
IHA(A+B) or HUA (C) (n)/ SH(mean)	94/ 1.9	106/ 1.91	46/ 2.9
Positive predictive value	0.37	0.42	0.54
Negative predictive value	0.81	0.85	0.91

0814

Glycaemic profile characteristics and frequency of impaired awareness of hypoglycaemia in subjects with T1D and repeated non-severe and severe hypoglycaemic episodes

M. Lara, M. Giménez, J. Nicolau, I. Conget;
Endocrinology Unit, Hospital Clinic i Universitari, Barcelona, Spain.

Background and Aims: Intensive insulin therapy significantly reduces the risk of complications in subjects with type 1 diabetes (T1D) and represents the standard treatment since the onset of the disease. However, this sort of therapy is unfailingly associated with a higher risk of non-severe (NSH) and severe hypoglycaemia (SH), precluding, in some cases, this type of therapy. Aim: To evaluate the prevalence of hypoglycaemia unawareness and continuous glucose profile characteristics in a group of T1D subjects with repeated NSH and SH.

Materials and Methods: Twenty subjects with T1D (aged 35.2 \pm 7.6 years, 9 women, T1D duration 16.4 \pm 6.2 years) receiving intensified insulin treatment fulfilling the following criteria: >4 NSH episodes/week (last 8 weeks) and >2 SH during the last 2–3 years, were included. General and metabolic characteristics, an evaluation of hypoglycaemia awareness (HA) and a 72-h continuous glucose monitoring (CGM) were performed. An acute induction of hypoglycaemia was performed with i.v. regular insulin and symptoms and signs of hypoglycaemia were evaluated after clamping of glycaemia at 2.5 – 2.8 mM.

Results: At entry, HbA_{1c} was 6.9 \pm 1.0%. All the subjects were classified as having hypoglycaemia unawareness by the HA test and only 4 of them displayed normal symptoms and signs response during induced hypoglycaemia (coefficient of correlation -0.61 , $p<0.012$; sensitivity 100%, specificity 25%, PPV 80%, kappa index 0.333). CGM of the whole group revealed 18% of measurements <70 mg/dl and this percentage was correlated with HA test score ($r=0.55$; $p<0.035$) and symptoms/signs during the induced hypoglycaemia ($r=-0.57$; $p<0.026$). In those subjects with an abnormal symptoms/signs response during induced hypoglycaemia, CGM% of values <70mg/dl was higher (22.6 \pm 8.4%) than in those with normal one (10.2 \pm 9.0%; $p<0.028$).

Conclusion: In subjects with T1D and repeated NSH and SH, the prevalence of impaired awareness is substantially common. Its presence is related with a high proportion of ambulatory glycaemia profile below desirable range. The detection of this alteration has to be considered for a safe approach to optimising metabolic control.

0815

Erythropoietin concentration and renin angiotensin system activity during hypoglycaemia in type 1 diabetes

P. L. Kristensen¹, T. Høi-Hansen¹, N. V. Olsen², U. Pedersen-Bjergaard³, B. Thorsteinnsson¹;

¹Division of Internal Medicine I, Nordsjællands Hospital – Hillerød, Denmark, ²The Department of Neuroanaesthesia, Copenhagen University Hospital, Denmark, ³Department of Internal Medicine I, Bispebjerg Hospital, Copenhagen, Denmark.

Background and Aims: High renin angiotensin system (RAS) activity is associated with increased risk of severe hypoglycaemia in patients with type 1 diabetes and more pronounced cognitive dysfunction during hypoglycaemia. An interaction between RAS and erythropoietin (EPO) has been established. EPO is neuroprotective in brain damage and may hypothetically improve cognitive function during hypoglycaemia. We therefore studied the impact of mild hypoglycaemia on EPO concentrations in patients with type 1 diabetes and high or low RAS activity.

Materials and Methods: Nine patients with high and nine with low RAS activity, as classified by ACE activity, angiotensinogen concentration and genotype of the angiotensin 2 receptor subtype 2, underwent a single-blinded,

placebo-controlled, cross-over study with either hypoglycaemia induced by intravenous insulin (100% of morning dose/hour) or stable glycaemia maintained by intravenous glucose and insulin administration dependent on blood glucose (control study).

Results: Nadir plasma glucose was 2.3 (0.3) mmol/l (mean (SD)) in the high RAS group and 2.5 (0.2) mmol/l in the low RAS group ($p=0.16$). During the control study, p-EPO did not change in either RAS group. During hypoglycaemia, p-EPO increased from 9.7 (3.6) U/l to 12.5 (5.4) U/l (29% increment) in the high RAS group, while p-EPO in the low RAS group increased from 9.0 (2.9) U/l to 9.6 (2.2) U/l (7% increment). Intervention and RAS group both had impact on the EPO level, with hypoglycaemia and high RAS activity being associated with significantly higher levels of EPO: Hypoglycaemia: estimate: + 1.7 U/l ($p = 0.02$), high RAS group: estimate 1.6 U/l ($p = 0.04$).

Conclusion: Plasma EPO concentrations increase significantly during mild hypoglycaemia in patients with type 1 diabetes. Subjects with high RAS activity have higher EPO levels and a higher EPO response. The mechanism and the clinical significance are unknown. The association between low RAS activity and low frequency of hypoglycaemia/better cognitive performance during hypoglycaemia does not seem to be mediated by the hypoglycaemic EPO response.

Experience of hypoglycaemic symptoms is associated with lower quality of life (EuroQoL) among patients with type 2 diabetes on oral antihyperglycaemic therapy in Europe

D. Yin¹, C. Morillas², R. Gomis³, G. Krishnarajah¹, R. Lyu⁴, P. Mavros¹;

¹Merck & Co, White house station, United States, ²Hospital Dr. Peset, Valencia, Spain, ³Hospital Clinic, Barcelona, Spain, ⁴Merck & Co, Shanghai, China.

Background and Aims: Some OHA are often associated with hypoglycaemia with varying degrees of severity. The impact of hypoglycaemia on patients' health related quality of life (QoL) in patients with type 2 diabetes (T2DM) is not well established. This study was undertaken to evaluate the experience of hypoglycaemia symptoms among patients with type 2 diabetes receiving OHA and its impact on QoL.

Materials and Methods: A retrospective clinical chart review and patient survey during physician visit (June 2006–Feb 2007) was conducted in 7 countries (Finland, France, Germany, Norway, Poland, Spain, UK). Patients recruited (aged ≥ 30 years at T2DM diagnosis) added SU or PPAR γ agonist to previous MF. Patients with gestational diabetes and those using insulin were excluded. Case report forms were used to collect clinical data from medical records. A1C refers to the most recent measurement within a year prior to enrollment. Questionnaires were used to ascertain patient reported experience of hypoglycaemia, and QoL as measured by the EQ-5D VAS. Adequate glycaemic control was defined according to the IDF (2005) recommendations as A1C $<6.5\%$. Unadjusted differences in QoL by experience and severity of hypoglycaemia was assessed using the t-test.

Results: 1709 patients were included in this analysis. Average age was 63 (SD=11) years, 45% were female, and 50% were diagnosed with diabetes for

more than 7 years. The mean A1C level was 7.1% (SD=1.1), while 28% (477 patients) had adequate glycaemic control. 652 (38%) reported ≥ 1 episode of hypoglycaemia during the past year. The corresponding values by country are provided in the table below.

Country	Experience of Hypoglycaemia – %	Mild only symptoms %	Moderate symptoms	Severe or Very Severe symptoms
Total	38.0 (652/1697)	68.1 (444/652)	26.8 (175/652)	5.1 (33/652)
Finland	48.1 (77/160)	72.7 (56/77)	24.7 (19/77)	2.6 (2/77)
France	38.7 (58/150)	65.5 (38/58)	25.9 (15/58)	8.6 (5/58)
Germany	24.2 (79/326)	67.1 (53/79)	27.9 (22/79)	5.1 (4/79)
Norway	35.4 (17/48)	64.7 (11/17)	17.7 (3/17)	17.7 (3/17)
Poland	32.9 (79/240)	88.8 (67/79)	13.9 (11/79)	1.3 (1/79)
Spain	37.0 (161/435)	74.5 (120/161)	22.4 (36/161)	3.1 (5/161)
UK	53.6 (181/338)	54.7 (99/181)	38.1 (69/181)	7.2 (13/181)

Patients experiencing hypoglycaemic symptoms reported lower QoL values than those not (EQ-5D VAS: 68.7 vs. 73.5; $p<0.0001$). More severe hypoglycaemia was significantly ($p<0.0001$) associated with lower QoL values (mean EQ-5D-VAS score: 70.9 for only mild symptoms, 65.8 for up to moderate symptoms, and 54.3 for severe or very severe symptoms).

Conclusions: Patient-reported experience of hypoglycaemic symptoms was common among patients with T2DM on OHA in Europe. The experience of hypoglycaemic symptoms in these patients was associated with lower health related quality of life.

0817

A logistic regression model predicting those with diabetes treated with alternative short-acting insulin regimens who report hypoglycaemia to their GP

A. Simpson¹, C. D. Poole², A. J. Tynan¹, C. J. Currie³;
¹Eli Lilly and Company Limited, Windlesham, United Kingdom, ²Healthcare Research, 360° Research, Penarth, United Kingdom, ³Department of Medicine, Cardiff University, United Kingdom.

Background and Aims: The pharmacokinetic profile of the rapid acting analogue insulins is known to reduce the likelihood of hypoglycaemia compared to short acting regular human insulin. The purpose of this study was to mathematically model those subjects who report hypoglycaemia to their GP.

Materials and Methods: Data was extracted from the General Practice Research Database (GPRD), a resource that describes the primary care histories of around 7% of the UK population from 1990 to 2007. Subjects were selected having been treated with one short-acting insulin (SAI) regimen, although patients treated with animal insulin regimens were excluded here. GPRD records in detail a number of experiences, including: diagnoses, treatments, biochemistry and other laboratory test results, blood pressure, height, weight, and mortality. A logistic regression model (LRM) was derived that characterised people who either did or did not report hypoglycaemia to their GP for the duration of their treatment on a basal-bolus regime that included either short acting analogue insulin (AI) or soluble regular human insulin (RHI). A wide range of explanatory variables were explored including HbA1c, age, sex and duration of diabetes.

Results: It was possible to identify 7,982 people treated with a single SAI regimen; 5,483 (68.7%) AI, and 2,499 (31.3%) RHI. The LRM is given in the table.

Conclusion: It was possible to model those people who were likely to report hypoglycaemia to their GP; and by inference, people who were more likely to experience hypoglycaemia. Those more likely to report hypoglycaemia had the following characteristics: type 1 diabetes, a longer duration of insulin therapy and used soluble regular human insulin.

TABLE. Logistic regression model predicting the odds of reporting hypoglycaemia to the GP.

Detemir causes similar counter-regulatory hormone response but increased symptom awareness during hypoglycaemia compared to regular human insulin

S. A. Schäfer, O. Tschritter, A. Bury, J. Klett, A. Hennige, H.-U. Häring, A. Fritsche;
Medizinische Klinik IV, University Tübingen, Germany.

Background and Aims: The long acting insulin analogue Detemir has structural and physicochemical properties which differ from human insulin. The aim of the present study was, therefore, to test whether this leads to altered hormone and symptom response to hypoglycaemia.

Materials and Methods: 12 (6f/6m, age 32±6 years (mean±SD), BMI 24.2±2.5 kg/m²) healthy subjects underwent a 200 min stepwise hypoglycaemic clamp (45 min steps of 4.4, 3.7, 3.0 and 2.3 mmol/l) with either insulin Detemir or Actrapid in random order. Detemir (Actrapid) was infused at a rate of 5 (2) mU/kg/min. At the start of the clamp, a bolus of 660 (60) mU/kg was given over 12 (6) minutes. Assessment of this dose was done in pilot hyperinsulinaemic euglycaemic clamp experiments. Blood was drawn and a semi-quantitative symptom questionnaire (20 real and 9 dummy symptoms) were administered before and after each plateau of the hypoglycaemic clamp. A stroop- and reaction time test was performed during each step.

Results: Although Detemir infusion resulted in ~35 times higher peripheral total insulin levels, blood glucose levels and glucose infusion rates (GIR) were similar during both conditions except of the 2.3 mmol/l plateau with higher GIR under Detemir. No significant differences between Detemir and Actrapid in glucagon, epinephrine, norepinephrine, cortisol or growth hormone response during hypoglycaemia were observed (MANOVA for repeated measures design). There were also no significant differences in cognitive function tests. The total symptom score was higher with Detemir during the 3 and 2.3 mmol step compared to Actrapid (p=0.048). Especially sweating was increased with Detemir versus Actrapid (p=0.02), and showed an earlier and faster increase during the hypoglycaemic clamp with Detemir (interaction insulin x time: p=0.04).

Conclusion: Hormonal counter-regulation and cognitive function during hypoglycaemia are not different with Detemir and human regular insulin. Symptom perception, especially sweating, is increased during hypoglycaemia induced by Detemir. Type 1 diabetic patients with hypoglycaemia unawareness may profit from increased sweating during hypoglycaemia.

Supported by Novo Nordisk

while weight was almost unchanged in IG/MET-treated patients (-0.1±0.5 kg, p=0.860). Incidence of hypoglycaemia was similar in EX/SU- and IG/SU-treated patients (EX, 30% vs. IG, 34%, p>0.99) but was significantly lower in patients treated with EX/MET compared with IG/MET (2.6% vs.17.4%, p=0.010). Although the incidence of nocturnal hypoglycaemia tended to be lower in EX/SU- compared with IG/SU-treated patients (7% vs. 16%, p=0.152), it was significantly less in patients treated with EX/MET compared with IG/MET (1.3% vs.13%, p=0.018). There were 7 episodes of severe hypoglycaemia in 3 IG-treated patients but none in EX-treated patients. In SU treated-patients who experienced hypoglycaemia, mean endpoint HbA_{1c} was lower in patients treated with EX (n=18, 7.01±0.97%) compared with IG (n=20, 7.58±1.07%). Median IG doses were similar in MET- and SU-treated patients with or without hypoglycaemia (MET, 24 vs. 25 U/day; SU, 24 vs. 23 U/day).

Conclusion: Higher incidences of overall and nocturnal hypoglycaemia in EX-treated patients tended to be associated with concomitant SU use; while in IG-treated patients, hypoglycaemia was observed independent of oral agent used. Severe hypoglycaemia was observed only in IG-treated patients. In addition, the risk of hypoglycaemia was greater in IG/SU-treated patients with poorer glycaemic control (higher HbA_{1c}). These data suggest that adding EX to a single oral agent can be an alternative to IG therapy resulting in similar HbA_{1c} improvements while reducing weight and hypoglycaemia risk, particularly in combination with MET.

Relationship between hypoglycaemia, background oral antidiabetic agent, and glycaemic control in patients treated with exenatide or insulin glargine

M. Trautmann¹, J. Burger¹, D. Johns¹, R. Brodows¹, T. Okerson², A. Roberts³, A. Barnett⁴;

¹Eli Lilly & Co., Indianapolis, United States, ²Amylin Pharmaceuticals, Inc., San Diego, United States, ³Endocrine Unit, Royal Adelaide Hospital, Australia, ⁴Dept of Diabetes/Endocrinology, University of Birmingham and Birmingham Heartlands and Solihull NHS Trust, United Kingdom.

Background and Aims: Hypoglycaemia is a limitation of many therapies for type 2 diabetes.

Materials and Methods: Incidence of hypoglycaemia and the relationship to changes in HbA_{1c} were analysed from a two-period (16 wks each), open-label, crossover study comparing exenatide (EX, 5µg BID for 4 wks, then 10µg BID for 12 wks) and insulin glargine (IG, QD targeting a fasting blood glucose ≤5.6 mmol/L). Patients continued treatment with metformin (MET, 56%) or a sulphonylurea (SU, 44%).

Results: Patients treated with EX or IG (n=114 completers) had similar reductions in mean HbA_{1c} (-1.43% vs. -1.41%, respectively, P=0.773). Reductions in HbA_{1c} were similar in EX patients treated with MET or SU (-1.48±1.20% and -1.38±0.14%, respectively) or in IG patients treated with MET or SU (-1.50±0.12% and -1.29±0.14%, respectively). EX-treated patients had a 2.6% decrease in body weight while IG-treated patients had a 1.8% increase in body weight (mean±SEM, -1.95±0.36 kg vs. 0.53±0.36, respectively; p<0.001). Mean weight was reduced in EX/SU-treated patients (-0.5±0.5 kg, p=0.328) and in EX/MET-treated patients (-3.1±0.5 kg, p<0.001). Mean weight gain was observed in IG/SU-treated patients (0.9±0.5 kg, p=0.096)

TTF-1, a homeodomain transcription factor-1, is associated with hyperphagia in the diabetic rat

I. Nam-Goong¹, E. Kim¹, J. Kim², C. Yun², B. Lee², Y. Kim¹;

¹Department of Internal Medicine, Ulsan University Hospital,

²Department of Biological Sciences, University of Ulsan, Republic of Korea.

Background and Aims: Thyroid transcription factor-1 (TTF-1) is a member of the NKx family of homeodomain genes and plays an important role in the control of neuroendocrine functions. Recently, our research group reported that a novel role for TTF-1 in the regulation of feeding behavior in the rat hypothalamus. Blockade of hypothalamic TTF-1 immensely reduced hyperphagia induced by food deprivation. Furthermore, expression of TTF-1 was significantly increased in the hypothalamus from fasted rats. Here, to determine whether TTF-1 is related with diabetic hyperphagia, we investigated the expression of TTF-1 in streptozotocin (STZ)-induced diabetic rats.

Materials and Methods: Two-month-old male Sprague-Dawley rats were used and diabetes was induced by a single intraperitoneal injection of 65 mg/kg STZ. To determine if TTF-1 is involved in the control of food intake in the diabetic rats, a phosphorothioate antisense (AS) TTF-1 oligodeoxynucleotide (ODN) was delivered into the vicinity of the hypothalamus. Changes in food intake were analysed by repeated measures ANOVA.

Results: STZ-induced diabetic rats had significant hyperphagic and weight loss compared with control rats. Level of hypothalamic TTF-1 synthesis significantly increased in diabetic rats (enhanced mRNA (2.4-fold induction, $p < 0.05$) and protein (3.3-fold induction, $p < 0.01$) expression) as compared with control rats. In addition, blockade of hypothalamic TTF-1 synthesis by intracerebroventricular administration of an AS TTF-1 ODN greatly prevented diabetic hyperphagia (36.7 g/day vs. 25.8 g/day, $F=13.029$, $p < 0.05$) and changed expression of neuropeptides relate to feeding behavior.

Conclusion: These results suggest the connection between hypothalamic TTF-1 synthesis and diabetic hyperphagia.

Influence of lifestyle change on Glucagon-Like Peptide-1 in new onset type 2 diabetes. Pilot study

T. Hart¹, D. Kerr², J. Begley³;

¹Clinical Biochemistry, Royal Bournemouth Hospital,

²BDEC, Bournemouth Diabetes and Endocrine Centre,

³Clinical Biochemistry, Royal Bournemouth Hospital and Bournemouth University, United Kingdom.

Background and Aims: Previously, Glucagon-like peptide-1 (GLP-1) levels and the GLP-1 responses to oral glucose have been shown to be attenuated in patients with established diabetes. Whether impaired secretion is a factor in the development of diabetes or is a consequence of chronic hyperglycaemia is unknown. The aim of this study was to evaluate GLP-1 levels in patients with newly diagnosed type 2 diabetes and to assess the effect of an initial period of lifestyle and dietary adjustment.

Methods: 9 newly-diagnosed type 2 diabetic (DM) patients (4 female, age 57.2 [8.1] years, BMI 27.6 [4.0]), time from diagnosis 24.7 [5.2] days) were compared with 9 controls, matched for age, sex and body weight. All participants had a standard 75g oral glucose tolerance test with blood samples taken via an indwelling cannula at 30 min intervals for 2½ hours for glucose, GLP-1, insulin, glucagon, and intermediate metabolites. Blood was also taken at baseline for HbA1c and blood lipids. DM patients had repeat testing after approximately three months (93.7 [17] days) of lifestyle intervention.

Results: In the DM group, weight fell by 0.5 [4.2] kg with lifestyle changes. 5 patients achieved weight loss (range 0.2 to 5 kg), the other four gained weight (range 2.7 to 6.5 Kg). HbA1c reduced from 7.31 [1.43] to 6.96 [1.19] %, $p=0.25$. When compared with controls, DM patients had higher glucagon levels (AUC 7164.5 vs. 73.94 ng/l.min, $p=0.04$), lower active GLP-1 levels at baseline before the glucose load, although overall AUC levels were not different (1317.1 vs. 761.62 pmol/l.min, $p = 0.2$). There were also elevated

levels of Free Fatty Acids (AUC 19.3 vs. 43.1 mmol/l.min, $p=0.001$) and β -OH Butyrate (AUC 2.19 vs. 7.02 mmol/l.min, $p=0.03$) in the diabetic group. After lifestyle changes active GLP-1 secretion was augmented in the diabetic group (AUC 855.9 vs. 971.7 pmol/l/min, $p = 0.018$) and this was independent of weight change. There was also a trend towards earlier insulin secretion at this time. Glucagon levels were unchanged.

Conclusion: Lifestyle treatment of new onset type 2 diabetes appears to improve GLP-1 responses to an oral glucose load without influencing glucagon levels.

0822

Cholinergic regulation of meal induced ghrelin and PYY release is impaired in obesity

C. Maier¹, M. Riedl¹, G. Vila¹, D. Haider¹, M. Wolzt², B. Ludvik¹, A. Luger¹;

¹Clinical Dep. of Endocrinology & Metabolism, Austria,

²Dep. of Clinical Pharmacology, Medical University of Vienna, Austria.

Background and Aims: Ghrelin and PYY are both hormones derived from the gastrointestinal tract involved in appetite regulation, ghrelin as orexigenic and PYY as anorexigenic agent. Ghrelin concentrations rise before expected meals and decrease upon food ingestion whereas PYY concentrations rise after meals. It has been shown repeatedly that the cholinergic part of the vagus nerve is involved in the regulation of glucose and insulin; the cholinergic antagonist atropine has been shown to decrease ghrelin plasma concentrations in lean, healthy subjects. The aim of the study was to examine the effects of atropine on ghrelin, PYY, glucose and insulin under basal conditions and after meal ingestion in lean and obese subjects.

Materials and Methods: The study design was randomised, double-blind, placebo controlled crossover with four study days. 8 obese (BMI 39.6 ± 2 , 6 female/2 male, aged 28.7 ± 2.4 , mean \pm s.e.m.) and 8 lean (BMI = 22.9 ± 1 kg/m²), age and gender distribution matched, healthy subjects were scheduled for a pre-study visit including a 180min OGTT and four study days in randomised order: A, Atropine 1 mg iv at time point -30 min + breakfast (2 rolls with butter and cocoa drink, 550 kcal) at time point 0; B, Atropine 1mg iv at time point -30 min + no breakfast; C, placebo at time point -30 min + breakfast at time point 0; D, placebo at time point -30 min + no breakfast. Blood samples were drawn at time points -30, -15, 0, 15, 30, 60 and 90 min for measurements of plasma ghrelin, ppy, insulin and glucose. At time points -30, -15, 0, 15, 30, 45, 60, 75 and 90 min subjects rated their hunger and satiety feelings on 10 cm visual analog scales. Blood pressure and heart rate were monitored throughout the study days. Differences between the four study days were analysed by ANOVA, followed by multiple t-tests with Bonferroni correction, if appropriate.

Results: Obese subjects were insulin resistant (HOMA = 5.24 ± 0.3 , OGIS = 379.7 ± 26.1) compared to lean controls (HOMA = 2.58 ± 0.4 , OGIS = 454.3 ± 12.7). Atropine led in lean individuals to a decrease in ghrelin concentrations comparable to and non-additive with breakfast ingestion (Δ baseline/+90min: A, -261.9 ± 59 ; B, -254.8 ± 38 ; C, -196.8 ± 31 , D, $+140.1 \pm 68$ pg/mL, A, B, C $p < 0.0001$ vs. D, and $p =$ n.s. from each other). In obese subjects atropine did not significantly change ghrelin concentrations and breakfast induced ghrelin decrease was impaired (A, -130 ± 44 ; B, -115 ± 55 ; C, -162.9 ± 52 ; D, $+62.5 \pm 49$, C vs. D $p = 0.025$, all others $p =$ n.s). Atropine significantly decreased both basal and meal induced PYY concentrations in lean subjects (A, -2 ± 6 ; B, -35 ± 5 ; C, $+16.3 \pm 5$; D, -5 ± 10 pg/mL) In obese subjects there were no significant changes of PYY concentrations at all. In contrast, atropine resulted in a comparable increase in heart rate in lean and obese subjects, and in a comparable decrease in meal induced glucose concentrations in lean and obese subjects. Only lean, but not obese subjects experienced sustained feelings of satiety (according to VAS ratings) after breakfast. Atropine did not significantly change hunger or satiety VAS ratings in either lean or obese subjects.

Conclusions: The impaired cholinergic regulation of the postprandial drop in (orexigenic) ghrelin concentrations and rise in (anorexigenic) PYY concentrations might be part of the deregulated food intake in obese subjects.

0823

Elucidating the minimum exercise requirements to overcome dietary-induced insulin resistanceF. J. Spargo¹, M. A. Febbraio², J. A. Hawley¹;¹Exercise Metabolism Group, RMIT University, Bundoora,²Cellular and Molecular Metabolism Laboratory, Baker Institute of Heart Research, Melbourne, Australia.

Background and Aims: During the past 50 years, the prevalence of a cluster of interrelated metabolic disease states including obesity, insulin resistance and type 2 diabetes mellitus has reached epidemic proportions. While there is irrefutable evidence that physical training is an effective therapeutic intervention to increase insulin action in skeletal muscle from obese and insulin resistant individuals, the minimum amount of exercise required to restore insulin tolerance is not known.

Materials and Methods: Thirty male Wistar rats (age ~9 wk) were fed standard chow (CHOW, n=6) or a 60% fat diet (FAT, n=24) for 6 wk. Fat-fed animals were then assigned to a control group (FAT, n=6) or one of three exercise groups; F100 (60 min/d for 6 d, n=6); F50 (50% volume of F100; 60 min/d for 3 d, n=6) or F25 (25% volume of F100; 30 min/d for 3 d, n=6). 24 hr after the last exercise session trained animals, as well as CHOW and FAT controls underwent an intraperitoneal insulin tolerance test (IPITT), before the red gastrocnemius was removed for analyses.

Results: CS activity was higher in all fat-fed groups compared to CHOW (all $P < 0.05$), while F50 CS activity was increased compared to FAT and F25. F100 CS activity was also increased compared to FAT, F25 and F50 (all $P < 0.05$). Compared to FAT, IPITT was improved in all exercise groups ($P < 0.05$). F100 also had greater insulin tolerance compared to both F25 and F50 ($P = 0.02$; Figure 1A). FAT glycogen was lower than CHOW ($P = 0.03$), F50 ($P = 0.05$) and F100 ($P = 0.05$), while F25 glycogen was lower than F100 ($P = 0.04$). There were no intramuscular triglyceride (TGm) differences between CHOW, FAT and F25, however both F50 and F100 had higher TGm compared to all other groups (all $P < 0.05$). There were no differences in total IRS1 or IRS1 tyrosine phosphorylation (relative to total IRS1). However, FAT, F25 and F50 had reduced IRS1-PI3 kinase association (relative to total IRS1) compared to CHOW and F100 (all $P < 0.05$). FAT, F25 and F50 GLUT4 was lower than both CHOW and F100 (all $P < 0.05$), while FAT GLUT4 was also lower than both F25 and F50 (both $P < 0.05$).

Conclusion: Insulin tolerance was improved in fat-fed animals after all exercise interventions. However, only the largest exercise dose (60 min/d for 6 d) was sufficient stimulus to overcome high fat feeding-induced down-regulation of the insulin signalling pathway. These data suggest that in order to overcome dietary-induced insulin resistance, daily moderate intensity activity of ~1 hr duration is recommended. (Fig. 1)

0824

Lifestyle-induced changes in transferrin are associated with changes in insulin sensitivityE. E. Blaak¹, C. Roumen¹, E. J. M. Feskens², W. H. M. Saris¹;¹Human Biology, Maastricht University,²Division of Human Nutrition, Wageningen University, The Netherlands.

Background and Aims: Indicators of iron status, like transferrin and ferritin levels may be related to diabetes risk. Ferritin and transferrin may be independent predictors of insulin resistance. Less is known on whether lifestyle intervention can improve serum levels of transferrin and ferritin. We evaluated the effect of a lifestyle intervention in a Dutch population with impaired glucose tolerance (IGT) and analysed the relationship between lifestyle-induced changes glucose tolerance, and insulin sensitivity and changes in transferrin and ferritin levels.

Materials and Methods: 147 IGT subjects were initially randomised into an intervention group; n=74 (INT) and control group; n=73 (CON). We studied 129 subjects after one year of study (INT n=64 and CON n=65). Subjects underwent measurements of body composition, body fat distribution, glucose tolerance (OGTT), and maximal aerobic capacity (VO_2 max). INT were individually guided with respect to diet and physical activity, based on general public health recommendations. We used simple linear regression to evaluate the relationship between lifestyle-induced changes in glucose tolerance, and insulin sensitivity and changes in transferrin and ferritin levels. We used stepwise and multiple linear regression to evaluate whether changes in transferrin were independently related to changes in insulin resistance (as assessed by HOMA-IR).

Results: INT decreased more in body weight and 2-hr glucose levels than CON, -2.32 ± 0.45 kg vs. 0.59 ± 0.47 kg ($p = 0.009$) and -0.63 ± 0.22 mM vs. 0.25 ± 0.27 mM (0.014). VO_2 max increased more in INT compared to CON ($p = 0.033$). HOMA-IR tended to decrease more in INT compared to CON ($p = 0.075$). At baseline, transferrin and ferritin were negatively associated ($\beta = -0.524$, $p < 0.001$) and lifestyle-induced changes in these parameters were also negatively associated ($\beta = -0.253$, $p = 0.004$). The lifestyle-induced decrease in fasting and 2-hr insulin and HOMA-IR were positively associated with decrease in transferrin ($p < 0.05$), but not with ferritin ($p > 0.05$). Multiple linear regression revealed that the change in transferrin was related to the change in HOMA-IR ($\beta = 0.143$, $p = 0.044$), independent of changes in body mass index, age and sex with these factors accounting for 44.6% of the variation. Stepwise linear regression analysis adjusted for age and sex revealed that the most important predictors of change in HOMA-IR were change in BMI ($\beta = 0.640$, $p < 0.001$) and change in transferrin ($\beta = 0.144$, $p = 0.035$).

Conclusion: Transferrin and ferritin were negatively associated and did not change between INT and CON. Transferrin appeared to be an important independent determinant of the improvements in insulin sensitivity. These data suggest that the iron metabolism may be involved in the development of insulin resistance and type 2 diabetes.

The effects of exercise- versus diet-induced weight reduction on the body fat composition and the vascular function in type 2 diabetes

B. Koo¹, K. Han¹, H.-J. Kim¹, E. Kim¹, H.-J. Kim¹, K. Pak¹, H. Son², K. Min¹;

¹Internal medicine, Eulji University School of Medicine,

²Internal medicine, The Catholic University of Korea College of Medicine, Seoul, Republic of Korea.

Background and Aims: Overweight individuals are at increased risk for developing cardiovascular disease. However, the effects of weight loss on the vascular structure and function and insulin resistance are inconclusive especially in regard to the difference in the modality of weight loss. The purpose of this study was to evaluate the effects of the increased daily usual physical activity versus diet restriction with comparable amount of weight loss on diverse metabolic parameters and markers of vascular functional or structural change in type 2 diabetic women.

Materials and Methods: We randomly assigned 70 women with type 2 diabetes to control (C), diet (D), exercise (E) or diet with exercise group (DE). The C were given the conventional education for diet and exercise, the D were restricted their calorie intake lower than 1400 kcal/day, and the E were encouraged to increase their daily activity more than 2000 kcal/day. For 12 weeks, we monitored their daily activities with Lifecorder® (Suzuken Co., Nagoya, Japan), their diet with diet records and body weight (BW) weekly, and excluded the subjects who could not reach their target level of diet or exercise.

Results: Finally, 55 subjects (C, n=15; D, n=18; E, n=11; DE, n=11) were included for the analysis. The mean age of subjects was 56±8 years, the duration of diabetes was 8±6 years, BW was 67.8±6.6 kg and BMI was 27.7±2.4kg/m² and there were no differences among 4 groups. After 12 week program, change and percent change of BW were significantly bigger in the D and the DE [D: -4.8±1.4 kg (-7.2 %), DE: -5.1 ± 2.7 kg (-7.5 %)] than other two groups [C: -1.5±1.6 kg (-2.2 %), E: -2.2±2.0 kg(-3.3 %)].

There was significant reduction in subcutaneous and visceral fat in the all intervention groups ($P<0.05$) except the C. However, the proportion of visceral fat to the total fat was decreased ($P<0.01$ in both) and insulin sensitivity calculated by K_{it} was improved ($P=0.002$ and 0.008 , respectively) only in the E and DE but not in the D. Flow mediated dilatation (FMD), endothelium-independent dilatation (EID) and augmentation index (AI) were significantly improved only in the DE ($P=0.001$, $P=0.010$, $P=0.008$, respectively) but there were no changes in carotid IMT, pulse wave velocity (PWV), and ankle-brachial index (ABI). In the case of D, there were no differences in the FMD, EID and AI, but a deteriorated tendency in PWV and ABI ($P=0.034$ and 0.021 , respectively). The changes of other parameters such as LDL cholesterol, free fatty acid, HbA1c, adiponectin and IL-6 were not significantly different among groups.

Conclusion: In conclusion, the increased daily physical activity with diet control for 12 weeks significantly reduced visceral fat % and improved insulin sensitivity, endothelial function and aortic stiffness, which were not observed in the diet control only in spite of the comparable amount of weight loss.

0826

The relationship between lifestyles and prediabetes with metabolic syndrome in newly developed type 2 diabetes mellitus – based on the Diabetes Case Management Program 2001, Taiwan

M. M. Fuh¹, H.-Y. Su², H.-Y. Chang³, C.-T. Chang⁴, R.-H. Chen⁴, C.-C. Chen⁴, C.-C. Lee⁵, C.-C. Lin⁶;

¹Diabetes Prevention and Control Center, China Medical University Hospital, Taichung, ²Dietetics, Taipei Medical University Hospital,

³Division of Health Policy, National Health Research Institute, Hsinchu,

⁴Medicine, China Medical University Hospital, Taichung,

⁵Neurology, China Medical University Hospital, Taichung,

⁶Family Medicine, China Medical University Hospital, Taichung, Taiwan.

Background and Aims: In order to evaluate the relationship between lifestyles and metabolic syndrome in the prediabetes state in newly developed type 2 diabetes mellitus (T2DM) and ensuing development of primary preventive interventions in high risk people, a nationally standardised, multi-professionally integrated, evidence-based and patient-center healthcare program – DCMP 2001 was implementing in a medical center, Mid-Taiwan.

Materials and Methods: From 2003 to Dec. 2006, 6928 diabetes were randomly recruited in DCMP 2001. Based on the number of metabolic syndrome criteria in the ATP III, all the newly developed T2DM (n=1331) was classified into 3 Groups, GI (2 or less), GII (3criteria), and GIII (more than 3). Accordingly, the lifestyle measurements (lifestyle I : no smoking, no alcoholic and regular exercise; lifestyle II : smoking and/or alcoholic and/or no exercise) were tri-monthly interviewed and recorded by the diabetes nurses following lifestyle intervention after seeing physician. From this cohort, all the newly developed T2DM were randomly sorted out and further divided up into 4 groups with different age ranges of onset of disease, ≤ 40 years, > 40 to ≤ 50 years, > 50 to ≤ 60 years, and over 60 years for study. Comparisons between groups were performed by using Chi-Square test. The significant level was set at $p<0.05$.

Results: In patients of younger onset of diabetes in GIII and GII, the lifestyle measures showed that almost 80% cases were living on lifestyle II. The older onset of diabetes in G III and GII, however, 50% cases were sticking on lifestyle I (Table 1 and 2 respectively). These differences in lifestyles between younger and older onset of T2DM with metabolic syndrome in prediabetes state at different age ranges were statistically significant not only in the GIII ($p<0.0001$) but also in the GII diabetes ($p< 0.0001$). Comparison between exercisers and non-exercisers in GIII and GII also shown that non-exercisers developed diabetes were significantly earlier than the exercisers ($p=0.004$ and $p<0.0001$ respectively).

Conclusion: The aforementioned results clearly indicated that lifestyles and regular physical activity would have significant impact on not only the ages of onset of diabetes but also the development of metabolic syndrome from the prediabetes state to newly developed T2DM.

Table 1. The case and percentage distributions of different lifestyles at different age ranges in newly developed type 2 diabetes mellitus with metabolic syndrome (GIII)

	Lifestyle I		Lifestyle II		p-value
	Case	%	Case	%	
≤ 40	12	22.2	42	77.8	<0.001
$>40 \leq 50$	15	20.0	60	80.0

The long-term effects of lifestyle intervention in impaired glucose tolerant subjects: determinants of intervention outcome

C. Roumen¹, E. J. M. Feskens², E. Corpeleijn¹, W. H. M. Saris¹, E. E. Blaak¹;

¹Human Biology, Maastricht University,

²Division of Human Nutrition, Wageningen University, The Netherlands.

Background and Aims: Lifestyle interventions may be effective in improving glucose tolerance and preventing diabetes. Less is known on what factors determine intervention outcome. Here, we evaluated the efficacy of a lifestyle intervention in a Dutch population with impaired glucose tolerance (IGT) and analysed which factors were predictive of changes in glucose tolerance and insulin sensitivity (as assessed by HOMA-IR)

Materials and Methods: We studied 147 IGT subjects, initially randomised into an intervention group; n=74 (INT) and control group; n=73 (CON) during a mean of 4.2 years lifestyle intervention. Subjects underwent

measurements of body composition, body fat distribution, glucose tolerance (OGTT), insulin sensitivity (estimated by HOMA-IR), and maximal aerobic capacity ($\text{VO}_2 \text{ max}$). Subjects in the intervention group were individually guided with respect to diet and a physical activity. Guidance was based on general public health recommendations.

Results: INT decreased their total fat and saturated fat intake and increased their carbohydrate and fibre intake, whereas this did not change in CON ($p < 0.05$ group \times time interaction). $\text{VO}_2 \text{ max}$ improved more in INT, compared to CON ($p = 0.042$). Body weight decreased in INT during the first 3 years, but increased again during the last part of the study, whereas body weight did not change in CON ($p = 0.20$ group \times time interaction). 2-hr glucose levels increased less in INT compared to CON ($+0.24 \pm 0.39$ mM vs 0.95 ± 0.38 mM, respectively, $p = 0.041$). Cumulative diabetes incidence increased less in INT ($n = 18$) than in CON ($n = 27$, $p = 0.052$ group \times time interaction). At baseline, low body fat mass, plasma resistin levels, high 2-hr glucose and Apo lipoprotein A (ApoA) levels were most predictive of a decrease in 2-hr glucose levels ($p < 0.05$). High fasting insulin and mono unsaturated fat intake at baseline were most predictive of a decrease in HOMA-IR ($\beta = -0.540$, $p = 0.001$ and $\beta = -0.329$, $p = 0.009$, respectively). Stepwise regression analysis in INT revealed that lifestyle-induced change in fasting glucose was most predictive for $\Delta 2\text{h}$ glucose ($\beta = 0.436$, $p = 0.009$) and Δ body fat mass was most predictive for Δ HOMA-IR ($\beta = 0.577$, $p = 0.001$).

Conclusion: In conclusion, our lifestyle intervention program, aiming at increasing physical activity and using a healthy diet, improved glucose tolerance and reduced diabetes incidence. INT subjects with high baseline 2-hr glucose improved more in glucose tolerance. Lifestyle-induced changes in body fat mass were most predictive for the improved insulin sensitivity.

Saturated dietary fats intake and the leisure-time physical activity among persons with high risk of type 2 diabetes. Results from National type 2 diabetes prevention programme in Finland (FIN-D2D)

M. E. H. Poskiparta¹, M. Vanhala², J. Villberg¹, S. Salmela¹, K. Vähäsarja¹;

¹Department of Health Sciences, University of Jyväskylä,

²Central Finland Hospital Districts, University of Kuopio, Jyväskylä, Finland.

Background: Lifestyle changes including increased physical activity, reduced fat and increased fibre have shown to be even more effective than medication in prevention of type 2 diabetes. The basis of behaviour change is the assessment of the need for change. FIN-D2D is a big prevention programme for type 2 diabetes in Finland and, in this, the use of the Transtheoretical model as a health counselling method is recommended.

Aims: To examine the baseline findings concerning the participants' self-reported use of saturated dietary fats and leisure-time physical activity and to determine which factors affect their need for change of use of saturated dietary fats and the leisure-time physical activity.

Materials and Methods: The data consists of 3397 adults (men 37 %, women 63 %, mean age 55 yrs, mean BMI 32.1 kg/m^2 (in men 31.5 and women 32.4), mean waist circumference 103.1 cm (in men 108.4 cm and women 100.4 cm) with high risk of T2D, who voluntarily participated and were referred to lifestyle counselling by primary care providers. The assessment of person characteristics, self-reported leisure-time physical activity and consumption of saturated dietary fats was based on questionnaires completed by participants and nurses. The Pearson's χ^2 -test and multivariate logistic regression were used.

Results: One third of all respondents were physically active. 27 % percent reported having a diet with high saturated dietary fat content. According to the logistic regression analysis, in women (BMI > 30) overweight increased the probability to the self-reported need of change saturated dietary fats use. In men abundant saturated dietary fats use and an age less than 65 increased the probability of the need for change fats use. The need for changing physical activity was more prevalent among overweight women < 45 years of age, and among physically in-active men with waist circumference < 94 cm.

Conclusion: The amount of high-risk persons, who eat too much saturated dietary fats and are insufficiently physical active, is alarming. Most of the participants reported that they are consciousness of their needs of behaviour changes. An assessment of the participants' knowledge and stages of change

should be carried out in more detail, making the content of counselling more effective, personal and relevant to the participants' needs

Effectiveness of a national diabetes prevention campaign for high risk groups in The Netherlands

I. de Weerd¹, H. P. Kuipers¹, G. Kok²;

¹NDF, Netherlands Diabetes Federation, Amersfoort,

²Psychology, University of Maastricht, The Netherlands.

Background and Aims: Currently 850.000 people in the Netherlands have diabetes and about 3.2 million is at risk for developing the disease in the coming years. Research has shown that a healthy lifestyle can delay the onset of diabetes or even prevent it. Determining which individuals are at risk for diabetes type 2 and stimulating these individuals to live healthily is thus imperative. Consequently, these goals are the main focus of the national prevention campaign entitled 'Look at Diabetes'. This campaign targets high-risk groups (people older than 45 years of age with overweight or obesity) and endeavours to make them aware that they are at risk for developing diabetes type 2. Special attention has been paid to people with a risk higher than average: people with a Turkish, Maroc or Hindu background and with a lower educational level. Those at risk are stimulated to perform the Dutch Diabetes Risk Test. When as a result of this test, people have a high risk of developing diabetes, they are advised to visit their GP for further diagnosis and advice. The campaign itself (April–December 2006) is based on behavioural theories and consists of national and local activities, both for target groups and intermediaries (GP's, practice nurses, dieticians, municipal health organisations).

Material and Methods: In order to assess the efficacy of the campaign on knowledge, risk perception (perceived seriousness and perceived vulnerability), perceived avoidability of risk and number of high risk persons detected, a study was performed using the best available design for evaluating mass media campaigns. This study consisted of an effect and process evaluation among target groups and professionals. In total 911 people older than 45 years of age and overweight were recruited for this study: 645 person with an autochthonous and 266 persons with an allochthonous background. To correct for the Hawthorne effects, 50% was asked to participate in the study three times (panel group) and 50% was asked to participate only once (new sample). Data collection took place prior and 3 months after the start, and at the end of the campaign using a combination of face to face interviews (allochthonous respondents) and interviews by phone (autochthonous respondents). Professionals completed a questionnaire concerning attitudes, self-efficacy and perceived barriers to diabetes prevention prior and after the campaign.

Results: The campaign was successful in reaching all target groups, especially those with an allochthonous background. Generally the campaign was effective in increasing knowledge concerning diabetes, perceived 'avoidability of risk' and risk perception. Due to the campaign a significant number of people were diagnosed as having diabetes or prediabetes. The study among professionals showed a very positive attitude to diabetes prevention interventions in general and to the campaign in specific. After the campaign the perceived barriers for taking an active role in diabetes prevention were significantly decreased.

Conclusion: The campaign was effective in reaching high risk groups with respect to their risk of diabetes and concerning this risk, taking adequate follow up, especially for allochthonous groups. The campaign was also effective in stimulating professionals to take an active role in accomplishing the main targets of the campaign. Based on the results, the national campaign will be further improved and continued for the forthcoming years.

Effects of rimonabant on metabolic parameters and pancreatic function in male ZDF rats: comparison with rosiglitazone

P. Chamiot-Clerc, C. Duquenne, J. Ludop-Maignel, V. Delion, F. Petoux, V. Duvivier, M.-P. Pruniaux, A.-M. Galzin; Sanofi-aventis R&D, Rueil-Malmaison, France.

Background and Aims: Recent clinical studies have shown evidence of a beneficial effect of Rimonabant (RIMO) in type 2 diabetic patients. The aim of the study was to compare the effects of RIMO and Rosiglitazone (ROSI) following chronic administration in male Zucker Diabetic Fatty (ZDF) rats, an animal model known to spontaneously develop type 2 diabetes from the age of 8 weeks, characterised by a rapid increase in glycaemia, concomitant with a decrease in insulin secretion and a loss in β cell function.

Materials and Methods: Male ZDF rats (8 week-old) were orally treated with RIMO (10 mg/kg/d), ROSI (3 mg/kg/d) or vehicle (VEH) during either 2 or 6 weeks. Glycaemia, insulinemia and body weight were measured weekly. At the end of each period (i.e. 2 or 6 weeks), pancreata were recovered from all groups for islet isolation. Insulin secretion was assessed by static incubation, in the presence of 2.8 mM and 16.7 mM glucose, and by perfusion with media containing the same glucose concentrations.

Results: In contrast to VEH-treated rats which developed a marked hyperglycaemia from the beginning until the end of the experiment (470 ± 13 mg/dl after 6 weeks), RIMO- like ROSI-treated animals maintained a close to normal glycaemia with values after 6 weeks of 126 ± 11 mg/dl ($p < 0.01$ vs. VEH) and 157 ± 34 mg/dl ($p < 0.01$ vs. VEH) respectively. Similarly, while insulinemia dramatically decreased from 13.2 ± 0.8 at the beginning of the study to 1.0 ± 0.1 ng/ml after 6 weeks in VEH, insulin levels in RIMO and ROSI animals, despite a decrease during the first 2 weeks, started to increase again to reach values at 6 weeks of 8.3 ± 1.2 ($p < 0.01$ vs. VEH) and 4.5 ± 0.5 ng/ml ($p < 0.01$ vs. VEH) respectively. As usually observed, ROSI induced a marked increase in body weight (+100% vs. baseline) while RIMO animals increased their body weight by 50% only over the 6 weeks study similar to body weight gain of healthy animals. Noteworthy, VEH rats displayed a very flat body weight curve (+20% vs. baseline after 6 weeks) due to their severe diabetic status. In static incubation experiments, RIMO and ROSI treatment increased isolated islets stimulation index (+507% and +553% $p < 0.001$ respectively vs. VEH at 6 weeks). This effect was mainly due to an increase in glucose-induced insulin secretion (21.3 ± 3.2 μ g/l, $p < 0.0005$, 22.0 ± 3.7 μ g/l, $p < 0.0005$, and 4.7 ± 0.4 μ g/l in RIMO, ROSI and VEH group respectively). Perfusion results showed that in islets from VEH-treated animals the insulin secretion profile were altered with a low first phase together with the absence of a second phase insulin response to 16.7 mM glucose. Conversely RIMO and ROSI treatments restored glucose-induced insulin secretion with the characteristic biphasic insulin secretion in isolated islets.

Conclusion: In conclusion, these results show that treatment with Rimonabant in ZDF rats prevents the development of hyperglycaemia, improves β cell function and maintains a normal profile of insulin secretion with a much lower impact on body weight compared to Rosiglitazone treatment.

Nuclear Medicine, MIRACLE, University Hospital K.U.Leuven, Belgium.

Background and Aims: The endocannabinoid system has been implicated in the central regulation of body weight. Cannabinoid-1 receptors (CB-1R)

are expressed throughout the human brain, and inverse agonists of these receptors have demonstrated weight loss efficacy in clinical trials. This study was designed to evaluate human brain CB-1R occupancy after SD and MD administration of taranabant, a structurally distinct CB-1R inverse agonist, as assessed by PET using the CB-1R ligand, [¹⁸F]MK-9470.

Materials and Methods: This was a randomised, double-blind, placebo-controlled study in which 15 healthy, lean male subjects were randomised to receive 1 of 5 14-day MD treatments (placebo, taranabant 1, 4 and 7.5 mg, or SD of taranabant 12 mg followed by 6 mg MD). PET scans using [¹⁸F]MK-9470 were performed at predose and at ~2 hours and/or ~24 hours following taranabant SD or MD administration. Blood samples were obtained for taranabant plasma concentration pre- and post-PET. The brain receptor occupancy data were fit with a curve described by a Hill equation: Occupancy (%) = $A y^{nH} / [(Occ_{50})^{nH} + y^{nH}]$, where y corresponds to taranabant plasma concentration, A was set to 100% (maximum occupancy) and the Hill coefficient nH set to 1.

Results and Conclusion: Taranabant was generally well tolerated and demonstrated dose-dependent occupancy of brain CB-1Rs after SD and MD administration as assessed by PET of the CB-1R ligand, [¹⁸F]MK-9470. PET may facilitate dose selection and help to define the therapeutic index for taranabant and other CB-1R inverse agonists in the treatment of overweight and obese patients.

Taranabant increases energy expenditure in overweight and moderately obese subjects

C. Addy¹, S. Heymsfield², C. Gilissen³, I. N. Gendrano III⁴, M. De Smet⁵, M. De Decker⁵, J. Yuan⁶, P. Larson⁶, S. Dunbar⁶, A. Stoch⁴, J. Wagner⁴;

⁶Clinical Biostatistics, Merck & Co., Inc., Rahway, United States.

Background and Aims: Cannabinoid-1 receptor (CB-1R) inverse agonists are associated with weight loss efficacy in clinical trials. Whether this is due to reduction in food intake, an increase in energy expenditure, or a combination of the two remains to be determined. This study was designed to evaluate the effect of single doses of taranabant, a structurally distinct CB-1R inverse agonist, compared to placebo on resting energy expenditure (REE) in overweight and moderately obese male volunteers.

Materials and Methods: This was a double-blind, double-dummy, active comparator- and placebo-controlled, 4-period crossover study in which 17 overweight and moderately obese male subjects were randomised to receive 1 of 4 single-dose treatments (placebo, taranabant 4 mg and 12 mg, and sibutramine 30 mg as a positive control). REE was assessed using indirect calorimetry over a 5 hour postdose period and at 24 hours postdose. Peak REE was obtained as the maximum of the average of 2 consecutive 30-minute measurements within 2–5 hours postdose.

Results: The ANOVA model contained the factors: subject, period, treatment, and 30-minute predose baseline (the average of the two 30 minute readings) REE. Baseline REE was detected as a significant covariate. A test for first order carryover effect was also performed, and no significant effect was observed. The peak REE geometric mean ratio (GMR) and 90% confidence interval (CI) for sibutramine 30 mg, taranabant 4 mg, and taranabant 12 mg versus placebo were 1.03 (0.99, 1.07), 1.02 (0.98, 1.05), and 1.06 (1.02, 1.09), respectively. Single doses of taranabant and sibutramine were generally well tolerated.

Conclusion: This appears to be one of the first clinical studies to demonstrate that a CB-1R inverse agonist is associated with increases in REE, which may, in part, explain the basis for weight loss efficacy with this mechanism. Taranabant was generally well tolerated and may show promise as a medication to induce weight loss in overweight and obese patients.

The CB-1R inverse agonist taranabant reduces acute food intake in overweight/obese male volunteers

D. Wright¹, C. Stevens¹, C. Cilissen², M. De Smet², D. Krupa³, P. Larson³, M. De Decker⁴, G. Herman¹, J. Wagner¹;

¹Clinical Pharmacology, Merck & Co., Inc., Rahway, United States,

²Clinical Pharmacology, Merck & Co., Inc., Brussels, Belgium,

³Biostatistics, Merck & Co., Inc., Rahway, United States,

⁴Research Unit Stuivenberg, SGS Biopharma, Antwerp, Belgium.

Background and Aims: Endogenous cannabinoids and exogenous agonists of the brain cannabinoid 1 receptor (CB-1R) are implicated in promoting appetite and food intake. We have previously described an experimental medicine paradigm to test anti-obesity compounds for acute anorexic effects. Herein, we illustrate the use of this paradigm as a platform to assess the mechanism of action, in part, of a CB-1R inverse agonist.

Materials and Methods: This study evaluated the potential in the clinic for dose-dependent anorexic effects as mediated by taranabant, an investigational CB-1R inverse agonist. A randomised, placebo-controlled, double-blind, 4-period, crossover study in 36 overweight/obese male subjects assessed the effects of taranabant and sibutramine (positive control) on *ad libitum* ('free choice') energy intake. Subjects received single doses of taranabant 12 mg or 4 mg, sibutramine 30 mg or placebo.

Results: At 3, 10, 13 and 24 hrs postdose, respectively, lunch, dinner, snack and breakfast meals were provided in ~5-fold excess over standard portions; subjects consumed these *ad libitum*. The amount of food consumed was transformed into caloric and macronutrient data. Sibutramine 30 mg significantly reduced energy intake ($p < 0.001$) by ~12% over 24 hrs and by

Figure 1. 24-hour & Meal Specific Energy Intake (kcal) After SD Administration of Placebo, Taranabant, or Sibutramine

~20% at the lunch meal vs. placebo. Taranabant 12 mg significantly reduced energy intake ($p < 0.0001$) by ~22% over 24 hrs and by ~27% at the lunch meal vs. placebo (Figure 1). The mean change (95% confidence interval) in energy intake over 24 hours, relative to placebo, was -3% (+5%, -10%), -22% (-16%, -28%), and -12% (-5%, -18%) for taranabant 4 mg and 12 mg, and sibutramine 30 mg, respectively. Effects were equally distributed across all macronutrients. Taranabant 4 mg had no significant effect on energy intake. Both compounds were well-tolerated.

Conclusion: Clinical administration of a CB-1R inverse agonist mediates acute, dose-dependent anorexic effects, as measured by short-term food intake reduction.

0834

Rimonabant reduces visceral fat in obese Japanese patients with cardiometabolic risk factors

K. Shirai;

Department of Internal Medicine, Toho University Sakura Medical Center, Chiba, Japan.

Background and Aims: We performed a dose-response, multicentre, double-blind, parallel-group study to evaluate the effect of rimonabant on body weight and multiple cardiometabolic risk factors, and to study for the first time its effect on visceral fat area (VFA) (assessed by computed tomography scan), in obese Japanese patients.

Materials and Methods: Patients were randomised to placebo (n=131) or rimonabant 5 mg (n=133), 10 mg (n=129) or 20 mg (n=131) for 24 weeks. Inclusion criteria were body mass index ≥ 25 kg/m², VFA ≥ 100 cm² and two of the following: impaired glucose tolerance or type 2 diabetes; untreated dyslipidaemia; hypertension. Efficacy endpoints included change from baseline in body weight, VFA, waist circumference, HDL-C and triglycerides.

Results: Rimonabant 20 mg significantly reduced body weight, VFA, waist circumference and triglycerides and increased HDL-C compared with placebo (table). A similar incidence of adverse events (AEs) was reported between groups, with no dose effect. Withdrawals due to AEs were lower with rimonabant 20 mg (4.5%) than placebo (7.6%). Completion rate was 86%. Rimonabant was generally well tolerated.

		Rimonabant			
		Placebo	5 mg	10 mg	20 mg
Body weight (kg)	Baseline	87.1	85.9	88.1	85.5
	Change	-1.7	-2.4	-2.7	-4.5
			NS	(p=0.03)	(p<0.0001)
VFA (cm ²)	Baseline	171.6	181.6	168.3	175.3
	Change	-20.3	-24.4	-30.4	-40.6
	% change	-11.3	-13.7	-16.7	-23.2
			NS	(p=0.04)	(p<0.0001)
Waist circumference (cm)	Baseline	102.1	101.2	102.9	100.7
	Change	-2.5	-3.1	-3.6	-4.7
			NS	(p=0.05)	(p=0.0001)
HDL-C (mmol/L)	Baseline	1.15	1.18	1.17	1.20
	% change	5.8	7.9	11.2	16.4
			NS	(p=0.005)	(p<0.0001)
Triglycerides (mmol/L)	Baseline	2.95	2.77	2.71	2.67
	% change	-2.8	-3.5	-1.5	-15.6
			NS	NS	(p=0.04)

Least-square mean change from mean baseline at Week 24 (p-value vs. placebo); NS, non-significant.

Conclusion: This is the first study to demonstrate that rimonabant 20 mg achieves reduction in VFA. Improvements in cardiometabolic risk factors, such as waist circumference, HDL-C and triglycerides, reported in the obese Japanese population were similar to those previously observed in the Caucasian population. This study confirmed the efficacy and tolerability of rimonabant 20 mg.

HbA_{1c} reductions plus weight loss and improved lipid profile with rimonabant in overweight/obese drug-naïve type 2 diabetes: the SERENADE trial in patients with BMI >27 kg/m²

J. Rosenstock¹, P. A. Hollander², A. Iranmanesh³;

¹Dallas Diabetes and Endocrine Center, Dallas, ²Endocrinology Center, Baylor University Medical Center, Dallas, ³Endocrine Section, Veterans Administration Medical Center, Salem, United States.

Background and Aims: The first selective CB₁ receptor blocker, rimonabant 20 mg, significantly improved glycaemic control, body weight, waist circumference and lipid parameters in drug-naïve type 2 diabetes patients, as shown in the SERENADE trial (n=278). The primary endpoint was HbA_{1c} and increased body weight was not an inclusion criterion. The aim of this additional analysis was to extend the initial report of SERENADE, to specifically assess the efficacy of rimonabant in overweight or obese patients (baseline BMI >27 kg/m², n=249) who participated in this study.

Materials and Methods: SERENADE was a 6-month, randomised, double-blind, placebo-controlled trial of rimonabant 20 mg/day in drug-naïve type 2 diabetes patients. For this analysis, the efficacy of rimonabant in overweight/obese patients was assessed by examining changes from baseline to 6 months in glycaemic control, body weight, waist circumference and lipid parameters.

Results: At 6 months, rimonabant significantly improved glycaemic control, body weight, waist circumference and lipid parameters (table). A larger effect on HbA_{1c} occurred in overweight/obese patients with HbA_{1c} ≥8.5 at baseline (−1.9% from baseline [p=0.0019 vs. placebo]). Rimonabant was generally well tolerated.

Conclusion: Overweight or obese drug-naïve type 2 diabetes patients on rimonabant 20 mg/day had clinically meaningful HbA_{1c} lowering plus weight loss, with improvements in HDL-C and triglyceride levels similar to those observed in the overall population in the SERENADE trial.

Treatment with rimonabant for overweight or obese patients with diabetes: health economic estimates for the UK

D. Getsios¹, J. Möller², P. McEwan³, K. Ishak⁴, C. Nicholls⁵, J. J. Caro⁶;

¹Research, Caro Research Institute, Halifax, Canada, ²Research, Caro Research Institute, Eslov, Sweden, ³Research, University Hospital of Wales, Cardiff, United Kingdom, ⁴Biostatistics, Caro Research Institute, Montreal, Canada, ⁵Sanofi-Aventis, Surrey, United Kingdom, ⁶Research, Caro Research Institute, Concord, United States.

Background and Aims: The RIO Diabetes trial demonstrated rimonabant's benefits in the treatment of overweight or obese patients with diabetes. Not only did patients lose weight, other cardiometabolic risk factors, including glycaemic and lipid levels, also improved. A discrete event simulation was developed to evaluate the cost-effectiveness of rimonabant in patients with diabetes and a BMI >27 in the UK.

Materials and Methods: Adding rimonabant 20mg to patients' existing antidiabetic treatments and a diet and exercise regimen was evaluated. Individual patients are assigned characteristics based on data from the Health Survey of England (HSE). Two populations were studied in the simulations: high risk patients in the HSE population and the overall HSE population. Predicted changes in risk factors are estimated using equations developed from RIO Diabetes. Treatment persistence and adverse events are also simulated based on analysis of clinical trial data. Individuals are followed over their lifetimes and their risk factor profiles are used to predict cardiovascular disease, microvascular disease and death, based on UKPDS, UK life tables and other published risk equations. In addition, consequent direct medical costs in 2005 £ and effects on health-related quality of life were based on data from Cardiff and the Vale National Health Service Trust, NHS reference costs, and other published sources.

Results: After 1 year of rimonabant, patients lose more weight and have better risk factor profiles compared with diet and exercise alone, with a mean weight loss over 3 kg higher with rimonabant. Patients on diet and exercise alone experience little change in lipid levels, while for those on rimonabant, mean HDL increases by an average of 0.11 mmol/L and triglycerides fall by 0.33 mmol/L. 38% of patients have HbA_{1c} levels >7% at baseline. While this falls to 30% with diet and exercise, it drops to 20% when rimonabant is added. Over the course of their lifetimes, 1,000 patients treated with rimonabant for 5 years avoid 45 cardiovascular events and 38 microvascular complications, with survival increasing by 234 years and by 320 when quality-adjusted. At a cost of £1.97 per day, the cost per discounted quality-adjusted life year is £8,700. Analyses restricted to HSE patients at the higher levels of CVD risk result in increased reductions in CVD risk. The proportion of patients with HbA_{1c} levels >7% falls from 34% at baseline to 19% with rimonabant. While CVD events avoided increases to 56, gains in quality adjusted survival are somewhat lower because of the older age of the population. Quality adjusted survival increases by 257 years, resulting in a cost per discounted quality-adjusted life year of £8,800, equivalent to that when all patients are treated.

Conclusions: These simulations indicate that weight loss and improvements in lipid and glycaemic levels for patients on rimonabant are likely to translate into meaningful reductions in disease in overweight and obese patients with diabetes. In the UK, these gains can be attained at reasonable costs, with cost-effectiveness estimates below £10,000/QALY gained.

Initial blood pressure response of high-risk patients with diabetes plus cardiovascular disease after 6-weeks Sibutramine treatment – an analysis of the Sibutramine Cardiovascular Outcomes (SCOUT) Trial

I. Caterson¹, W. Coutinho², N. Finer³, L. Van Gaal⁴, A. P. Maggioni⁵, A. M. Sharma⁶, C. Torp-Pedersen⁷, W. P. T. James⁸;
¹Human Nutrition Unit, Univ of Sydney, Australia, ²Obes & Eating Dis Res Gp, Catholic Univ. of Rio de Janeiro, Brazil, ³Wellcome Trust Clin. Res. Facility, Univ of Cambridge, United Kingdom, ⁴Dept. of Diab, Metabol & Clin Nutr, Univ Hosp of Antwerp, Belgium, ⁵Res Center, ANMCO Res Center, Florence, Italy, ⁶Obes Res, McMaster Univ Hosp, Hamilton, Canada, ⁷Dept of Cardiol, Bispebjerg Univ Hosp, Copenhagen, Denmark, ⁸Dept of Nutrition, London Sch of Hyg & Trop Med, United Kingdom.

Background: Type 2 diabetes mellitus (DM) is a common cause of morbidity/mortality in obese subjects. DM subjects may be 4 times more likely to have cardiovascular (CV) disease than those without DM; in this disease state, obesity plays a major role in contributing to this outcome. Lifestyle changes are important, but weight reduction is often unsuccessful without pharmacotherapy. Sibutramine (SIB) is an effective weight-management medication, but due to its potential to increase blood pressure (BP), patients with DM and associated CV disease may be contraindicated. Data from the 6-week single-blind period of the ongoing SCOUT trial are utilised to assess SIB plus weight management on BP in this hypertensive, high-risk DM population.

Method: SCOUT is a double-blind, randomised, placebo-controlled outcome trial. Eligible patients included those with CV disease and/or DM with another risk factor. Patients with BP >160/100mmHg were excluded. All patients entered a single-blind, 6-week lead-in period and received SIB. At entry, BP was stratified according to BP levels: Normotensive [NT]/Controlled HT <130/80mmHg; Grade 1 HT 130-<160/80-<100mmHg, and Grade 2 HT ≥160/100mmHg. Anti-hypertensive BP-medication class use (none, 1, ≥2) at entry was to be held constant and determined for patients according to their BP category. Changes in BP in DM patients were assessed over this period.

Results: Of the 10,742 patients who received SIB 10 mg, 9015 (84%) had pre-existing DM. At week -6, 20%, 78%, and 2% of DM patients were classified as BP category: NT/Controlled HT, Grade 1 HT or Grade 2 HT, respectively. The majority (63%) of NT/Controlled HT patients required ≥2 anti-hypertensive medication classes to achieve BP goals. The majority (72%) with Grade 1 HT was also receiving ≥2 anti-hypertensive medication classes. Median change in body weight and waist circumference to endpoint was -2.1 kg (-2.3%) and -2.0 cm.

Median SBP/DBP Changes from Week -6 to Lead-in Period Endpoint

Week -6 BP category	Anti-HT Medication: No. of Classes	Median SBP/DBP (mmHg)	
		Initial	Change
NT/Controlled HT	None	121.0/69.0	2.0/2.0
	1	122.5/70.0	1.0/1.5
	≥2	122.5/69.5	2.5/2.0
Grade 1 HT	None	139.5/80.0	-4.5/-1.0
	1	142.0/80.0	-3.5/-1.0
	≥2	142.5/80.5	-5.0/-2.0
Grade 2 HT	None	163.5/89.5	-16.0/-8.5
	1	162.0/84.0	-9.5/-2.5
	≥2	161.5/84.5	-13.0/-3.0

Further analysis showed BP reduction in HT patients even in the absence of weight loss.

Conclusion: High-risk DM patients with increased BP (≥Grade 1 HT) on entry to the 6-week period had an appreciable reduction in SBP and DBP, regardless of weight loss, even in those patients receiving ≥2 classes of anti-hypertensive medication. Normotensive/Controlled HT patients had small median increases in BP similar to those previously observed.

Sustained weight loss following 1-year pramlintide treatment as an adjunct to lifestyle intervention in obesity

A. Halseth¹, S. Smith², E. Klein³, C. Burns¹, N. Kesty¹, C. Weyer¹;
¹Amylin Pharmaceuticals, Inc., San Diego, ²Pennington Biomedical Research Center, Louisiana State University System, Baton Rouge, ³Capital Clinical Research Center, Olympia, United States.

Background and Aims: In a previously reported 4 mo, randomised, placebo-controlled, dose-ranging study, treatment with the amylin analog pramlintide (120, 240, 360 µg, BID/TID) used in conjunction with lifestyle intervention (LSI) resulted in additional weight loss than observed with LSI alone. To assess the durability of this effect, we instituted a single-blind, placebo-controlled extension protocol that assessed body weight and safety for an additional 8 mo.

Fig. 1

Materials and Methods: Of subjects completing 4 mo, 75% of subjects (ITT n=209; 76% female; weight 106.0±18.4 kg; mean±SD) opted to continue treatment with either pramlintide (120, 240, 360 µg, BID/TID) or placebo administered 15 min before meals. Throughout the extension, LSI was geared towards weight maintenance (not loss).

Results: By Mo 12, the withdrawal rate was 26% for pramlintide- vs. 37% for placebo-treated subjects (Evaluable N=146). Initial weight loss was largely regained in the placebo group, but was maintained in all but one pramlintide group (see figure, below).

At 12 mo, 40 and 43% of evaluable subjects treated with 120 µg TID and 360 µg BID, respectively, achieved ≥10% weight loss (vs. 12% for placebo). The incidence of nausea was low and similar between pramlintide- (0–9%) and placebo-treated subjects (7%).

Conclusion: In this study, pramlintide treatment, as an adjunct to LSI, elicited sustained weight loss and helped obese subjects maintain lost weight over time compared to LSI alone. These findings support further development of pramlintide as a potential treatment for obesity. (Fig. 1)

¹¹Med Clinic, Medical University, Pécs, Hungary.

Background and Aims: The prevalence rate and the clinical significance of the metabolic syndrome in type 1 diabetic patients remain to be established. The aim of this study was to estimate the prevalence rate of the metabolic syndrome in Hungarian type 1 diabetic patients.

Materials and Methods: Adult patients with type 1 diabetes (n=533; 256 men, 277 women; age: 35.6±11.6 years; duration of diabetes: 18.0±11.1 years; BMI: 25.3±4.3 kg/m², HbA1c: 8.29±1.59%; x±SD) were consecutively enrolled from 11 diabetes outpatient departments. Data on medical history, actual treatment, anthropometric and laboratory parameters as well as actual blood pressure were registered while eating habits, education level and physical activity were evaluated by standardised questionnaires. The metabolic syndrome was defined according to the IDF and ATP III criteria. All subjects fulfilled the criteria for hyperglycaemia by definition.

Results: The prevalence rate of the metabolic syndrome according to the ATP III criteria was 31.1% (29.7% men, 32.7% women; p>0.05) while the prevalence rate was higher according to the IDF criteria (36.2% men: 32.8%, women 39.4%; p>0.05). According to ATP III criteria elevated blood pressure was detected in 55.5%, high triglycerides level in 22.3%, abdominal obesity in 19.3% and elevated HDL-cholesterol in 18.0% of patients. Patients with the metabolic syndrome were significantly (p<0.01) older (40.2±11.8 vs. 33.6±10.9 years), had longer duration of diabetes (19.9±10.8 vs. 17.2±11.2 years), used higher daily insulin dose (59.9±22.6 vs. 46.9±15.8 IU) and had higher BMI (28.7±4.8 vs. 23.7±3.0 kg/m²) than those without the metabolic syndrome. The HbA1c and calculated GFR values did not differ significantly in patients with versus without the metabolic syndrome. The prevalence rate of the metabolic syndrome increased with albuminuria (p<0.001). There was an inverse relationship between the prevalence rate of the metabolic syndrome and patients' education level (p<0.001). According to the stepwise logistic regression analysis, the prevalence rate of the metabolic syndrome was associated in a decreasing tendency with waist circumference, serum triglycerides, antihypertensive medication, HDL-cholesterol (p<0.0001), diastolic blood pressure and serum creatinine (p<0.001), and systolic blood pressure, duration of diabetes (p=0.05).

Conclusion: In Hungary the metabolic syndrome can be frequently detected among adult patients with type 1 diabetes. The prevalence rate of the metabolic syndrome is predominantly associated with the higher waist circumference. In order to reduce cardiovascular risk in adult patients with type 1 diabetes, prevention of abdominal obesity is of great importance.

Endogenous cortisol homeostasis affects glucose metabolism and fibrinogen levels in patients with metabolic syndrome

S. Ayturk, N. B. Tutuncu, A. N. Demirer, A. Gursoy, N. G. Demirag; Endocrinology and Metabolism, Baskent University Faculty of Medicine, Ankara, Turkey.

Background and Aims: Cushing's syndrome and metabolic syndrome share many common findings which make one to think that metabolic syndrome represents a variant form of hypercortisolism. In this regard we aimed at screening the presence of endogenous hypercortisolism in a group of patients diagnosed as having metabolic syndrome.

Materials and Methods: A total of 375 (335 female, 40 male) patients diagnosed with metabolic syndrome using the criteria of NCEP-2001 (ATP-

III) guidelines were enrolled for this study. Patients were analysed in detail to find out their degree of metabolic derangements. Blood was drawn for the determination of glucose tolerance (by 75 gm oral glucose tolerance test), fasting insulin, fibrinogen and lipoprotein levels including lipoprotein a. HOMA-IR calculation, blood pressure monitoring, and anthropometric measurements were done for each patient. Screening for the presence of endogenous hypercortisolism was done by 1 mg Dexamethasone suppression test and 1.8 µg/dl of fasting morning plasma cortisol level was the cut-off limit. Patients were analysed with respect to their degree of fasting cortisol suppression and metabolic and anthropometric parameters.

Results: Mean age of the patients was 48.4±13.3 years. Glucose intolerance was detected in 201 patients (49 overt diabetic, 90 with impaired fasting glucose, 20 with impaired glucose tolerance and 41 with both impaired fasting glucose and glucose intolerance). There were 17 patients (4.5%) with nonsuppressed cortisol levels. Those having insulin resistance revealed similar degrees of cortisol suppression. Fasting glucose levels were significantly correlated with the degree fasting cortisol levels after dexamethasone (pearson=0.227; p=0.000). As the degree of glucose intolerance increased, the level of fasting cortisol after dexamethasone also increased. This difference was especially prominent for those with overt diabetics (pearson=0.148, p=0.007). Similar positive correlation was also seen for the plasma fibrinogen levels and the suppressed cortisol levels after dexamethasone (pearson=0.174; p=0.000).

Conclusion: Endogenous hypercortisolism in patients with diagnosed metabolic syndrome seems to be important for the metabolic homeostasis especially with regard to glucose metabolism and acute phase reactants like fibrinogen.

0841

The effect of CLA on endothelial function and traits of the metabolic syndrome

K. Fielitz^{1,2}, U. Helwig¹, M. Pfeuffer¹, P. Winkler², C. Laue², E. Schwedhelm³, R. H. Böger³, D. Bell⁴, J. Schrezenmeir¹;

¹Institute of Physiology and Biochemistry of Nutrition, Federal Research Centre for Nutrition and Food (BfEL), Kiel, Germany, ²Tecura GmbH Medizin & Biotechnik, Kiel, Germany, ³Institute for Experimental and Clinical Pharmacology and Toxicology, University Medical Center Hamburg-Eppendorf, Germany, ⁴Nutrition & Health – Global R & D, Cognis Germany GmbH & Co. KG, Monheim, Germany.

Background and Aims: Conjugated linoleic acid (CLA) has several effects e.g. on insulin sensitivity, lipid metabolism, body composition, particularly shown in animal studies. However, in human studies these findings were inconsistent and the dietary fat used as control differed. It was mostly olive oil, which may have effects of its own. Moreover, the content of antioxidative substances in the preparations used was not declared. The aim of the study was to assess the effect of CLA supplementation on endothelial function and risk factors of the metabolic syndrome compared to 3 different control fats: native safflower oil, oxidised safflower oil, and native olive oil. All fats contained the identical amount of tocopherol (1051 µg/g).

Materials and Methods: 81 healthy overweight men (mean±SD: age 61.5±5.3y, BMI 28.3±2.1 kg/m²) were randomly allocated to either a total of 4.5g/d CLA isomeric mixture (c9,t11:t10,c12), native safflower oil, oxidised safflower oil, or olive oil in form of 2x4 capsules daily in a 4 week double-blind study. The endothelial function (primary parameter) was assessed using finger volume pulse waves (PAT index) fasting and 4 hours after intake of a liquid standardised mixed meal (Oral Metabolic Tolerance Test = OMTT). Blood samples for safety, inflammatory and postprandial (pp) parameters were taken before, during and 9 hours after the OMTT before and after intervention. Data were analysed using SPSS software. All data are expressed by mean±SEM.

Results: The fasting PAT index remained unaltered by CLA (Δ-0.03±0.1) while all other groups tended to impair endothelial function (safflower oil native Δ-0.08±0.13, safflower oil ox. Δ-0.15±0.15, olive oil Δ-0.18±0.12). The pp PAT index improved in the CLA group compared to olive oil (Δ0.2±0.1 vs. Δ-0.14±0.07; p<0.05). Body weight decreased by Δ-1.13±0.36 kg within the CLA group (p<0.01) and compared to all other groups (p<0.05). Consistent with these results the alteration of BMI differed within the CLA group (Δ-0.35±0.11, p<0.01) and compared to all other groups (p<0.05). Systolic blood pressure (RR) decreased within the CLA group (Δ-10.81±3.81 mmHg, p<0.05) and the native safflower oil group (Δ-9.14±2.44, p=0.001). Diastolic RR also decreased within the CLA group (Δ-6.86±2.37 mmHg, p<0.01) and

compared to the oxidised safflower oil group (p<0.05). The alterations of fasting glucose (Δ-1.73±1.49 mg/dl) were more pronounced in the CLA group compared to the group receiving oxidised safflower oil (p<0.05). LDL-C (Δ-10.6±4.18 mg/dl, p<0.05) and cholesterol (Δ-10.97±4.99 mg/dl, p<0.05) decreased within the CLA group. Triglycerides and HDL-C were unchanged. F₂-isoprostanes were increased by CLA (Δ146.96±19.49 pg/ml Crea, p<0.001). This alteration differed from all other groups (p<0.001).

Conclusion: These results suggest that CLA induces beneficial metabolic effects. The fasting endothelial function remained constant and was postprandially even improved by CLA. The impact of increased F₂-isoprostane levels needs to be clarified.

0842

Subjects affected by central obesity are resistant to the platelet antiaggregating effects exerted by the AMP-activated protein kinase (AMPK) via nitric oxide

I. Russo, P. Del Mese, G. Doronzo, P. Poy, L. Mattiello, M. Trovati, G. Anfossi;

Department of Clinical and Biological Sciences, University of Turin, Orbassano Italy.

Background and Aims: We previously observed that platelets from patients affected by central obesity -a condition characterised by an increased atherothrombotic risk- are resistant to the anti-aggregating effects of insulin, nitric oxide and prostacyclin. This study aims to present new molecular aspects of the reduced platelet sensitivity to anti-aggregating agents observed in central obesity. AMP-activated Protein Kinase (AMPK) is an intracellular enzyme system which acts as a sensor of cell energy balance and it is involved in the cell signalling of the adipocytokines leptin and adiponectin and in the mechanism of action of the insulin sensitiser metformin and thiazolidinediones. Aim of this study is to investigate whether AMPK influences platelet function by evaluating the effect of a specific AMPK activator on the ADP-induced aggregation and on the nitric oxide (NO)/cGMP/PKG/VASP pathway in platelets from lean subjects and patients affected by central obesity. It is known that NO increases cGMP production, and cGMP, via the cGMP-dependent Protein Kinase (PKG), phosphorylates VASP, a protein deeply involved in platelet anti-aggregation.

Materials and Methods: Platelet-rich plasma and washed platelets were obtained from 18 lean (7 M, 11 F; age:33.2±1.4 yrs; BMI: 22.2±0.4 kg/m²; waist circumference 81.2±1.4cm; HOMA IR: 1.3±0.3) and 10 obese subjects (4 M, 6 F; age: 36.3±2.8 yrs; BMI: 33.5±1.9; waist circumference 108.9±2.1cm; HOMA IR: 5.1±0.9). In platelet samples incubated for 10 min with the AMPK activator 5-amino-4-imidazolecarboxamide riboside phosphate (AICAR;0.01–1mmol/l) we evaluated: i) the response to 4 µmol/l ADP both in the absence and in the presence of the specific AMPK inhibitor Compound C (5 µmol/l) and of NO synthase (eNOS) inhibitor L-NAME (100 µmol/l); ii) the phosphorylation of eNOS at Ser¹¹⁷⁷ and of Vasodilator-Stimulated Phosphoprotein (VASP) at Ser²³⁹ (cGMP-dependent) (Western blots with monoclonal antibodies).

Results: AICAR decreased platelet response to ADP in a concentration-dependent way in lean subjects (IC-50:0.81±0.16 mmol/l) but not in obese subjects (IC-50 not detectable). In lean subjects, the effect of AICAR (1mmol/l) on ADP-induced aggregation was significantly reduced by Compound C (Maximal aggregation:78.0±16.0 vs. 35.6±9.6 with AICAR alone; p<0.05) and by L-NAME (Maximal aggregation:74.8±13.9 vs. 35.6±9.6 with AICAR alone; p<0.05). Platelet exposure to AICAR induced phosphorylation of eNOS at Ser¹¹⁷⁷ and of VASP at Ser²³⁹ both in lean and in obese subjects; at each concentration AICAR, however, the effect was much lower in platelets from obese subjects as far as phosphorylation of both eNOS and VASP are concerned.

Conclusions: In platelets from lean, insulin sensitive subjects AICAR exerts antiaggregating effects through activation of the NO/cGMP pathway via eNOS phosphorylation. These effects were deeply reduced in obese subjects, likely owing to a reduced AMPK-induced phosphorylation of NOS and, consequently, a reduced NO-dependent activation of the cGMP/PKG/VASP pathway. These results suggest that AMPK exerts antiaggregating mechanisms via endogenous NO. The lack of sensitivity to AMPK effects in obese subjects can be involved in their increased atherothrombotic risk.

Thrombocyte surface P-selectin, soluble P-selectin levels and the formation of microparticles of thrombocyte origin in relation to the intima media thickness of the carotid artery in obesityÉ. Csongrádi¹, B. Nagy², A. Juhász¹, Z. Karányi¹, J. Kappelmayer², G. Paragh¹, M. Káplár¹;¹Ist. Department of Internal Medicine, ²Department of Clinical Biochemistry and Molecular Pathology, University of Debrecen, Hungary.

Background: Increased thrombocyte activation analogous to type 2 diabetes mellitus and the shift in prothrombotic coagulation is observed in relation to obesity. While the role of thrombocyte hyperfunction in the formation of atherosclerosis is known, in obesity it is an important risk factor of type 2 diabetes mellitus that is rarely examined. A sensitive marker of thrombocyte activation is P-selectin. Soluble P-selectin levels vary in healthy individuals in accordance with T715P polymorphism; according to literature data the protective effect of lower levels associated with the homo- and heterozygote forms is presumed in atherosclerotic processes. The hemostatic effect of microparticles dislodging from thrombocytes can be considerable in the formation of thrombus and inflammatory processes.

Aim: To determine the activation of thrombocytes and the number and activity of microparticles of thrombocyte origin. To determine the correlation between thrombocyte activation parameters, vascular risk factors and intima media thickness of the carotid artery, as well as the examination of the influence of T715P polymorphism of P-selectin on these factors.

Patients and methods: In our examination 142 obese patients (age: 41.6 ± 11.1 years; BMI: 37.8 ± 7.83 kg/m²) and 64 healthy control individuals (age: 38.5 ± 10.0 year; BMI: 22.1 ± 1.97 kg/m²) were involved. The examination of the thrombocyte surface P-selectin, the number of microparticles of thrombocyte origin and the microparticles expressing P-selectin too were investigated by cytometric flow analysis using monoclonal antibodies. The soluble P-selectin was determined by the ELISA procedure. The genotype examination was carried out by PCR-RFLP analysis.

Results: The thrombocyte surface and soluble P-selectin levels in obesity were significantly increased ($p < 0.05$), in contrast to the control group (median and quartile values of surface P-selectin: obese group: 1.29 (0.70–2.24) %, control: 0.75 (0.40–1.21) %; soluble P-selectin: obese group: 44.9 (38.7–55.0) ng/ml, control: 36.0 (25.1–48.6) ng/ml). The number of microparticles of thrombocyte origin (obese group: 82.0 (52.0–136.0)/μl, control: 48.5 (21.0–73.0)/μl) as well as the number of activated microparticles (obese group: 34.0 (18.0–59.0)/μl, control: 16.5 (8.0–26.0)/μl) were significantly higher in the obese group compared to the control group also. Both the thrombocyte activation parameters and the microparticles of thrombocyte origin showed a significant positive relation to waist circumference, BMI, CRP and HbA_{1c} values. We found a significant positive correlation between the thrombocyte surface P-selectin and the intima media thickness of the carotid artery. In the homo- and heterozygote forms of T715P polymorphism the soluble P-selectin levels was significantly lower in comparison to the wild type; this difference could not be observed in obesity.

Conclusions: Our results show the close relationship between increased thrombocyte activity and intima media thickness, which highlights the higher risks of developing vascular complications. In obesity the presumed protective effect of soluble P-selectin levels in relation to P-allele could not be observed as compared to healthy individuals.

0844

Gender-specific hypertriglyceridaemic waist phenotype significantly associates with glycosylated haemoglobin (HbA_{1c}) in subjects with normal glucose tolerance and perfectly normal HbA_{1c} values

E. Voidonikola, C. Papamichael, K. Stamatelopoulos, A. Protogerou, G. Kollias, E. Chrysoschoou, N. Zakopoulos, M. Alevizaki, M. Theodorakis; Dept. Clinical Therapeutics, University of Athens Medical School, Athens, Greece.

Background and Aims: Much attention has been drawn to the association between phenotype characteristics of subjects exhibiting features of the metabolic syndrome and its functional correlates that could translate into earlier detection of populations at risk by using readily available markers. Waist circumference (WC), especially of the “hypertriglyceridemic” phenotype has recently emerged as a key determinant of augmented propensity towards

cardiovascular morbidity later in life as it strongly associates with early manifestations of coronary artery disease in patients with impaired glucose tolerance and type 2 diabetes. We sought to investigate this relationship further in euglycemic subjects with perfectly normal values of glycosylated hemoglobin (HbA_{1c})

Materials and Methods: We screened 352 healthy volunteers, without concurrent disease or history for diabetes, hypertension, dyslipidemia and on no medications by carrying out an OGTT for 2 hours with two blood samples per subject (baseline and 2 hours post-glucose (75 grams) ingestion). From those we recruited 252 subjects (100 men and 152 women, age 46±1 yrs, BMI 25±1, WC 85±1 cm), who all had normal glucose tolerance (both fasting and 2h-plasma glucose levels were <100 mg/dl (88±1) and <140mg/dl (99±2), respectively, for assessment of features of the metabolic syndrome according to the latest IDF definition.

Results: In the population as a whole, waist circumference, plasma triglyceride (TG) concentration and the homeostatic model assessment (HOMA-IR) insulin resistance index, significantly associated with glycosylated hemoglobin across its normal range of values ($r^2=0.045$; $p=0.0009$, $r^2=0.051$; $p=0.0003$, and $r^2=0.035$; $p=0.003$, respectively). This association was also retained when we only looked at men or women (men: ($r^2=0.061$; $p=0.0016$, $r^2=0.12$; $p=0.0006$, and $r^2=0.088$; $p=0.0041$ – women: $r^2=0.032$; $p=0.0030$, $r^2=0.041$; $p=0.0012$, and $r^2=0.028$; $p=0.003$, respectively). Also, when the IDF-defined WC cut-off points were applied, apart from the TG and HOMA-IR, only HbA_{1c} was significantly different between groups, both in women (4.70±0.04 vs. 4.83±0.05; $p < 0.05$ for women with a WC <82 or > 82 cm, respectively) and in men (4.74±0.05 vs. 4.93±0.09; $p < 0.0001$ for men with a WC <90 or > 90 cm, respectively). Fasting and 2h- plasma glucose, insulin, total-, HDL- and LDL cholesterol, and arterial blood pressure did not differ between groups within genders.

Conclusion: In otherwise healthy non-obese individuals with perfectly normal glucose tolerance and HbA_{1c}, emergence of elements of the hypertriglyceridemic waist phenotype (increased waist circumference, elevated plasma triglyceride levels) and the insulin resistance index strongly associate with increasing values even within its normal range. An HbA_{1c} value of 4.7 appears to be on the critical threshold. Detecting altered HbA_{1c} might therefore be of particular significance early in the pathophysiology of insulin resistant states such as the metabolic syndrome.

0845

Evaluation of TNFα, IL-6 and adiponectin in obese patients with and without obstructive sleep apnea syndrome (OSAS)E. Benetti¹, C. Baldessari², B. Masserini¹, L. Sburlati¹, F. Donadio¹, M. E. Lunati¹, R. Bossi², P. Beck-Peccoz¹, E. Orsi¹;¹Department of Medical Sciences, Endocrine and Diabetologic Unit, University of Milan, Fondazione IRCCS Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, ²Department of Cardiovascular and Respiratory Disease, Center of Sleep Respiratory Disorders, University of Milan, Fondazione IRCCS Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy.

Background and Aims: The prevalence of OSAS among obese patients is 40–50% and these patients have an increased risk of myocardial infarction, stroke and mortality as compared to those without OSAS. Aim of the study was to investigate if an increased cardiovascular risk could be explained by altered inflammatory response and reduced adiponectin levels.

Materials and Methods: 46 obese patients (24 F, 22 M, age 54±10 yrs, BMI 38.5±6.1 kg/m²) were evaluated for the presence of OSAS (polysomnography), anthropometric parameters, biochemical parameters (lipid profile, HbA_{1c}, urate, HOMA-IR, oral glucose tolerance test, adiponectin, TNFα, IL-6).

Results: according to polysomnography results, patients were subdivided in two groups: I. OSAS (n=25, age 55.2±12.9 yrs, BMI 39.6±7.1 kg/m²), II. non OSAS (n=21, age 55.4±9.6 yrs, BMI 37.5±4.7 kg/m²). Group I shown higher level of apnea/hypopnea index (AHI) (40.62±27.51 vs. 1.54±1.37, $P < 0.0001$), waist circumference (121.5±14.5 vs. 113.3±10.3 cm, $P < 0.05$), HOMA-IR (6.1±5.07 vs. 5.02±2.96, $P < 0.05$), IL-6 (9.33±2.4 vs. 5.77±2.14 ng/ml, $P < 0.001$), TNFα (68.18±13.41 vs. 50.75±15.42 pg/ml, $P < 0.001$) and lower levels of total cholesterol (200.62±57.92 vs. 231.25±36.86 mg/dl, $P < 0.05$) and adiponectin (7.3±2.93 vs. 9.25±3.87 mg/L, $P < 0.05$) than Group II. No difference in the other parameters between the two groups was observed. Moreover, we observed a negative correlation between adiponectin levels and AHI, a positive correlation between IL-6 and AHI and between TNFα and

AHI. No correlation between HOMA-IR and TNF α and IL-6 was found. In a subgroup of 13 OSAS patients adiponectin, IL-6 and TNF α was evaluated also after one whole night Continuous Positive Air Pressure therapy. No differences in adiponectin levels were observed, but a significant reduction in TNF α and IL-6.

Conclusion: the present study shows altered inflammatory response in OSAS patients characterised by elevated cytokine levels and insulin-resistance and reduced adiponectin level. Therefore, hypoxia seems to be an additional factor to cause alterations of cytokine levels, but its role is less clear about adiponectin. These metabolic features contribute to the elevated cardiovascular risk and mortality in patients with OSAS.

Insulin resistance and aminoterminal pro-brain natriuretic peptide (NT-proBNP) is associated with sleep-disordered breathing in morbid obesity

J. Ybarra¹, F. Planas², E. Escudero³, C. Ballesta-Lopez², M. Isart², S. Torrejon⁴, J. Jurado⁵, J. Merce³, F. Navarro-Lopez², J. M. Pou⁴; ¹Centro Medico Teknon, Instituto de Cardiología Avanzada y Medicina (ICAMED), Barcelona, ²Instituto Cardiología Avanzada, ICAMED, Centro Medico Teknon, ³Dept. Biochemistry, Autonomous University of Barcelona, Hospital de la Sta. Creu i S. Pau, ⁴Dept. Endocrinology and Nutrition, Autonomous University of Barcelona, Hospital de la Sta. Creu i S. Pau, ⁵Primary Care Center, Catalan Health Institute, Olot, Girona, Spain.

Background and Aims: Sleep-disordered breathing and obstructive sleep apnea are encountered in morbid obesity (MO) patients in conjunction with insulin resistance and several cardiovascular risk factors. Aminoterminal pro-brain natriuretic peptide (NT-proBNP) is secreted by myocytes in the ventricular wall in response to increased wall stress stands and could become a promising marker for left ventricular dysfunction. We wanted to explore the relationships between NT-proBNP in morbid obesity patients with sleep-disorders breathing and obstructive sleep apnea (SDB) and other parameters as hypertension and insulin resistance.

Materials and Methods: Cross-sectional pilot-study involving 110 MO young female patients which underwent a detailed clinical, biochemical and echo-cardiography study and completed the Berlin Questionnaire (BQ) to assess risk of SDB pre-operatively (bariatric surgery). Insulin Resistance (IR) was assessed using fasting insulin concentrations (IRI). Echo-cardiograms were performed to quantify ejection fraction values (EF), cardiac output (CO), left ventricular mass (LVM), inter-ventricular (IVWTh) and posterior wall thickness (PWTh) and LV diastolic indexes such as the Em/Am and E/Em ratios, left atria size (LA), and inter-ventricular relaxation time (IVRT). Serum NT-proBNP was measured using an electrochemiluminescence immunoassay (Elecsys[®], Roche Diagnostics, Indianapolis, Inc.).

Results: Age=37.4 \pm 1.0, BMI=45.5 Kg.m⁻². Hypertension and type 2 diabetes mellitus prevalence averaged 25 and 4% (respectively). Log-transformed NT-proBNP levels correlated with log IRI ($r=-0.208$; $P=0.023$) and BQ categories ($r=0.492$; $P<0.0005$) and the relationship was even more robust if only hypertensive participants were considered ($r=0.618$; $P=0.008$). All patients disclosed normal EF. NT-proBNP levels, diastolic indexes and LVMI increase significantly along with BQ categories ($P<0.0001$). Stepwise multiple regression analysis identified log IRI and BQ as the independent variables predicting as much as 43.6% of log-transformed NT-proBNP's variability (dependent variable).

Conclusion: Sleep-disordered breathing worsens along with left ventricular hypertrophy and diastolic dysfunction. NTpro-BNP levels increase proportionally with SDB and are independently predicted by insulin resistance and the BQ score in female MO patients. Larger prospective trials are warranted.

Variability of nocturnal glycaemia related to severity of sleep apnea in type 2 diabetics: results of continuous glucose monitoring

M. Pallayova, V. Donic, Z. Tomori; Department of Physiology and Sleep Laboratory, Faculty of Medicine, PJ Safarik University, Kosice, Slovakia.

Background and Aims: It is suggested that severe sleep-disordered breathing (SDB) with recurrent episodes of airflow obstruction and hypoxemia may adversely affect glucose control in patients who also suffer from type 2 diabetes. Our aim was to assess and evaluate nocturnal glycemic variability in type 2 diabetics with various degrees of SDB using the continuous glucose monitoring system (CGMS; Medtronic MiniMed).

Materials and Methods: Twenty-nine type 2 diabetic patients on diet/oral hypoglycemic therapy (19 men, 10 women; mean age 55.41 \pm 7.5years, BMI 35.64 \pm 8.46, duration of diabetes 3.14 \pm 1.48years, HbA1c/HPLC method 6.85 \pm 0.98%) were tested for SDB using sleep questionnaire, ApneaLink sleep screener with oximetry (ResMed), and/or overnight polysomnography (Alice 3; Respironics). Subjects were divided according to their apnea-hypopnea index (AHI) into three groups: [A] normal with an AHI<10/h, [B] with mild to moderate sleep apnea and AHI greater than or equal to 10/h but less than or equal to 25/h, and [C] with severe sleep apnea and AHI>25/h. All patients were monitored using the CGMS. Overnight glucose standard deviation (SD) and mean of nocturnal glucose differences (MOND) were used to assess the degree of glycemic variability during the night. The secondary parameters assessed included AHI and mean nocturnal glucose levels. The differences between groups were tested using ANOVA.

Results: 86 nocturnal CGMS glucose profiles (mean length of sensor wear 82.72 \pm 31.96h; correlation coefficient 0.89 \pm 0.15; mean absolute difference 11.96 \pm 6.0%) showed the most stable overnight glucose control in [A] (n=15; 46 nocturnal CGMS profiles; AHI<10/h; BMI 31.73 \pm 8.26, HbA1c 6.41 \pm 0.68%) with overnight glucose SD 0.41 \pm 0.13 and MOND 1.7 \pm 0.57mmol/l. Less stable diabetes control was found in [B] (n=6; 19 nocturnal CGMS profiles; AHI 12.73 \pm 3.56/h; BMI 39.53 \pm 7.5, HbA1c 7.4 \pm 1.09%) with overnight glucose SD 0.63 \pm 0.22 and MOND 2.52 \pm 0.77mmol/l. The most labile nocturnal glucose control was observed in [C] (n=8; 21 nocturnal CGMS profiles; AHI 42.08 \pm 21.65/h; BMI 40.04 \pm 6.48, HbA1c 7.26 \pm 1.1%) with overnight glucose SD 1.05 \pm 0.53 and MOND 4.07 \pm 2.12mmol/l. ANOVA showed significant differences in overnight glucose SD between [A] and [B] ($p=0.0015$), [A] and [C] ($p<0.0001$), and significant differences in MOND between [A] and [B] ($p=0.0036$), and [A] and [C] ($p<0.0001$). Mean nocturnal glucose values were significantly higher in [C] as compared to [A] (9.01 \pm 1.74mmol/l vs. 5.84 \pm 1.03mmol/l; $p<0.0001$) and significantly higher in [B] as compared to [A] (8.51 \pm 2.42mmol/l vs. 5.84 \pm 1.03mmol/l; $p<0.0001$). Despite no significant difference neither in mean nocturnal glycemia nor in HbA1c between [B] and [C], ANOVA showed significant differences in MOND and in overnight glucose SD between these groups (both $p<0.0001$) indicating that HbA1c and average glucose levels does not provide information about fluctuations or peaks in glycemia.

Conclusion: Although glucose variability is usually less pronounced in type 2 diabetic patients in whom endogenous insulin secretion exists, our CGMS results indicate that sleep apnea in type 2 diabetics may lead to enhanced nocturnal glycemic variability, which increases with increasing severity of SDB, as compared to type 2 diabetic state without sleep apnea. Glucose variability seems to be an important feature of a nocturnal glucose pattern distinguishing between type 2 diabetics with and without sleep apnea.

Efficacy and safety of continuous, intravenous glucagon-like-peptide 1 (GLP-1) in comparison to insulin infusion for normalisation of hyperglycaemia in patients with type 2 diabetes

I. Schmoelzer, E. Kettler-Schmutt, H. Pressl, H. Sourij, T. C. Wascher; Diabetic Angiopathy Research Group, Medical University, Graz, Austria.

Background and Aims: In critical situations such as acute vascular events or during surgery normalisation of glucose concentrations should be obtained in patients with type 2 diabetes. Usually it is tried to achieve normoglycemia by continuous intravenous administration of normal human insulin (NHI) at a glucose concentration-driven, variable dose. This treatment demands manpower-intensive tests of glycemia with subsequent adjustment of insulin dose and hypoglycaemia may occur as a side effect of therapy. Glucagon-like-Peptide-1 (GLP-1) lowers plasma glucose by a glycemia-dependent stimulation of pancreatic insulin secretion and continuous administration of fixed doses of GLP-1 normalise blood glucose in type 2 diabetic without any reported hypoglycaemia. Efficacy of both therapies in comparison has not been investigated before. The aim of the present study was to compare an established treatment regimen of intravenous normal insulin in variable doses with continuous intravenous GLP-1 infusion (1.2 pmol/kg/min).

Materials and Methods: 8 patients with type 2 diabetes were included in this prospective, open, randomised study. Each subject participated in two examinations separated by 3 days. 30 minutes after a standardised breakfast they were treated either with a dose-adapted infusion of normal insulin or continuous infusion of GLP-1 (1.2 pmol/kg/min) over a period of 8 hours. Serum samples for determination of glucose and insulin were drawn every 30 minutes. Following parameters were targeted: maximum glycemia, glycemia after 2 and 4 hours and time until glycemia <115 mg/dl. Statistical analyses were done with ANOVA for repeated measurements and paired student's t-test. All data are MW±SD, level of significance was defined as $p < 0.05$.

Results: Blood glucose levels before start of therapy were comparable on both examination days (NHI: 252 ± 42 , GLP-1 244 ± 24 mg/dl; ns). Maximum glycemia (312 ± 51 vs. 254 ± 48 mg/dl; $p = 0.007$) and glycemia after 2 (208 ± 51 vs. 137 ± 48 mg/dl; $p = 0.012$) and 4 hours (155 ± 51 vs. 116 ± 27 mg/dl; $p = 0.021$) were significantly lower under therapy with GLP-1. Time until achievement of glycemia <115 mg/dl was 252 ± 51 minutes under GLP-1 treatment and 321 ± 43 minutes under therapy with normal insulin ($p = 0.008$). After the observation period of 8 hours glycemia was comparable in both groups (NHI: 110 ± 24 , GLP-1: 103 ± 22 mg/dl; ns). Under treatment with NHI we observed one symptomatic hypoglycaemia (48 mg/dl), under GLP-1 no hypoglycaemia occurred.

Conclusion: Both, intravenous infusion of normal insulin as with GLP-1 infusion effectively normalise glycemia in type 2 diabetic patients. Achievement of normoglycemia, however, is faster and no dose adjustments are needed by use of GLP-1. Therefore we conclude that intravenous application of GLP-1 is a safe and effective alternative to intravenous NHI.

Pharmacokinetics and pharmacodynamics of exenatide long-acting release after single- and multiple-dosing

L. MacConell¹, K. Taylor¹, D. Zhuang¹, P. Kothare², K. Mace², W.-I. Li³, S. Flanagan¹, M. Fineman¹;

¹Amylin Pharmaceuticals, Inc., San Diego, United States,

²Eli Lilly and Company, Indianapolis, United States,

³Alkermes, Inc., Cambridge, MA, United States.

Background and Aims: Glucagon-like peptide-1 (GLP-1) is an incretin hormone secreted by the gut in response to ingestion of food. It has several effects, including stimulating glucose-dependent insulin secretion and reducing appetite. The incretin mimetic, exenatide, shares several effects with GLP-1, leading to improved glycaemic control. Current studies assessed the pharmacokinetics (PK) and pharmacodynamics (PD) of single and repeated weekly subcutaneous injections of exenatide long-acting release (LAR) formulation in patients with type 2 diabetes (T2DM).

Materials and Methods: 62 and 45 patients with T2DM were treated in single and repeat dose exenatide LAR trials, respectively. Single dose patients received LAR (2.5 mg, 5.0 mg, 7.0 mg or 10.0 mg) or placebo (PBO). Doses were escalated based on safety and tolerability of the preceding lower dose. Weekly dose PK was predicted from non-parametric superposition of single dose data. Weekly dose patients received LAR (0.8mg or 2.0mg, targeting the low and high concentrations achieved by therapeutic doses of exenatide BID) or PBO for 15 weeks. Plasma exenatide, fasting (FPG) and postprandial plasma glucose (PPG), and body weight were assessed. Data were analysed non-compartmentally.

Results: Plasma exenatide concentrations were measurable for approximately 9 weeks after a single injection; exposure increased dose dependently. Reductions in FPG and PPG correlated with increasing exenatide concentrations. Repeat doses of LAR predicted plasma exenatide concentration profiles consistent with observed data. Weekly dosing yielded mean steady-state exenatide plasma concentrations spanning the targeted therapeutic range, leading to significant reductions in mean PPG and body weight with 2.0mg LAR. Mean FPG was significantly reduced independent of dose. Generally, adverse events were transient and mild to moderate in intensity.

Conclusion: Single dose PK supported and predicted weekly dose PK. Weekly LAR doses targeting the therapeutic exenatide plasma concentration range were well tolerated. Dose-dependent effects on PPG and body weight, but not FPG, suggested differential exposure-response relationships across the pharmacology of exenatide. These data indicated LAR prolonged the rate of exenatide delivery to the circulation, while retaining the PD action of exenatide.

Pharmacokinetic modelling of the once-daily human glucagon-like peptide-1 analogue, liraglutide, in healthy volunteers and comparison to exenatide

D. M. Jonker, E. Watson, A. D. Toft, P. Kristensen, L. B. Knudsen, S. H. Ingwersen;

Novo Nordisk A/S, Bagsvaerd, Denmark.

Background and Aims: Glucagon-like peptide-1 (GLP-1) is an incretin hormone that has been shown to stimulate insulin secretion in a glucose-dependent manner, to inhibit glucagon secretion and to delay gastric emptying. These are promising properties for treatment of type 2 diabetes. Liraglutide is a long-acting human GLP-1 analogue that was designed to be eliminated considerably slower than the natural hormone. The aim of this modelling was to develop a pharmacokinetic model on available data on liraglutide and exenatide in man, and thereby compare their pharmacokinetic properties.

Material and Methods: The pharmacokinetics of liraglutide were studied in 72 healthy male subjects using a dose escalation design. Each subject received a single sc injection of 1.25 up to 20 µg/kg liraglutide or vehicle and 22 venous blood samples were collected up to 48 hours after dosing. A population-based modelling approach was taken to describe the time course of liraglutide concentrations and its between-subject variability (BSV) using NONMEM V. During model building, goodness-of-fit was assessed by the objective function value and a range of graphical procedures. The estimates from the final model were used to generate a predicted PK profile for once daily sc dosing. Similarly, a PK profile for twice daily sc dosing of exenatide was generated from literature data.

Results: The absorption of liraglutide following subcutaneous (sc) administration was slow, with peak concentrations occurring at 9–12 hours post-dosing. Liraglutide absorption was adequately described by a dose proportional zero order process and a subsequent first order process. A one-compartment model with a central volume amounting to 0.086 L/kg (rSE 11%, BSV 33%) was estimated, showing that after absorption, liraglutide is mainly confined to the central circulation. Clearance was independent of dose and was estimated to be 0.0060 L/hr/kg (rSE 6.8%, BSV 13%). The mean elimination half-life after sc dosing was 13 hr (by non-compartmental analysis). The absolute bioavailability was found to be 51% (rSE 8%, BSV 30%). The Figure shows the PK profiles for 20 µg/kg liraglutide once daily sc (solid line) and for 10 µg/kg exenatide twice daily sc (dashed line).

Conclusion: The model and data demonstrate suitable pharmacokinetic properties for 24h-coverage with once daily sc administration of liraglutide. In addition, the PK profile of once daily liraglutide was found to have a lower peak to trough variation than that of twice-daily exenatide.

The long-acting human GLP-1 analogue liraglutide given once daily significantly improves glycaemic control by reducing fasting and post-prandial glucose levels in subjects of Japanese origin with type 2 diabetes

Y. Seino¹, K. Kaku², K. Nishijima³, M. F. Rasmussen⁴, M. Zdravkovic⁴, P. Kristensen⁴;

¹Division of Diabetes and Clinical Nutrition, Kansai-Denryoku Hospital, Osaka, Japan, ²Endocrinology, Kwasaki Medical School, Okayama, Japan,

³Novo Nordisk Pharma Ltd, Tokyo, Japan,

⁴Novo Nordisk A/S, Bagsvaerd, Denmark.

Background and Aims: In this 14-week study we assessed the efficacy and safety of the long-acting daily GLP-1 analogue liraglutide in 226 Japanese subjects with type 2 diabetes treated with diet (54%) or a single oral anti-diabetic drug.

Material and Methods: Subjects were randomised after an 8-week wash out period to four doses of liraglutide (0.1, 0.3, 0.6 and 0.9 mg) or placebo. The two highest doses were reached by weekly increments of 0.3 mg until final dose was reached.

Results: HbA_{1c} decreased dose-dependently in all treatment groups compared to placebo from a baseline value of 8.3% by -0.8, -1.2, -1.6 and -1.9%, respectively ($p < 0.0001$). HbA_{1c} <7.0% was achieved by 22, 43, 62 and 75% of the subjects in the liraglutide groups compared to 9% in the placebo group. A dose-dependent decrease of fasting plasma glucose by -14, -23, -41, and -45 mg/dL vs. placebo, respectively ($p < 0.0001$) was seen and postprandial glucose (2 h post-meal) decreased by -26, -51, -76 and -94 mg/dL, respectively compared to placebo. Liraglutide was well tolerated and there were no reports of major or minor hypoglycaemic events. Main gastrointestinal system adverse events in the high dose group vs. placebo were: constipation 7% vs. 9%; diarrhoea 9% vs. 4%; gastritis 7% vs. 0%; nausea 7% vs. 2%. No increase in liraglutide antibodies was seen.

Conclusion: Liraglutide given once-daily as monotherapy improves glycaemic control by reducing fasting and post-prandial glucose levels without risk of major or minor hypoglycaemia in Japanese subjects with type 2 diabetes and is well tolerated.

Pharmacokinetics of the long-acting human GLP-1 analogue liraglutide in subjects with renal impairment

L. V. Jacobsen¹, C. Hindsberger¹, R. Robson², M. Zdravkovic¹;

¹Novo Nordisk A/S, Bagsvaerd, Denmark,

²Christchurch Clinical Studies Trust, Christchurch, New Zealand.

Background and Aims: Liraglutide is a long-acting GLP-1 analogue to be used as a once-daily treatment in patients with type 2 diabetes.

Materials and Methods: The effect of renal impairment on the pharmacokinetics (PK) of liraglutide was investigated in a single centre, open label trial. Six subjects with normal renal function (creatinine clearance >80 mL/min), 6 with mild renal impairment (>50–<80 mL/min), 7 with moderate (>30–<50 mL/min), 5 with severe renal impairment (<30 mL/min) and 6 subjects with end-stage renal disease requiring dialysis entered the trial. All subjects received a single 0.75 mg sc dose of liraglutide and completed a 72-h blood sampling period for plasma liraglutide concentrations. An ANOVA of the log transformed PK endpoints adjusted for renal group, age and log (weight) was performed. Equivalence was declared if the 90% CI for an endpoint ratio was contained in the interval 0.70 to 1.43.

Results: While the comparison between subjects with normal renal function and severe renal function did not show equivalence ($AUC^{severe}/AUC^{normal}$ ratio: 0.73 [90% CI: 0.57–0.94]) a regression analysis on the other hand failed to show a significant effect of decreasing creatinine clearance on AUC of liraglutide. Furthermore, the expected AUC ratio (based on the regression model) between two subjects with the lowest (severe) and highest (normal) creatinine clearance in the study (132 and 14 mL/min) with the same age and weight was estimated to be 0.88 [95% CI: 0.58–1.34] (NS). The comparison between subjects with normal renal function and subjects in dialysis showed an estimated $AUC^{dialysis}/AUC^{normal}$ ratio of 0.74 [90% CI: 0.56–0.97]. The liraglutide concentration in urine and in dialysis fluid was negligible. The degree of renal impairment did not appear to be associated with increased risk of adverse events.

Conclusion: Patients with diabetes and renal impairment should use standard treatment regimens of liraglutide and be dosed according to their glycaemic control.

0853

Predictors of achieving glycaemic targets in patients with type 2 diabetes treated with exenatide or insulin

R. Brodows¹, D. Milton¹, J. Mao¹, M. Wintle², M. Trautmann¹;

¹Eli Lilly and Company, Indianapolis, United States,

²Amylin Pharmaceuticals, San Diego, United States.

Background and Aims: In two comparator trials (10µg exenatide BID vs. either insulin glargine or biphasic insulin aspart), both exenatide and insulin treatment achieved similar reductions in HbA_{1c} for approximately 6 months, while exenatide was associated with weight reduction and insulin was associated with weight gain. The aim of this analysis was to identify characteristics associated with achievement of glycaemic targets in the pooled sample of patients.

Materials and Methods: Data were pooled from these two studies (N=1050) to examine whether patients' baseline characteristics (HbA_{1c}, fasting serum glucose [FSG], weight, age, duration of diabetes, origin, and gender) were associated with an endpoint HbA_{1c} of ≤6.5% and ≤7%, for exenatide or insulin treatment on background of metformin (MET) and a sulphonylurea (SU).

Results: Mean (±SD) baseline HbA_{1c} (8.4±1.0%) was similar for both treatment groups, and treatment was not a significant predictor for achieving an HbA_{1c} ≤7%. However, exenatide-treated patients were 1.69 (odds ratio, 95% CI 1.21–2.35, $p=0.002$) times more likely to have achieved an HbA_{1c} ≤6.5% than insulin-treated patients. In the exenatide group, lower baseline HbA_{1c} (odds ratio 0.40 [95% CI 0.29–0.54]) and lower baseline FSG (odds ratio 0.87 [95% CI 0.78–0.96]) were significant predictors for achieving HbA_{1c} ≤6.5%; lower baseline HbA_{1c} (odds ratio 0.47 [95% CI 0.36–0.62]), lower baseline FSG (odds ratio 0.87 [95% CI 0.79–0.96]), and older age (odds ratio 1.04 [95% CI 1.01–1.06]) were significant predictors for achieving HbA_{1c} ≤7%. For insulin patients, lower baseline HbA_{1c} was the only significant factor associated with reaching an HbA_{1c} ≤6.5% (odds ratio 0.36 [95% CI 0.27–0.50]) or HbA_{1c} ≤7% (odds ratio 0.30 [95% CI 0.23–0.40]).

Conclusion: In patients with type 2 diabetes failing on SU and MET for whom the next step may be insulin, exenatide treatment was associated with a greater percentage of patients achieving an HbA_{1c} ≤6.5% than insulin, with no increase in overall hypoglycaemia. In these trials, exenatide was associated with a lower rate of nocturnal hypoglycaemia and mean weight reduction, while insulin patients gained weight. Irrespective of treatment, a lower baseline HbA_{1c} value was associated with a higher probability of achieving glycaemic targets.

Potent antidiabetic effects of rivoglitazone, a novel PPAR γ agonist, in obese diabetic rodent models

J. Ohsumi, S. Kanda, J. Tanaka, K. Takahashi, R. Nakashima, N. Koieyama, Y. Hagsiwa, K. Araki;
Biological Research Laboratories II, Daiichi Sankyo Co., Ltd., Tokyo, Japan.

Background and Aims: Rivoglitazone (Rivo) is a novel peroxisome proliferator-activated receptor γ (PPAR γ) agonist. The antidiabetic effects of Rivo were characterised and compared with the effects of rosiglitazone (Rosi) and pioglitazone (Pio) in Zucker Diabetic Fatty (ZDF) rats and *db/db* mice. Also, the mechanism of action of Rivo was assessed in ZDF rats and non-diabetic Zucker Fatty (ZF) rats.

Materials and Methods: Male ZDF rats and *db/db* mice were orally administered Rivo (0.03–1mg/kg/day), Pio (3–100mg/kg/day) or Rosi (0.3–100mg/kg/day) for 10 or 14 days. Subsequently, plasma glucose (PG), free fatty acid (FFA), triglyceride (TG) and adiponectin levels and pancreatic insulin content were determined. A hyperinsulinemic-euglycemic clamp study was performed in ZF rats given Rivo (0.1mg/kg/day) for 8 days. Also, the effects of Rivo on plasma TG production and clearance, and expression of PPAR α target genes and genes implicated in cardiac function, were assessed in ZF rats and ZDF rats, respectively, with Wy-14,643 (Wy), a PPAR α agonist, as a comparator.

Results: In ZDF rats, Rivo was approximately 100-fold more potent at reducing PG than either Rosi (ED₅₀=0.20 [Rivo] vs. 28mg/kg [Rosi]) or Pio (ED₅₀=0.19 [Rivo] vs. 34mg/kg [Pio]). Rivo also lowered plasma TG and FFA levels, and increased pancreatic insulin content, more potently than either Rosi or Pio. Similarly, in *db/db* mice, Rivo reduced PG and TG over 100-fold more potently than Pio (PG reduction: ED₅₀=0.47 [Rivo] vs. 70mg/kg [Pio]; TG reduction: ED₅₀=0.093 [Rivo] vs. 4.6mg/kg [Pio]) after 14 days of treatment. After 10 days, Rivo was approximately 9-fold more potent at lowering PG than Rosi. Interestingly, in *db/db* mice, Rivo increased plasma adiponectin levels more effectively than Pio. In the hyperinsulinemic-euglycemic clamp study, Rivo increased the glucose infusion rate to 36.6±1.1mg/kg/min compared with 26.0±0.4mg/kg/min in vehicle-treated controls. In ZF rats, Wy and Rivo reduced plasma TG, primarily by decreasing hepatic TG production and by accelerating TG clearance, respectively. Consistent with this, Wy decreased hepatic expression of *Apolipoprotein C-III* (*ApoCIII*; 26±2% of control), and increased expression of PPAR α target genes implicated in fatty acid β -oxidation such as *acyl-coenzyme A oxidase I* (*ACO*; 1054±30%) and *carnitine palmitoyltransferase 1b* (*CPT1b*; 3574±196%) in ZDF rats. Rivo had no detectable effects on the expression of *ApoCIII* and, in contrast to Wy, decreased hepatic expression of *ACO* (72±4%) and *CPT1b* (65±5%). Rivo decreased cardiac expression of *ACO* (66±2% of control), *pyruvate dehydrogenase kinase 4* (10±1%) and *medium chain acyl-CoA dehydrogenase* (46±6%) and increased expression of *glucose transporter 4* (147±8%). Furthermore, Rivo did not alter the expression of genes involved in cardiac function, such as *myosin heavy chain α* and β , or *sarco/endoplasmic reticulum Ca²⁺ ATPase 2*.

Conclusions: In obese diabetic rodents, Rivo modifies glucose and lipid metabolism by enhancing insulin sensitivity without affecting expression of PPAR α target genes. The gene expression profile suggests that Rivo may enhance glucose utilisation and reduces oxidative stress in the diabetic heart. In the models examined, Rivo demonstrated greater potency than both Rosi and Pio, suggesting that it may be more efficacious in clinical practice.

0855

Effect of rosiglitazone and exercise on Na⁺K⁺ATPase function in insulin resistant rat skeletal muscle

S. F. Fraser, S. L. La Vita, S. Lessard, J. A. Hawley;
School of Medical Science, RMIT University, Bundoora, Australia.

Background: Rosiglitazone is an oral antidiabetic drug, that improves hyperglycaemia and hyperinsulinemia in insulin resistant and type 2 diabetic patients via insulin sensitising mechanisms but may also have a detrimental effect on membrane lipids which is integral to the functioning of Na⁺-K⁺-ATPase. Chronic exercise training has been shown to decrease skeletal

muscle insulin resistance in insulin resistant animal models and diabetics as well as upregulate Na⁺-K⁺-ATPase content in healthy skeletal muscle. The main purpose of the present study was to evaluate the effects of rosiglitazone and exercise on Na⁺-K⁺-ATPase function and membrane phospholipids in the skeletal muscle of high fat fed Sprague Dawley rats.

Methodology: Rats were assigned into a high fat (D12330) diet group High Fat (HF), rosiglitazone treatment groups HF Rosi (HF R), while the exercise groups (HFX) and Exercise + Rosi (HFXR) undertook 6 weeks of endurance training on a rat treadmill. Glucose uptake was measured using [¹⁴C]-glucose. Red gastrocnemius (RG) was extracted from the rat hind limb and analysed for 3-O-MFPase activity and [3H]-ouabain binding site content. RG was further analysed for determination of the fatty acid (FA) profile and molecular species composition of phospholipid in the membrane using Electrospray ionisation mass spectrometry.

Results: With insulin stimulation, there was still no significant difference in glucose uptake in RG between HF and HFIns (HF 2.32 ± 0.85 and HFIns 4.11 ± 0.56 mmol.g⁻¹.hr⁻¹), indicating established insulin resistance. There was a significant increase in 3-O-MFPase activity when insulin resistant rats were treated with exercise. Compared to the HF, exercise training caused a significant 58% ($P < 0.001$) and 46% ($P < 0.01$) rise in maximal 3-O-MFPase activity in HFX and HFXR groups respectively (HF 412 ± 27, HFX 652 ± 38 and HFXR 600 ± 24 nmol.min⁻¹.g⁻¹ wet wt). Exercise training had a significant effect on rats with HFX and HFXR showing increases in Na⁺-ATPase content when compared to HF control (HF 307 ± 18, HFX 471 ± 28 and HFXR 549 ± 23 pmol.mg⁻¹ wet wt). The phospholipid fatty acid (FA) composition in RG membranes was determined by measuring the content of individual FA types and representing them as a percentage of the total FA content. Mixed results were shown which potentially impacted in membrane fluidity and membrane bound enzyme function.

Conclusions: The results investigated the effect of a therapeutic dose of Rosiglitazone, and exercise training in high fat fed rats. The most important finding was the positive effect exercise training had on the reduced Na⁺-ATPase capacity found with insulin resistance. Exercise training significantly increased skeletal muscle Na⁺-ATPase content and its corresponding maximal activity but had a mixed effect on the membrane phospholipid profile. Rosiglitazone did not have the same desired effect, furthermore at therapeutic doses, did not have any effect.

Pioglitazone inhibit high-glucose-induced human umbilical vein endothelial cells apoptosis: involvement of intracellular ceramide signaling event

D. Huang¹, M. Lei¹, X. He², E. H. Schuchman³, B. Chen³;
¹Department of Endocrinology, Xiangya Hospital, Changsha, China,
²Department of Human Genetics, Mount Sinai School of Medicine,
New York, United States, ³Modern Analytical Testing Center,
Central South University, Changsha, China.

Background and Aims: Ceramide (CER) is an important second messenger to play a role in the induction of cell apoptosis. Thiazolidinediones has been shown to exert direct effects on vascular cells to potentially retard the atherosclerotic process. The aim of the present study was to examine the effect of pioglitazone on high-glucose-induced apoptosis in human umbilical vein endothelial cells (HUVECs) and the role of the ceramide signal pathway involved.

Materials and Methods: HUVECs were incubated with 5mM, 30mM glucose, and with 30mM glucose+ pioglitazone (0.1,1,10 μ M), 30mM glucose+2 μ M Desipramine, 30mM glucose+10 μ M pioglitazone + 50 μ M exogenous C2-CER, 30mM glucose+10 μ M pioglitazone+ 1U/ml exogenous acidic sphingomyelinase (A-SMase), 30mM glucose+2 μ M Desipramine+50 μ M C2-CER, and with C2-CER(25,50 μ M), A-SMase in a series of concentrations (0.01,0.1,1U/ml) respectively for 24,48h, apoptosis of HUVEC were observed by terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeling (TUNEL) assay, and quantitated by flow cytometry using Annexin-FITC/propidiumiodid(PI)staining. HUVECs were incubated with 5mM, 30mM glucose respectively for 2,4,8,12,16,24h, and with glucose in a series of concentrations (5,10,20,30mM), 30mM glucose+ pioglitazone (0.1,1,10 μ M), 30mM glucose+2 μ M Desipramine respectively for 16h, cellular ceramide (cell membrane fraction and cytosol plus organelle fraction) were detected by liquid chromatography/ion spray ionization tandem mass spectrometry (LC/

MS/MS). HUVECs were incubated with 5mM, 30mM glucose respectively for 0.5,1,2,4,8,12h, and with 30mM glucose+2 μ M Desipramine, 30mM glucose+ pioglitazone (0.1,1,10 μ M) respectively for 2h, intracellular A-SMase activity were determined using the fluorescent substrate BODIPY C12-sphingomyelin and reverse-phase high-performance liquid chromatography (HPLC).

Results: High glucose increase the apoptosis in HUVECs in 48h. Pioglitazone can inhibit the high glucose-induced apoptosis in manner of concentration-dependent in HUVECs, exogenous CER and A-SMase can reverse the inhibition of pioglitazone. Desipramine also shows the same effect on HUVECs as Pioglitazone, exogenous ceramide can reverse the inhibition of Desipramine. Exogenous 50 μ M C2-CER and 1U/ml A-SMase can increase the apoptosis in HUVECs in 48h significantly. High glucose caused a concentration-dependent increase of intracellular ceramide, and the increase in 16h is the most significant, but the contents of membranous ceramide remained unaltered. High glucose caused the increase in the intracellular A-SMase activity, and the increase in 2h is the most significant. Pioglitazone and Desipramine can inhibit both the intracellular A-SMase activity and ceramide increase.

Conclusion: High glucose prominently utilizes the lysosomal acidic SMase-ceramide signal pathway in the induction of apoptosis in HUVECs. Pioglitazone attenuates high glucose-induced HUVEC apoptosis through its inhibition on intracellular A-SMase and ceramide.

Role of adiponectin in thiazolidinedione mediated plasminogen activator inhibitor-1 suppression in type 2 diabetic subjects

W. S. Chow¹, R. L. C. Hoo¹, M. H. Yau¹, A. Xu^{1,2}, H. F. Tse^{1,2}, A. W. K. Tso¹, C. H. Y. Fong¹, S. Tam^{2,3}, L. Chan⁴, K. S. L. Lam^{1,2};

¹Department of Medicine, The University of Hong Kong, China,

²Research Centre of Heart, Brain, Hormone, and Healthy Aging, The University of Hong Kong, China, ³Clinical Biochemistry Unit, Queen Mary Hospital, Hong Kong, China,

⁴Baylor College of Medicine, University of Texas, United States.

Background and Aims: Circulating levels of plasminogen activator inhibitor-1 (PAI-1), which correlate with cardiovascular events in clinical studies, are increased in type 2 diabetes and, by reducing fibrinolysis, may contribute to the increased cardiovascular mortality in patients with type 2 diabetes. Recent studies suggest that plasma PAI-1 levels can be lowered by the thiazolidinedione insulin-sensitizers. In this study, we examined the effect of rosiglitazone, relative to sulfonylurea, on plasma PAI-1 levels, in type 2 diabetic subjects with suboptimal glycemic control. We also investigated whether this beneficial effect was mediated through adiponectin, a fat-derived hormone with various metabolic activities, in clinical and animal studies.

Materials and Methods: The effects of 24-week add-on therapy with rosiglitazone (n=32) or sulfonylurea (n=32) on glycemic control (HbA1c), insulin resistance (homeostasis model assessment, HOMA-IR), circulating PAI-1 level, serum adiponectin, markers of inflammation and oxidative stress were studied in 64 orally treated type 2 diabetic subjects in a randomised controlled trial. We also evaluated the inter-relationship between PAI-1 and adiponectin by using an adiponectin-deficient mouse model and adenovirus-mediated over-expression of adiponectin.

Results: Our clinical data showed that after 24-week add-on therapy, both the rosiglitazone- and sulfonylurea-treated groups had significant reductions in PAI-1 levels (p<0.001 vs. baseline), with the reduction being significantly greater in the rosiglitazone group (p=0.002 vs. sulfonylurea treatment). Stepwise multiple linear regression analysis, including all independent variables with significant changes only in the rosiglitazone group (p<0.05 after Bonferroni correction), showed that only the reduction in plasma fasting glucose and increase in plasma adiponectin levels were independently associated with the reduction in PAI-1 concentration. Consistent with the clinical findings, adipose tissue PAI-1 mRNA expression was significantly decreased in high-fat (HF) induced C57BL/6N mice after rosiglitazone treatment. This suppressive effect on PAI-1 expression was attenuated in high-fat induced adiponectin (ADPN) knockout (KO) mice. Similar trend was observed in its plasma concentration. Plasma glucose concentration, however, was significantly decreased in both HF-C57BL/6N mice and HF-ADPN-KO mice to a similar extent after rosiglitazone treatment. We also found that adenovirus-mediated over-expression of adiponectin alone could

lead to a suppression of adipose tissue PAI-1 expression in both lean and db/db diabetic mice.

Conclusion: Both the human and animal studies showed that, in addition to its glucose-lowering action, rosiglitazone, a thiazolidinedione, can also reduce the prothrombotic tendency in type 2 diabetes by suppressing PAI-1 production, in part via adiponectin.

A one-year follow-up study: comparing the cardiovascular safety of rosiglitazone and metformin with plasma BNP levels and myocardial performance index in type 2 diabetes mellitus

Y. T. Kemal¹, N. G. Demirağ¹, A. Yıldırım², A. Atar², S. T. Eroğlu², A. D. Unal¹, N. B. Tütüncü¹, Z. Bıyıklıoğlu³;

¹Department of Endocrinology and Metabolism, Baskent University,

²Department of Cardiology, Baskent University, ³Department of Biostatistics, Ankara University, Faculty of Medicine, Ankara, Turkey.

Background and Aims: Thiazolidinediones (TZDs) are powerful tools that specifically augment insulin sensitivity and counter insulin resistance in patients with type 2 diabetes mellitus. There has been increasing discussion about whether TZDs affect cardiovascular function, and evidence suggests that those agents exert both negative and positive effects on myocardial performance. We aimed to evaluate the long term effects of rosiglitazone on cardiac functions and fluid dynamics.

Materials and Methods: Thirty-nine type 2 diabetic patients -without any symptoms and findings of heart failure were randomised to three treatment groups after receiving approval from the local Ethical Committee. Group 1 (n=12) received 8mg rosiglitazone per day and performed diabetic diet, group 2 (n=14) received 1700mg metformin per day and performed diabetic diet and group 3 (n=13) only performed diabetic diet. Before the treatment all subjects were evaluated for fasting and postprandial plasma glucose levels, HbA1c, plasma brain natriuretic peptide (BNP) levels, body mass index (BMI) and myocardial performance index (MPI: a parameter of left ventricular global function, measured by tissue Doppler imaging echocardiography). After twelve months all these parameters were repeated. During that 12-month study period, the patients were asked to report any adverse effects and underwent a physical examination and biochemical analyses each month.

Results: Before the treatment there were no significant differences between the groups in the duration of diabetes, HbA1c and BNP levels, body mass index and MPIs. After one year follow-up period plasma BNP levels, interventricular septum and lateral wall MPIs didn't change significantly in all treatment groups (all p>0.05). During the study period no patient exhibited congestive heart failure, elevated levels of liver enzymes or creatinine.

Conclusion: In patients with type 2 diabetes, long term TZD treatment might be as safe as metformin treatment. However, these findings must be supported and strengthened with large scale clinical trials.

Universite de Lausanne, Switzerland, ⁴Internal Medicine, Radboud

University Nijmegen Medical Center, The Netherlands.

Background and Aims: Treatment with thiazolidinedione derivatives (TZD) is associated with fluid retention. Animal studies suggest that TZD-related fluid retention is caused by upregulation of the epithelial sodium channel (ENaC) in the distal part of the nephron. So far, this has not been studied in humans. Besides, several case reports and one clinical trial suggest that TZD-related edema is resistant to loop diuretic therapy, but again, this hypothesis has not been addressed appropriately. Therefore, we investigated both at

the functional and molecular level whether rosiglitazone (RSG) induces furosemide resistance and/or upregulation of ENaC.

Materials and Methods: We conducted a randomised, double blind, placebo-controlled, cross-over study in 12 subjects with insulin resistance, characterised by two features of the metabolic syndrome but with normal glucose intolerance. Subjects were treated for 9 weeks with either placebo or rosiglitazone 4mg bid. The wash out period was 4 weeks. At the end of each treatment period, the response to an intravenous dose of furosemide and amiloride was quantified. Total sodium excretion was measured after a bolus injection of furosemide 40mg. In order to construct concentration response curves, the urinary excretion rates of furosemide and sodium were calculated in all urine samples over an 8 hour-period. Amiloride, a direct inhibitor of ENaC, was administered as a bolus injection followed by a continuous infusion, to obtain a target plasma amiloride concentration for 5 hours. Again, total sodium excretion over 8- and 24-hour-periods were measured. Separately, the morning urine before furosemide injection was freshly collected in buffer and centrifuged for isolation of urinary exosomes, in which ENaC expression was analysed by Western Blotting.

Results: RSG did not alter the furosemide concentration response curve (E_{max} : RSG 3166±1201 $\mu\text{mol Na/min}$ versus PLAC 3263±1065 $\mu\text{mol Na/min}$ $P=0.49$; Log EC_{50} : RSG 2.20±0.57 $\mu\text{g furosemide/min}$ versus PLAC 2.16±0.28 $P=0.56$). There was no difference in 8 hour total sodium excretion [RSG 257±46 mmol vs. PLAC 251±64 mmol ($P=0.66$)]. In addition, we did not observe differences in the 8 and 24-hour sodium excretion after start of the amiloride infusion [RSG 313±73 mmol vs. PLAC 315±68 mmol ($P=0.90$)]. Finally, rosiglitazone did not change ENaC expression in the urinary exosomes.

Conclusion: Rosiglitazone did not induce furosemide resistance or upregulate ENaC, neither at a functional nor at a molecular level. The results of this well-controlled accurate clinical study challenges previous findings in animals and suggest that fluid retention by rosiglitazone should respond normally to diuretic treatment.

Oral antidiabetics thiazolidinediones directly inhibit hepatic gluconeogenesis in perfused liver cells

C. Sanchez¹, J. M. Recio², N. Sanz¹, G. R-Villanueva¹, J. M. Lopez-Novoa¹, D. Detaille¹, X. Leverve³, M. El-Mir¹;

¹Fisiología y Farmacología, Universidad de Salamanca, Spain,

²Servicio de Endocrinología, Hospital Universitario de Salamanca,

Salamanca, Spain, ³Univ. Grenoble 1, INSERM E0221, Grenoble, France.

Background and Aims: The Thiazolidinediones (TZDs) are new antidiabetic oral agents which exert indirectly their hypoglycemic effects by selective activation of the peroxisome proliferator-activated receptor-gamma (PPARgamma). But it's also known that TZDs could exert some of their antidiabetic effects in the liver and the skeletal muscle where usually the PPARgamma receptors are not very abundant. So, it's possible that the TZDs could exert DIRECT EFFECTS on the hepatic metabolism in independent way not mediated by activation of the PPAR gamma receptors. We decided to investigate the direct effects (hepatic gluconeogenesis and glycolysis) of the thiazolidinediones in perfused liver cells.

Materials and Methods: Hepatocytes were isolated from 24h starved rats according to the method of Berry and Friend. They were perfused (5 ml/min) at 37°C with Krebs-bicarbonate-calcium saturated with O_2/CO_2 at a flow rate of 5 ml/min and titrated with increasing substrate concentrations of dihydroxyacetone (0.15; 0.3; 0.6; 1.2; 2.4; 4.8 mM) in the presence or absence of 25 μM Rosiglitazone (RGZ) or Pioglitazone (PGZ) to get seven consecutive steady states. For each steady state we measured glucose, pyruvate and lactate concentrations in cellular perfusate. Dihydroxyacetone phosphate (DHAP), glucose-6-phosphate (G6P) and fructose-6-phosphate (F6P) concentrations were measured fluorimetrically in the cellular fraction.

Results: In perfused hepatocytes, Pioglitazone and Rosiglitazone inhibited hepatic glucose production (J_{glucose}) by 40% (DHA 2.4 mM; $p<.001$) and 57% (DHA 2.4 mM; $p<.001$) compared with control. Nevertheless, both PGZ and RGZ stimulated hepatic glycolysis by similar way (15%; $p<.05$). Both molecules inhibited total DHA metabolism by 8% in case of PGZ ($p<.05$) and by 16% in case of RGZ ($p<.001$). TZDs increased cytosolic NADH/NAD⁺ redox state, estimated as lactate/pyruvate ratio, by 24% in case of RGZ (DHA 2.4 mM; $p<.001$) and by 10% in case of PGZ (DHA 2.4 mM; $p<.05$). Also, Rosiglitazone and Pioglitazone changed the relationship between J_{glucose} and DHAP, F6P or G6P compared with control. The TZDs decreased DHAP, F6P

and G6P concentrations at each steady state, obtaining a double relationship between J_{glucose} and DHAP, F6P or G6P.

Conclusions: The TZDs Pioglitazone and Rosiglitazone, besides their known antidiabetic effects by activation of PPAR gamma receptors, exert DIRECT and ACUTE hypoglycaemic effects on the liver by inhibition of hepatic gluconeogenesis. This decrease in presence of TZDs could occur by a possible inhibition of the enzyme glucose-6-phosphatase.

Comparison of the effects of pioglitazone and metformin on hepatic and extra-hepatic insulin action in people with type 2 diabetes

R. Basu¹, B. Norby¹, A. Basu¹, V. Chandramouli², B. Dicke¹, O. Cohen³, P. Shah⁴, B. Landau², R. Rizza¹;

¹Endocrinology, Mayo Clinic College Of Medicine, Rochester, United States,

²Clinical and Molecular Endocrinology, Case Western Reserve, Cleveland,

United States, ³Endocrinology, Chaim Sheba Medical Center, Tel Aviv, Israel,

⁴Endocrinology, MD Anderson Cancer Center, Houston, United States.

Background and Aims: Pioglitazone (Pio) and metformin (Met) are both considered "insulin sensitizers". We wished to determine if these drugs have different effects on hepatic and extra-hepatic insulin action in the presence of insulin concentrations that are commonly present under the conditions of daily living.

Materials and Methods: In order to do so 31 subjects with type 2 diabetes treated with either metformin alone (n=24), diet alone (n=3) or a sulfonylurea (n=4) were randomly assigned to Pio (45 mg qd) or Met (2000 mg qd) for four months.

Results: Glucose was clamped before and after therapy at ~5 mmol/l, insulin raised to ~180 pmol/l, C-peptide suppressed with somatostatin, glucagon replaced at ~75 pg/ml and glycerol maintained at ~270 $\mu\text{mol/l}$ to insure comparable and equal portal concentrations on all occasions. HbA1c remained unchanged (6.5±0.2 vs. 6.2±0.2 %) during Pio and but increased slightly (6.3±0.2 vs. 7.0±0.3%; $p<0.05$) during Met. The glucose infusion rate (GIR) required to maintain euglycemia increased during Pio (17±3 vs. 24±3 $\mu\text{mol/kg/min}$; $p<0.01$) but did not change (19±4 vs. 22±4 $\mu\text{mol/kg/min}$) during Met. The increase in GIR with Pio was entirely explained by enhanced insulin induced suppression (6.0±1 vs. 0.2±2 $\mu\text{mol/kg/min}$; $p<0.001$) of endogenous glucose production (EGP) since glucose uptake (GU) did not differ (23±3 vs. 24±2 $\mu\text{mol/kg/min}$). Neither EGP (5.6±1.0 vs. 5.0±0.8 $\mu\text{mol/kg/min}$) nor GU (25±4 vs. 24±3 $\mu\text{mol/kg/min}$) differed before and during Met. Pio enhanced ($p<0.001$) insulin induced suppression of gluconeogenesis measured with the $^2\text{H}_2\text{O}$ method (n=7: 4.3±0.8 vs. 1.6±0.9 $\mu\text{mol/kg/min}$). On the other hand, there was no change in suppression of gluconeogenesis during Met (n=6: 4.4±1.1 vs. 3.3±1.2 $\mu\text{mol/kg/min}$). Pio also enhanced ($p<0.001$) insulin induced suppression of free fatty acids (0.14±0.03 vs. 0.06±0.01 $\mu\text{mol/l}$) whereas Met had no effect (0.12±0.04 vs. 0.15±0.07 $\mu\text{mol/l}$).

Conclusion: Thus relative to metformin, pioglitazone improves hepatic insulin action in people with type 2 diabetes by enhancing insulin induced suppression of glucose production, gluconeogenesis and free fatty acids. On the other hand, extra-hepatic insulin action is comparable following treatment with pioglitazone or metformin.

Determinants of monotherapy failure in ADOPT (A Diabetes Outcome Progression Trial)

R. R. Holman¹, S. E. Kahn², S. M. Haffner³, B. Zinman⁴, G. F. Viberti⁵, W. H. Herman⁶, J. M. Lachin⁷, B. G. Kravitz⁸, M. A. Heise⁸;
¹Diabetes Trials Unit, OCDEM, Churchill Hospital, Oxford, United Kingdom, ²Department of Medicine, VA Puget Sound Health Care System, Seattle, United States, ³Medicine/Clinical Epidemiology, University of Texas Health Science Center at San Antonio, United States, ⁴Medicine, Mount Sinai Hospital, Toronto, Canada, ⁵Department of Diabetes & Endocrinology, King's College London School of Medicine, United Kingdom, ⁶Internal Medicine – Metabolism, Endocrinology and Diabetes (MEND), University of Michigan, Ann Arbor, MI, United States, ⁷The Biostatistics Center, George Washington University, Rockville, United States, ⁸GlaxoSmithKline, King of Prussia, United States.

Background and Aims: ADOPT (A Diabetes Outcome Progression Trial), a double-blind, randomised clinical trial in 4360 recently diagnosed type 2 diabetic patients, assessed the efficacy of rosiglitazone (RSG), glyburide (GLY) and metformin (MET) as initial therapy. This 4-year study showed that, compared with GLY or MET, RSG slowed progression to monotherapy failure (MTF), defined as the time to the first of two successive fasting plasma glucose (FPG) values >180 mg/dl. To address whether tailoring glucose-lowering medication based on individual phenotypes would promote the achievement and maintenance of glycemic targets, data from ADOPT were analysed to assess which phenotypic features at baseline most influenced time to MTF.

Materials and Methods: Patient demographic and baseline characteristics by allocated therapy were analysed using a multivariate proportional hazards model.

Results: Significant factors ($p < 0.05$) with hazard ratios (HR), 95% confidence intervals and Madalla R^2 values were:

	Rosiglitazone		Metformin		Glyburide	
	HR	R ² %	HR	R ² %	HR	R ² %
Age (per year)	0.92 (0.90–0.94)	4.7	0.96 (0.94–0.97)	2.1	0.96 (0.95–0.97)	3.6
HbA _{1c} (per 1%)	1.50 (1.21–1.86)	1.1	1.46 (1.25–1.71)	1.7	1.25 (1.09–1.44)	0.8
FPG (per mg/dl)			1.01 (1.00–1.02)	0.6	1.01 (1.01–1.02)	1.7
HOMA%B (per unit)	0.98 (0.97–0.99)	1.1				
HOMA%S (per unit)	1.01 (1.006–1.014)	1.5			0.99 (0.98–1.00)	0.3
Proinsulin: insulin (per unit)					2.06 (1.37–3.09)	1.0

For all therapies, increasing age was associated with decreasing risk of MTF, with time to MTF increasing; the greatest effect of age (R^2) was seen in the RSG group ($p < 0.05$). High levels of HbA_{1c} and FPG were the next greatest influences in the MET and GLY treatment groups, with both reducing the time to MTF. In the RSG group, HOMA%S had the next greatest impact, with higher levels increasing time to MTF. Lower HOMA%B levels and higher HbA_{1c} levels reduced time to MTF in the RSG group. For GLY, a higher proinsulin: insulin ratio (another measure of beta-cell function) increased time to MTF, and higher HOMA%S levels reduced time to MTF.

Conclusion: Hyperglycaemic progression is slower in older patients. The next most important determinants for the rate of progression to MTF were initial hyperglycaemia in the MET and GLY groups, and lower insulin resistance (assessed by HOMA%S) in the RSG group.

The effect of combining rosiglitazone and metformin on insulin resistance in women with polycystic ovary syndrome

K. O. Lee¹, J. Dong², Y. Xin³, Y. Tian⁴, S. C. F. Liew¹, J. Zhao³, L. Liao³;
¹Medicine, National University of Singapore, Singapore, ²Obstetrics and Gynecology, Shandong Provincial Hospital, Jinan, China, ³Endocrinology, Shandong Provincial Hospital, Jinan, China, ⁴Endocrinology, Qilu Hospital, Medical School of Shandong University, Shandong, China.

Background and Aims: Women with the polycystic ovary syndrome (PCOs) are often insulin resistant and predisposed to developing type 2 diabetes. Thiazolidinediones (TZDs) and metformin both improve insulin sensitivity but studies on the efficacy and safety of TZDs in PCOs have been limited. We performed this randomised open-label parallel two group pilot study to compare the impact of metformin alone (Group M) versus combining metformin with rosiglitazone (Group M+R) in reducing insulin resistance.

Materials and Methods: We enrolled 58 patients with PCOs (Inclusion criteria: hyperandrogenaemia, chronic menstrual abnormality, ultrasound proven polycystic ovaries) and insulin resistance. Patients were assigned to receive metformin only (1500mg, n=29), or metformin (1500mg) and rosiglitazone (4mg) (n=29), daily for 6 months. Oral glucose tolerance tests (OGTT), with venous glucose and insulin measurements, and other endocrine parameters, were assessed before and after the treatment period. Treatment was discontinued immediately if a patient became pregnant.

Results: The study had 3 drop-outs (1 in Group M, 2 in Group M+R). There was no significant difference in the OGTT glucose concentrations between the two groups pre or post-treatment, but fasting and post-OGTT insulin concentrations decreased significantly after treatment (table with Mean + Standard Deviation) and more significantly in Group M+R compared to Group M (see table; $p < 0.01$).

	Metformin		Metformin PLUS Rosiglitazone	
	Pre	Post	Pre	Post
GLUCOSE 0 min	4.2+1.03	4.1+0.96	4.5+0.85	3.9+0.73
60	7.9+2.15	7.4+2.10	7.8+1.91	7.0+1.03
120	6.7+1.81	6.3+1.76	6.2+1.84	5.5+0.82
INSULIN 0 min	26.4+7.4	15.8+5.4*	27.1+8.2	12.7+6.7*
60	141.8+47.4	90.7+46.5	140.0+43.6	76.7+34.0*
120	195.6+57.6	101.1+52.3*	198.7+47.0	65.2+19.1*
HOMA-IR	4.97+4.15	2.88+3.54	5.42+4.21	2.20+3.41*
BMI	27.7+2.9	22.5+2.2	27.8+2.7	26.7+3.3

* $p < 0.05$ between pre and post values within groups.

There were 2 pregnancies in the M group and 6 in the M+R group. All the babies have been followed for more than 12 months and do not show any abnormality.

Conclusions: Rosiglitazone and metformin combination is more effective in decreasing hyperinsulinaemia in PCOs than metformin alone. Rosiglitazone during the first trimester of pregnancy did not show any abnormality in the 6 babies followed up to 12 months in our study patients.

0864

The effects of pioglitazone vs glimepiride on adipose tissue distribution in patients with type 2 diabetes: results from the CHICAGO TrialM. Davidson¹, R. D'Agostino, Sr², S. Feinstein¹, S. Haffner³, G. Kondos⁴, P. Meyer⁵, A. Perez⁶, T. Mazzone⁷;¹Section of Cardiology, Rush Presbyterian–St. Luke's Medical Center, Chicago, ²Statistics and Consulting Unit, Boston University, Boston, ³Department of Medicine, University of Texas Health Science Center, San Antonio, ⁴Section of Cardiology, University of Illinois, Chicago, ⁵Department of Preventive Medicine, University of Illinois College of Medicine, Chicago, ⁶Takeda Global Research and Development Center, Inc., Deerfield, ⁷Section of Diabetes and Metabolism, University of Illinois at Chicago, Chicago, United States.**Background and Aims:** Weight gain is a known side effect of most type 2 diabetes (T2D) therapies, including insulin, sulfonylureas, and thiazolidinediones (TZDs). Weight gain that occurs with TZDs is likely due to fluid retention, increases in adipose tissue, or both. During the recently completed CHICAGO study, there was a mean weight gain of 3.2 kg with pioglitazone (PIO) and 1.0 kg with the comparator glimepiride (GLM). Here we report changes in BMI, waist-hip ratio, and abdominal adipose tissue distribution observed during the trial.**Materials and Methods:** CHICAGO was a randomised, double-blind, multicenter, 72-week study designed to compare carotid intima-media thickness during treatment with PIO (N=230) vs. GLM (N=228) in patients with T2D. Abdominal adipose tissue content and distribution (as measured by electron beam tomography) and BMI were determined at baseline and the final visit (week 72 or the time of withdrawal).**Results:** There were significantly greater increases in BMI with PIO vs. GLM, whereas waist-hip ratio decreased with PIO and increased with GLM. Total abdominal adipose tissue volume increased for both PIO and GLM. For PIO, the increase was largely accounted for by accretion of subcutaneous tissue, which increased to a significantly greater extent with PIO vs. GLM. Therefore, the ratio of visceral to total adipose tissue volume tended to increase with GLM and decrease with PIO.**Changes in BMI, Waist Measurements, and Adipose Tissue Distribution**

		GLM Mean (SD)	PIO Mean (SD)
BMI (kg/m ²)	BL	31.9 (4.9)	32.1 (5.2)
	Change	0.4 (1.4)	1.1 (1.8)†
Waist circumference (in)	BL	41.7 (5.1)	42.0 (5.1)
	Change	0.3 (2.4)	0.6 (2.7)
Waist/hip ratio	BL	0.953 (0.078)	0.956 (0.073)
	Change	0.008 (0.054)	−0.006 (0.059)*
Abdominal Adipose Tissue Volume		LS mean (SE)	LS mean (SE)
	Total (cm ³)	BL 309.48 (7.84) Change 14.11 (6.05)	321.85 (7.74) 25.52 (6.03)
Visceral (cm ³)	BL	126.27 (3.73)	129.38 (3.66)
	Change	7.94 (3.12)	7.35 (3.13)
Subcutaneous (cm ³)	BL	186.95 (6.34)	196.71 (6.26)
	Change	4.12 (4.88)	18.93 (4.84)*
Visceral/Total ratio	BL	0.41 (0.01)	0.39 (0.01)
	Change	0.01 (0.01)	−0.01 (0.01)

BL=Baseline; P-value is for the treatment-group difference; change is from baseline to Final Visit (Week 72 or time of withdrawal). *P<0.05, †P<0.0001

Conclusion: These results indicate that subcutaneous rather than visceral abdominal fat largely accounts for the increase in adipose tissue noted with PIO therapy. This altered distribution of visceral to subcutaneous fat may contribute to improved insulin sensitivity.

Effects of 30 mg of pioglitazone vs 4 mg of rosiglitazone on hyperglycaemia and dyslipidaemia: results from a head-to-head trialT. McCall¹, S. Kupfer², S. Gbenado², S. Jacober³, M. H. Tan³;¹Takeda Pharmaceuticals North America, Inc., Deerfield, ²Takeda Global Research & Development Center, Inc., Deerfield, ³Eli Lilly and Company, Indianapolis, United States.**Background and Aims:** The GLAI study supported the hypothesis that the thiazolidinediones pioglitazone (PIO) and rosiglitazone (ROSI) have similar glucose-lowering effects but differing effects on lipids. This head-to-head study showed that PIO and ROSI lowered HbA1c to a similar extent, but that PIO was associated with more favorable changes in triglycerides (TG), HDL-C, and non-HDL-C. The purpose of the present analysis was to evaluate the effectiveness of the starting doses of PIO (30 mg) and ROSI (4 mg) used in GLAI.**Materials and Methods:** GLAI was a 6-month, randomised, double-blind trial in patients with type 2 diabetes (treated with diet or oral monotherapy only) and dyslipidemia (TG ≥150, <600 mg/dL and LDL-C ≤130 mg/dL) who were not receiving lipid-altering drugs. Patients were assigned to treatment with PIO (N=369) or ROSI (N=366), both of which were titrated to their respective maximum effective dose: patients received 3 months of PIO 30mg QD or ROSI 4mg QD, followed by an additional 3 months of PIO 45mg QD or ROSI 8mg (4mg BID). The primary variable was change in TG at the final visit (ie, month 6 or the time of withdrawal). For the present analysis, change from baseline in lipid and HbA1c values were evaluated at month 3 (ie, before dose titration).**Results:** As observed for maximum doses, the starting doses of PIO and ROSI differed significantly in their effects on TG (P<0.001), HDL-C (P<0.001), and non-HDL-C (P=0.003) in favor of PIO. However, unlike for the maximum doses, the 30mg dose of PIO led to a significantly greater reduction in HbA1c than the 4mg dose of ROSI (P=0.017). (See table).**Conclusion:** Initial treatment with the 30mg dose of PIO was more effective than use of the 4mg dose of ROSI in terms of improving measures of hyperglycemia and dyslipidemia.

Change from Baseline to Month 3 in Lipid and HbA1c Levels

		PIO N=330	ROSI N=320	P-Value
TG (mg/dL)	Baseline (SE)	257.8 (8.2)	235.3 (6.6)	<0.001
	LS mean % change (SE)	−11.95 (2.63)	19.32 (2.64)	
HDL-C (mg/dL)	Baseline (SE)	38.8 (0.5)	39.8 (0.6)	<0.001
	LS mean % change (SE)	13.30 (1.09)	4.26 (1.10)	
non-HDL-C (mg/dL)	Baseline (SE)	154.8 (1.6)	153.6 (1.6)	0.003
	LS mean % change (SE)	−6.53	12.67	
HbA1c (%)	Baseline (SE)	7.6 (0.1)	7.5 (0.1)	0.017
	LS mean change (SE)	−0.46 (0.05)	−0.31 (0.05)

Insulin sensitivity and metabolic control in response to pioglitazone treatment differ between patients with type 2 diabetes with and without the Pro12Ala variant in the PPARG2 geneH. Vestergaard¹, J. Clausen², R. Benediktsson³, V. A. Lyssenko⁴, D. Larsson⁵, K. N. Valnes⁶, M. Lilja⁷, P. J. Dahl²;¹Department of Endocrinology, Herlev Hospital, University of Copenhagen, Herlev, Denmark, ²Eli Lilly A/S, Lyngby, Denmark, ³Department of Endocrinology and Metabolism, Landspítali – University Hospital, Reykjavík, Iceland, ⁴Department of Clinical Sciences, Diabetes and Endocrinology, University Hospital Malmö, Wallenberg Laboratory, Malmö, Sweden, ⁵General practitioner, Degeberga, Sweden, ⁶Senior Consultant, Oslo, Norway, ⁷The Research and Development Unit, Jämtland, Sweden.**Background and Aims:** To evaluate the possible modifying effect of the peroxisome-proliferator-activated receptor γ gene (PPARG) polymorphism on the efficiency of pioglitazone (Actos[®]) treatment with regard to glycaemic control in both men and women with type 2 diabetes (T2D).

Materials and Methods: A total of 326 patients with T2D, in a normal clinical practice setting, were treated with pioglitazone at the dose of 15–30 mg/day for 26 weeks, added to existing oral anti-diabetic medication. All were genotyped for the Pro12Ala variant of the PPAR γ . Insulin resistance and β -cell function was calculated using HOMA model.

Results: There were 248 patients with the Pro12Pro genotype and 78 with the Pro12Ala genotype, no difference between females and males ($p=0.78$). HbA $_{1c}$ decreased significantly between visits, in both females and males ($p<0.001$). The difference between visits across gender depended on genotype, with a significantly larger decrease in the Pro12Pro genotype ($p=0.026$). Insulin resistance fell significantly across gender and genotype between visits ($p<0.001$), but the change across gender was significantly greater for the Pro12Pro genotype ($p=0.034$), compared to baseline.

Conclusion: In patients with T2D, the effects of pioglitazone treatment on metabolic control and insulin sensitivity may vary dependent on the wild type Pro12Pro variant of the PPAR γ gene. Therefore, assessment of the Pro12Pro variant may in future prove to have clinical significance in the identification of patients with T2D who will benefit from pioglitazone treatment.

Comparison of resources utilization (RU) and cost in drug-naïve type 2 diabetes (T2D) patients treated with rosiglitazone (RSG) vs. sulfonylurea (SU) monotherapy

M. S. Duh¹, A. Gosselin¹, N. Beaulieu¹, M. Arana¹, B. Arondekar²;

¹Health Care, Analysis Group inc., Boston,

²GlaxoSmithKline, Philadelphia, United States.

Background and Aims: The objective of this study was to compare RU and costs for drug-naïve patients (pts) treated with RSG versus SU first-line monotherapy using real-world claims data.

Material and Methods: Based on medical, pharmacy (Rx), and disability insurance claims data between 10/2001 and 12/2004, patients with a diagnosis T2D who were newly initiated on an OAD (no OAD in previous 6 months), ≥ 18 years old, and had ≥ 60 days of uninterrupted treatment were analysed. Frequency of inpatient (inpt) and outpatient (outpt) visits and average direct (inpt, outpt, and Rx) and indirect (workloss) costs were compared between the RSG and SU groups.

Results: 3,377 RSG and 11,778 SU pts met the inclusion criteria with RSG pts being younger (63.8 vs. 66.9 years, $p<.001$) with less comorbidities (Charlson comorbidity index 0.95 vs. 1.23, $p<.01$) at baseline. During treatment, the RSG group incurred statistically significantly less frequent inpt visits (0.47 vs. 0.77 visits per pt per year (PPPY), $p<.001$), outpt visits (17.0 vs. 17.9 visits PPPY, $p<.001$), and number of hospital days (1.6 vs. 2.9 days PPPY, $p<.001$) than the SU group. The total direct medical cost was significantly lower in the RSG group (\$1,065 vs. \$1,315 per pt per month (PPPM), $p<.001$) than the SU group, including significantly lower inpt and outpt cost (\$717 vs. \$1,046 PPPM, $p<.001$) but higher Rx cost (\$348 vs. \$270 PPPM, $p<.001$). After taking into account the indirect workloss cost, the total direct and indirect cost was significantly lower in the RSG group (\$1,103 vs. \$1,355 PPPM, $p<.001$). Multivariate analysis controlling for age, gender, comorbidities, and other covariates confirmed that the RSG group was associated with a significantly lower total cost than the SU group (cost difference: \$92.75 PPPM, $p=0.012$).

Conclusion: This observational study of over 15,000 pts initiated on first-line monotherapy shows that RSG pts incur significantly lower resource utilisation and costs than SU pts, outweighing higher pharmacy cost.

Economic analysis of thiazolidinedione add-on therapy relative to insulin add-on therapy in individuals treated with sulfonylureas: a third party payer's perspective

S. Balu¹, W. Lee², B. Arondekar³, R. Horblyuk³, C. Pashos¹;

¹HERQuLES, Abt Associates Inc., Lexington, ²HERQuLES, Abt Associates Inc., Bethesda, ³GlaxoSmithKline, Philadelphia, United States.

Background and Aims: This study evaluated the economic impact to a managed care organisation's budget of adding a thiazolidinedione versus insulin to sulfonylurea monotherapy for the management of type 2 diabetes.

Materials and Methods: Using an integrated medical and pharmacy claims database from 07/01 to 06/02, we identified type 2 diabetes patients treated with sulfonylurea monotherapy, who subsequently received a thiazolidinedione or insulin in addition to sulfonylurea monotherapy. Per-member per-month (PMPM) total healthcare costs and pharmacy costs during two-years of follow-up were assessed. Multivariate generalised linear models were used to assess the cost differential of thiazolidinedione add-on versus insulin add-on accounting for differences in baseline demographics, comorbidities, and pre-index health care costs.

Results: A total of 994 individuals (Mean [SD]: 53.4 [10.4] years; 51.0% males) were identified, with 384 initiating insulin add-on and 610 initiating thiazolidinedione add-on to sulfonylurea monotherapy. There were no significant differences in age or gender across the two groups, however, insulin add-on patients had greater cardiovascular comorbidities and other complications. Although overall PMPM pharmacy costs were lower for the thiazolidinedione add-on group (\$262 [\$3,739] vs. \$360 [\$4,026], $p<0.01$), diabetes-related pharmacy costs were greater for thiazolidinedione-add on group (\$109.4 [\$3,336] vs. \$96.1 [\$2,067]; $P=0.04$). Despite higher PMPM diabetes-related pharmacy costs, patients with thiazolidinedione-add on therapy realised cost savings of \$96 PMPM over two years as compared to patients with insulin (\$229 [\$6,448.] vs. \$325 [\$9,159]; $p=0.01$). After adjusting for differences in baseline characteristics, patients with insulin add-on therapy incurred 22% ($p<0.05$) higher total health care costs compared to patients on thiazolidinedione add-on therapy.

Conclusion: The findings from this study demonstrate that the addition of thiazolidinedione to sulfonylurea monotherapy was associated with a significant 22% reduction in PMPM total health care costs versus add-on therapy with insulin.

Economic impact of add-on therapy with thiazolidinedione versus insulin to metformin monotherapy

B. Arondekar¹, S. Balu², W. Lee³, R. Horblyuk¹, C. Pashos²;

¹GlaxoSmithKline, Philadelphia, United States,

²HERQuLES, Abt Associates Inc., Lexington, United States,

³HERQuLES, Abt Associates Inc., Bethesda, United States.

Background and Aims: Changes to pharmacotherapy for type 2 diabetes are generally based on stability of glycemic control and therapy tolerability. Differences in glycemic control often influence resource utilisation which in-turn impacts health care costs. This study assessed the economic impact of addition of a thiazolidinedione versus insulin to type 2 diabetes patients receiving monotherapy with metformin.

Materials and Methods: Administrative claims data from a large integrated medical and pharmacy claims database was used. Type 2 diabetes adults on metformin monotherapy who received add-on therapy with thiazolidinedione or insulin were identified based on pharmacy claims from 07/2001 through 06/2002. Primary endpoints included differences in baseline comorbidities and unadjusted two-year follow-up total cost. Multivariate generalised linear models were used to assess the cost differential of thiazolidinedione add-on versus insulin add-on accounting for differences in baseline demographics, comorbidities, and pre-index health care costs.

Results: A total of 1,608 individuals were identified with 1,153 receiving add-on therapy with thiazolidinedione versus 455 receiving insulin add-on therapy. Although there were no significant differences in age or gender between thiazolidinedione (mean=51.4 years, 46.4% males) and insulin (mean=51.5 years, 47.9% males) add-on cohorts, patients with thiazolidinedione-add on had decreased prevalence of cardiovascular disease

(15.4% vs. 19.6%; $p < 0.01$) and increased prevalence of hypertension (45% vs. 39.3%; $p = 0.04$) at baseline. The unadjusted two-year follow-up total costs were significantly lower among thiazolidinedione users as compared to insulin users (\$17,339.80 vs. \$21,150.30; $P = 0.03$). This difference persisted after adjusting for differences in baseline characteristics, with patients on insulin plus metformin incurring 20% ($p < 0.05$) higher total health care costs compared to patients on thiazolidinedione plus metformin.

Conclusion: Controlling for differences in comorbidities, this analysis showed significant reduction in costs with thiazolidinedione versus insulin as add-on therapy to metformin monotherapy. These differences indicate that selection of a thiazolidinedione as the second agent can have an important economic impact on healthcare costs for type 2 diabetes.

Patient characteristics of new users of oral antidiabetic drugs in daily clinical practice

S. van der Bij¹, J. Koerselman¹, J. A. Erkens¹, S. Kessabi², M. T. Groot²,

F. J. A. Penning-van Beest¹, R. M. C. Herings¹;

¹PHARMO Institute, Utrecht, The Netherlands,

²Novartis Pharma AG, Basel, Switzerland.

Background and aim: Pharmacological treatment of type 2 diabetes mellitus consists of oral antidiabetic drugs (OADs) and, in case of insufficient effect, insulin therapy. Currently, metformin, sulphonylureas (SU), and thiazolidinediones (TZD), are the most frequently used OAD classes. Channeling of drugs into patients may occur. The aim of this study was to characterise new users of OADs in daily clinical practice.

Methods: From the PHARMO record linkage system, comprising among others linked drug-dispensing, clinical laboratory, and hospital data of >2.3 million inhabitants in The Netherlands, new users of OADs were identified in the period between January 1, 1999 and December 31, 2005. Patient characteristics, i.e. gender, age, type of prescriber of first OAD, year of start OAD-therapy, and HbA1c level at start, were determined per type of initial OAD. Also, patients were classified into sub-cohorts of high-risk patients: A) elderly, age ≥ 65 years; B) elderly with a history of cardiac, hepatic, or renal failure; and C) any age with a history of cardiac, hepatic, or renal failure.

Results: The study included 35,514 new users of OADs. Of these, 40% started on monotherapy with metformin ($n = 14,277$), 53% with SU-monotherapy ($n = 18,876$), 0.9% with TZD-monotherapy ($n = 310$), and 1,499 patients (4%) started on combination therapy with metformin+SU ($n = 1,426$), or metformin+TZD ($n = 73$). For each initial OAD, male and female gender was about equally divided, and a general practitioner was the most frequent prescriber, ranging from 67% of first TZD-dispensings to 88% in case of SU. The percentage of patients ≥ 65 years of age, ranged from 33% for metformin+TZD to 54% in case of SU. Also, for each initial OAD, many patients were classified as high-risk patient; e.g. the percentage of patients with a history of cardiac, hepatic, or renal failure ranged from 58% for metformin+TZD to 66% in case of TZD, alone. Of a subpopulation (4,051 patients), baseline HbA1c-measurements were available. Mean baseline-HbA1c was lowest for patients on initial TZD ($7.4 \pm 1.5\%$), and highest for patients who started on metformin+SU ($8.7 \pm 2.2\%$).

Conclusion: The majority of patients starting with OAD-therapy in daily clinical practice are high-risk patients, marked by age ≥ 65 years and symptomatic cardiovascular, renal or hepatic disease, and started their therapy by a GP. Differences between initial OADs were observed with respect to age and baseline-HbA1c indicating that combination therapy is started more often in younger patients and in patients with higher HbA1c.

One-third of new users of oral antidiabetic drugs fail to attain HbA_{1c}-goal in the first year after start of therapy

J. A. Erkens¹, J. Koerselman¹, S. van der Bij¹, S. Kessabi², M. T. Groot²,

F. J. A. Penning-van Beest¹, R. M. C. Herings¹;

¹PHARMO Institute, Utrecht, The Netherlands,

²Novartis Pharma AG, Basel, Switzerland.

Background and Aims: The major objective of the treatment of type 2 diabetes mellitus (T2DM) is to control glycemic parameters in order to minimise the risk of long-term complications and to alleviate any symptoms present. Within the Dutch guidelines for treatment of T2DM, the target value of HbA1c has been set at < 7%. The aim of this study was to determine mean levels of HbA1c over time among new users of oral antidiabetic drugs (OADs) in daily clinical practice, and the proportion of patients attaining goal within the first year of follow-up.

Methods: From the PHARMO record linkage system, comprising among others linked drug-dispensing, clinical laboratory, and hospital data of >2.3 million inhabitants in The Netherlands, new users of OADs were identified in the period between January 1, 1999 and December 31, 2005. Patients

who started on monotherapy with metformin, a sulphonylurea (SU), or a thiazolidinedione (TZD), or on combination therapy with metformin+SU, or metformin+TZD, with a baseline HbA1c-measurement, and at least one HbA1c-measurement in the one-year period after treatment onset, were included in the study-cohort. Patients were not required to be still on initial OAD-therapy, at the time of each HbA1c-measurement. Mean HbA1c-levels over time were assessed per quarter of the first year of follow-up. Kaplan Meier survival analyses were used for the assessment of time to goal (HbA1c < 7%). For the latter analysis, only patients with a baseline HbA1c-value \geq 7% were included.

Results: The study included 4,051 new T2DM-patients with a HbA1c-measurement at baseline. Of these, 3,398 (84%) had at least one measurement during the first year of follow-up. Across all OAD classes mean HbA1c (\pm sd) at baseline was $8.2 \pm 1.8\%$, and ranged from $7.4 \pm 1.5\%$ among patients who started on TZD-monotherapy, to $8.7 \pm 2.2\%$ for patients who started on metformin+SU combination therapy (patients on initial metformin+TZD were not included due to too low numbers). Overall, about 75% of the patients had a baseline HbA1c \geq 7%, except for the TZD-monotherapy group, in which 53% of the patients had a HbA1c \geq 7% at baseline. During follow-up, overall, the mean level of HbA1c (\pm sd) was $7.6 \pm 1.4\%$ in the first quarter, and $6.9 \pm 0.9\%$ in subsequent quarters of the first year of follow-up. Mean HbA1c-levels during follow-up were lower in TZD-patients (e.g. $7.0 \pm 1.3\%$ in the first quarter, and $6.5 \pm 0.7\%$ in the fourth quarter of follow-up). Six months after start of therapy, the proportion of patients who had attained goal was 15% for metformin alone and metformin+SU, 19% for TZD alone, and 20% for SU alone. After one-year of follow-up, these proportions on goal were between 60% and 75%.

Conclusion: The results of this study indicate that 75% of new users of OADs in daily clinical practice have a HbA1c-level \geq 7% at start of therapy, and that about two-thirds of these patients attain goal, i.e. HbA1c < 7%, in the first year of follow-up. This percentage includes both patients still on initial therapy, and with a change in OAD-treatment. However, it is not known whether these patients remained at goal after goal-attainment.

0872

In too many patients a change in initial therapy with oral antidiabetic drugs is already required in the first year of treatment

F. J. A. Penning-van Beest¹, J. Koerselman¹, S. van der Bij¹, S. Kessabi², M. T. Groot², J. A. Erkens¹, R. M. C. Herings¹;

¹PHARMO Institute, Utrecht, The Netherlands,

²Novartis Pharma AG, Basel, Switzerland.

Background and aim: Oral antidiabetic drugs (OADs) are first choice in the pharmacological treatment of type 2 diabetes mellitus (T2DM). OAD-therapy is tailored to the patient's needs dependent on its observed effect in glycemic control. In case of insufficient effect, an add-on with, or a switch to another OAD or even insulin, may occur. Accordingly, the aim of this study was to determine the persistence and treatment pattern with initial OAD-therapy in the first year of treatment in daily clinical practice.

Methods: From the PHARMO record linkage system, comprising among others linked drug-dispensing, and hospital data of >2.3 million inhabitants in The Netherlands, new users of OADs were identified in the period between January 1, 1999 and December 31, 2005. Patients starting with monotherapy of metformin, a sulphonylurea (SU), or a thiazolidinedione (TZD), or on combination therapy with metformin+SU, or metformin+TZD, and with at least one year of follow-up, were included in the study cohort. One-year persistence with initial treatment was determined by using episodes of each OAD-treatment, based on the method of Catalan allowing for drug holidays. For non-persistent patients, the first change in OAD-treatment (add-on, switch, or discontinuation) in the one-year period after starting treatment was determined.

Results: The study included 34,962 new users of OADs. Of these, 40% started on monotherapy with metformin (n=14,277), 53% with SU-monotherapy (n=18,876), and 0.9% with TZD-monotherapy (n=310), and 1,499 patients (4%) started on combination therapy with metformin+SU (n=1,426), or metformin+TZD (n=73). Overall, after one year, 59% of the OAD-users were persistent with the initial OAD-treatment. One-year persistence-rates ranged from 46% among patients who started on TZD-monotherapy, to 60% for patients who started on SU-monotherapy. Among the non-persistent patients

starting on OAD-monotherapy, add-on and discontinuation were the most frequent first treatment changes in the one-year period after starting treatment (38–43% and 38–50%, respectively). In patients starting on combination therapy, a switch was the most frequent first treatment change (67–69% of the non-persistent patients). Overall, mean duration (\pm sd) to first add-on or switch among non-persistent patients was 4.0 (\pm 3.4) months. The most frequent add-on to metformin monotherapy was SU (81%), and the most frequent add-on to SU-monotherapy was metformin (91%). Patients starting on metformin+SU combination therapy most often switched to mono-use of either SU (46%) or metformin (35%).

Conclusion: The results of this study indicate that in many T2DM-patients (about 40%) a change in initial OAD-therapy is already required in the first year of treatment, particularly in case of initial TZD-monotherapy. Among non-persistent patients, initial OAD-monotherapy most often changed to combination therapy with OADs, and initial OAD combination therapy most often changed to monotherapy with an OAD.

How should patients with diabetes and heart failure have their blood sugars controlled? A systematic review and meta-analysis of the available literature

D. T. Eurich^{1,2}, F. A. McAlister^{3,1}, D. F. Blackburn⁴, S. R. Majumdar^{3,1}, R. T. Tsuyuki^{5,1}, J. Varney², J. A. Johnson^{1,2};

¹School of Public Health, University of Alberta, Edmonton,

²Institute of Health Economics, Edmonton, ³Division of Internal Medicine, Department of Medicine, University of Alberta, Edmonton,

⁴College of Pharmacy and Nutrition, University of Saskatchewan, Saskatoon,

⁵Division of Cardiology, Department of Medicine, University of Alberta, Edmonton, Canada.

Background and Aims: To systematically review the literature on the relationship between different antidiabetic therapies and morbidity and mortality in people with heart failure (HF) and diabetes.

Materials and Methods: Literature search from 1966 to 2007 (e.g., Medline, Embase, trial registries) identified controlled studies (either randomised trials or cohort studies) evaluating antidiabetic agents and outcomes (i.e., death, hospitalizations) in patients with HF and diabetes. References were hand-searched and investigators of included studies contacted. Two reviewers independently extracted data. Risk estimates for specific therapies were abstracted, and pooled estimates derived by meta-analysis only when appropriate.

Results: Of 9,68 references initially identified, only six studies (four cohort studies, two subgroup analyses of randomised trials) were included. In four studies of 19,205 patients, use of insulin was associated with a marked increased risk for all-cause mortality in 3 studies and no effect in 1 study, risk estimates ranging from 0.96–3.42. In three studies of 21,125 patients, use of metformin was associated with a significant reduction in all-cause mortality in two studies (risk estimate from 0.61–0.86), and a similar trend in the third. Metformin was not associated with increased all-cause or HF-specific hospitalisations in any studies. There were two studies of thiazolidinediones in 19,022 patients; one study demonstrated a significant reduction in all-cause mortality (risk estimate 0.87), and the other found no association. Thiazolidinediones were associated with an increased risk of HF-specific hospitalisations in both studies (pooled odd ratio 1.14, 95%CI 1.04–1.25, I²=0%, p=0.004). There were no studies of nonsulphonylurea secretagogues or acarbose in this setting, and no randomised trials that addressed the question.

Conclusion: Our systematic review suggests that metformin is the only agent studied that is not associated with measurable harm in patients with HF and diabetes; in fact, it was associated with reduced all-cause mortality. Unfortunately, it is also contraindicated in this population. It is imperative, therefore, that further valid evidence is generated. In the meantime, consideration to labeling changes for metformin should be strongly considered.

0874

Impact of type of sulfonylureas on survival in diabetic patients with acute myocardial infarction

⁹Société Française de Cardiologie, Paris, France.

Background and Aims: Questions have been raised as to the cardiovascular safety of sulfonylureas (SU). Glibenclamide is a non-selective sulfonylurea known to inhibit ischemic preconditioning of the myocardium, unlike the newer SU (gliclazide, glimepiride). Aim: To assess early and 6-month mortality according to the previous use and type of SU in diabetic patients admitted for AMI in a nationwide French registry.

Materials and Methods: The FAST-MI registry included consecutive patients admitted for ST-elevation or non-ST elevation myocardial infarction \leq 48 hours of symptom onset, in 223 French intensive care units over 2 months from October 2005. In the 1316 diabetic patients, 3 groups were defined according to their antidiabetic treatment before admission: no SU (SU0, n=851), Glibenclamide (SU1, n=120), new SU with pancreatic beta-cell selectivity (glimepiride/gliclazide, n=339) (SU2).

Results: Age was not significantly different between the 3 groups (70 ± 12 , 71 ± 10 , 69 ± 11 , respectively for SU0, SU1 and SU2); 39%, 37% and 35%, respectively had a diabetes duration $>$ 5 years (NS). Concomitant risk factors were similar in the 3 groups and the GRACE risk score was not significantly different (170 ± 38 , 162 ± 35 , 166 ± 38 , respectively). Patients with SU2 were less often co-treated with insulin (SU2: 9%, SU1: 16%, SU0: 40%, $p < 0.001$) and those without SU received less metformin (SU0: 30%, SU1: 53%, SU2: 40%, $p < 0.001$). Entry glycaemia was not significantly different for SU1 patients (2.32 ± 1.06 g/L) and SU2 patients (2.19 ± 1.07) but was lower in SU0 patients (2.02 ± 1.05 , $p < 0.005$). HbA1c was available in half of the patients; it was higher in SU1 ($8.0 \pm 1.5\%$) than in SU0 or SU2 (7.5%) ($p < 0.05$). Time from onset of symptoms to admission was similar in the 3 groups and reperfusion therapy was used in a similar proportion of the patients. Five-day mortality was 5.3% in SU0, 2.5% in SU1, and 0.9% in SU2 patients ($p < 0.001$). 6-month mortality was significantly higher in SU0 (18.3%) and SU1 (13.4%) compared with SU2 (8.7%) ($p < 0.001$). Mortality was the lowest in patients on SU2, both in those on metformin or insulin and in those not receiving these medications. Using Cox multivariate analysis, the odds ratio for 6-month mortality versus patients without SU was 0.82; (95% CI: 0.47–1.43, $p = \text{NS}$) in patients on SU1, and 0.42 (95% CI: 0.27–0.65, $p < 0.001$) in patients on SU2.

Conclusion: Patients on new sulfonylureas have an improved early and 6-month survival, compared with patients with non-selective sulfonylureas or no SU.

Functional and molecular effects of gliclazide and glibenclamide on isolated human islets cultured at high glucose concentration

S. Del Guerra¹, M. Grupillo¹, R. Lupi¹, M. Bugliani¹, S. Torri¹, R. Mancarella¹, M. Galli¹, V. D'Aleo¹, M. Del Chiaro², U. Boggi³, F. Filippini², F. Mosca³, S. Del Prato¹, P. Marchetti¹;

¹Endocrinology and Metabolism, ²Oncology, Transplantation and Advanced Technologies in Med, ³Oncology, Transplantation and Advanced Technologies, University of Pisa, Italy.

Background and Aims: Decreased beta-cell functional mass is crucial for the development and progression of type 2 diabetes. Chronic exposure to high glucose levels (glucotoxicity) is a probable underlying mechanism, whereas the role of oral anti-diabetic agents is still unsettled. We have recently found that gliclazide protected human beta-cells from apoptosis induced by intermittent high glucose, an effect that was due, at least in part, to the anti-oxidant properties of the molecule. The aim of the present study was to further investigate on this issue at functional and molecular levels.

Materials and Methods: For this study 9 pancreata from non-diabetic multiorgan donors (age 58.5 ± 14.5 , gender 5M/4F, body mass index 24.8 ± 2.9 kg/m²) were used. Islet isolation was performed by collagenase digestion and

gradient purification. The islets were then cultured for 5 days in continuous normal glucose concentration (NG, 5.5 mmol/L) or normal and high (HG, 16.7 mmol/L) glucose levels (alternating every 24h), with or without the addition of therapeutic concentration of gliclazide (10 $\mu\text{mol/l}$) or glibenclamide (1.0 $\mu\text{mol/l}$). At the end of incubation, islet function as well as gene and protein expression of molecules involved in islet function, survival and regeneration were assessed by glucose-stimulated insulin secretion, quantitative Real-Time RT-PCR and Western Blot experiments.

Results: Insulin secretion, expressed as stimulation index, SI, differed significantly between the groups (NG: 3.4 ± 1.5 , HG: 2.1 ± 0.8 , HG+gliclazide: 2.3 ± 1.0 , HG+glibenclamide: 1.4 ± 0.2 , $p < 0.01$ by ANOVA), and the value with glibenclamide was lower compared to NG ($p < 0.05$ by the Bonferroni correction). Compared to NG, insulin expression decreased significantly at HG ($-70.5 \pm 3.1\%$), and increased similarly with gliclazide or glibenclamide ($+144 \pm 50$ and $+118 \pm 52\%$, respectively). In addition, gliclazide, but not glibenclamide exposure significantly induced the expression of PDX-1, a fundamental beta-cell differentiation transcription factor ($+44.0 \pm 14.5\%$) and Ki67, a marker of proliferation ($+86.9 \pm 36.2\%$). These results were confirmed by Western Blot experiments ($+65.4 \pm 20.1$ and $+19.0 \pm 8.3\%$ for PDX-1 and Ki67 protein expression, respectively). Gliclazide and glibenclamide did not differ as for the effects on gene expression of the antiapoptotic molecule Bcl2 (increased significantly with both) and the proapoptotic molecule Bax (decreased significantly with both).

Conclusion: Gliclazide could counteract part of the deleterious effects of glucotoxicity on human pancreatic islets at both the functional and molecular level.

Impact of gliclazide on DNA damage and repair in type 2 diabetic patients – a preliminary report

J. Drzewoski¹, A. Sliwiska¹, J. Blasiak², J. Kasznicki¹;

¹Department of Internal Diseases, Diabetology and Clinical Pharmacology, Medical University of Lodz, Zgierz,

²Department of Molecular Genetics, University of Lodz, Poland.

Background and Aims: Type 2 diabetes mellitus (T2DM) is associated with increased oxidative stress and a reduced antioxidant defense system. Reactive oxygen species can cause damage to biological molecules, including DNA. It is also documented that in diabetic patients, the efficacy of DNA repair mechanisms is reduced. DNA damage and repair play a primary role in neoplastic transformation. Mutations in DNA repair genes may be associated with cancer, and the efficacy of DNA repair may determine the susceptibility to carcinogens. Gliclazide is an oral hypoglycemic drug with antioxidant properties that may diminish oxidative stress and its consequences in patients with T2DM. The aim of our study was to assess the impact of gliclazide on: (i) endogenous DNA damage (ii) DNA damage induced by hydrogen peroxide and (iii) the efficacy of the removal of DNA damage induced by hydrogen peroxide in patients with T2DM and in healthy individuals.

Materials and Methods: The DNA damage and the kinetics of DNA repair in peripheral blood lymphocytes of 15 (6 male) T2DM patients (age 59.5 ± 11.1 years; body mass index, 31.5 ± 6.8 ; glucose level, 227 ± 72 mg/dL; duration of diabetes, 9.6 ± 5 years) and 15 (8 male) healthy individuals (age 64 ± 14.9 years; body mass index, 25.5 ± 2.9 ; glucose level, 92 ± 18 mg/dL) were evaluated by alkaline single cell electrophoresis (comet) assay. Oxidative DNA damage was assayed with the use of the DNA repair enzyme endonuclease III (Endo III) and formamidopyrimidine-DNA glycosylase (Fpg), recognizing oxidized DNA bases.

Results: Basal endogenous and oxidative DNA damage was higher in T2DM patients, although not significantly. Gliclazide significantly decreased the level of DNA damage induced by hydrogen peroxide in both groups (Table 1). We did not observe any impact of gliclazide on the repair of hydrogen peroxide-induced DNA damage during the 120 minutes of the repair incubation (data not shown). Table1: Impact of gliclazide on endogenous basal DNA damage and oxidative DNA damage induced by hydrogen peroxide (H₂O₂) in human peripheral blood lymphocytes of healthy individuals and type 2 diabetic patients. Cells were treated or not with $10 \mu\text{M}$ H₂O₂ for 10 minutes at 4 °C in the presence or absence of $20 \mu\text{M}$ gliclazide, and received subsequent treatment with endonuclease III (Endo III) or formamidopyrimidine-DNA glycosylase (Fpg) at $1 \mu\text{g/ml}$. The damage was measured as the percentage of tail DNA in the alkaline comet assay.

Abstract 0876	Healthy individuals (n=15)	Type 2 diabetes mellitus patients (n=15)				
	No enzyme	Endo III	Fpg	No enzyme	Endo III	Fpg
Endogenous basal DNA damage	0.635 ± 0.152	0.580 ± 0.375	0.907 ± 0.398	2.670 ± 0.387 ***	3.254 ± 0.785 **	3.871 ± 0.876 **
Impact of 20 µ M gliclazide on endogenous basal DNA damage	0.692 ± 0.165	0.804 ± 0.321	0.760 ± 0.275	1.945 ± 0.326 **	2.749 ± 0.673 *	2.397 ± 0.594 *
Oxidative DNA damage induced by 10 µ M H ₂ O ₂	18.889 ± 2.068	23.072 ± 2.727	21.689 ± 2.836	20.955 ± 1.612	29.952 ± 2.448	30.291 ± 2.405 *
Impact of 20 µ M gliclazide on oxidative DNA damage induced by 10 µ M H ₂ O ₂	2.993 ± 0.548 #	2.922 ± 0.740 #	3.521 ± 0.858 #	4.751 ± 0.662 #	5.884 ± 1.172 *	5.040 ± 1.155 #

P* < 0.05, *P* < 0.01, ****P* < 0.001 as compared with a sample of healthy individuals; #*P* < 0.001 as compared with a gliclazide-untreated sample

Conclusion: We confirm that the level of basal endogenous DNA damage is higher in T2DM patients. Our results indicate that gliclazide may reduce the toxic effect of free radicals on DNA, and thereby decrease the risk of genomic instability in T2DM patients.

ADOPT: The effectiveness of metformin versus glyburide in type 2 diabetes

W. H. Herman¹, S. M. Haffner², S. E. Kahn³, B. Zinman⁴, R. R. Holman⁵, G. F. Viberti⁶, J. M. Lachin⁷, B. G. Kravitz⁸, M. A. Heise⁸,
¹Internal Medicine – Metabolism, Endocrinology and Diabetes (MEND), University of Michigan, Ann Arbor, United States, ²Medicine/Clinical Epidemiology, University of Texas Health Science Center at San Antonio, United States, ³Department of Medicine, VA Puget Sound Health Care System, Seattle, United States, ⁴Medicine, Mount Sinai Hospital, Toronto, Canada, ⁵Diabetes Trials Unit, OCDEM, Churchill Hospital, Oxford, United Kingdom, ⁶Department of Diabetes & Endocrinology, King's College London School of Medicine, United Kingdom, ⁷The Biostatistics Center, George Washington University, Rockville, United States, ⁸GlaxoSmithKline, King of Prussia, United States.

Background and Aims: UKPDS reported similar HbA_{1c} responses in overweight (≥120% ideal body weight, mean BMI 31.4 kg/m²) type 2 diabetic patients treated with metformin (MET) or sulphonylurea. ADOPT (A Diabetes Outcome Progression Trial) compared initial oral monotherapies in recently diagnosed type 2 diabetic patients and found rosiglitazone (RSG) to be superior to MET and glyburide (GLY), as assessed by time to monotherapy failure (time to the first of two successive fasting plasma glucose [FPG] values >180mg/dl). Here, we present a prespecified secondary analysis from ADOPT comparing the efficacy of MET and GLY.

Materials and Methods: Eligible patients (diagnosed with type 2 diabetes within 3 years) were 30–75 years of age and had FPG levels 126–180 mg/dl with lifestyle management alone. Mean BMI was 32.2 kg/m². Treatment was randomised and study medication was titrated to a total daily dose of 2 g MET (n=1454) or 15 mg GLY (n=1441).

Results: Compared with GLY, the risk of monotherapy failure was reduced by 46.5% with MET treatment (*p*<0.01). At 4 years, 36% of patients in the MET group had HbA_{1c} <7% and remained on monotherapy compared with 26% in the GLY group (*p*<0.01). A longitudinal linear model showed that MET maintained a group mean HbA_{1c} of <7% until month 45, while GLY did so until month 33. Higher incidences of gastrointestinal adverse events were reported with MET treatment (38% vs. 22%, *p*<0.01); however, the occurrence of hypoglycemia was lower (12% vs. 39%, *p*<0.01). In contrast to patients treated with MET, GLY-treated patients gained weight at 4 years (–2.53 kg vs. 1.81 kg, respectively, *p*<0.01).

Conclusion: ADOPT demonstrated that in patients with recently diagnosed type 2 diabetes, MET is more effective than GLY, providing more durable glycemic control with less hypoglycemia and without weight gain.

Alogliptin (SYR-322) is a novel, potent, highly selective dipeptidyl peptidase-IV inhibitor that improves glucose tolerance and β cell function in *ob/ob* mice

K. Takeuchi¹, Y. Moritoh¹, T. Asakawa¹, O. Kataoka¹, L. Shi², H. Odaka¹;
¹Takeda Pharmaceutical Company, Ltd, Osaka, Japan,
²Takeda San Diego, Inc, San Diego, United States.

Background and Aims: Alogliptin (ALO; SYR-322) is a novel, oral dipeptidyl peptidase-IV (DPP-4) inhibitor under development for the treatment for type 2 diabetes (T2D). DPP-4 inhibitors are a new class of antihyperglycemic agents that increase active glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide levels in plasma by inhibiting their rapid degradation by DPP-4. These incretin hormones induce glucose-dependent insulin secretion and play an important role in glucose homeostasis. Non-selective DPP-4 inhibitors that also target DPP-8 and DPP-9 have been associated with vascular/skin lesions in monkeys and other toxic effects in rats and dogs, suggesting that high selectivity for DPP-4 over other, related serine proteases is an important characteristic for this class of agents. The aim of this work was 1) to assess the potency and selectivity of ALO for DPP-4 *in vitro*; and 2) to assess the pharmacodynamics and efficacy of chronic administration of ALO in *ob/ob* mice, an obese model of T2D.

Materials and Methods: The selectivity of ALO for recombinant human DPP-4 over DPP-2, DPP-8, DPP-9, FAP/seprase, PREP, and trypsinase was determined *in vitro*. In the first *in vivo* study, ALO was administered to *ob/ob* mice as a dietary admixture at 2.8 and 14.1 mg/kg/day for 4 weeks. In the second study, ALO was administered to *ob/ob* mice as a dietary admixture at 42.2 mg/kg/day for 4 weeks; the mice were then fed a compound-free diet for 24 hours, fasted for a further 18 hours, and subjected to an oral meal tolerance test (OMTT).

Results: ALO potently inhibited human DPP-4 enzymatic activity with an IC₅₀ of ~6.9 nM and exhibited >10,000 selectivity for DPP-4 over other, related serine proteases *in vitro* (IC₅₀ >100,000 nM vs. DPP-2, DPP-8, DPP-9, FAP/seprase, PREP, and trypsinase). In the first *ob/ob* mouse study, ALO dose dependently inhibited plasma DPP-4 (24% and 62% for 2.8 and 14.1 mg/kg/day, respectively) and significantly increased active GLP-1 (2.3- and 5.3-fold, respectively) after 4 weeks. In addition, decreased glycosylated hemoglobin (0.4% and 0.7%, respectively), increased plasma insulin (1.5- and 1.8-fold, respectively), increased pancreatic insulin content (1.5- and 1.9-fold, respectively), decreased glucagon (26% and 23%, respectively), and significantly decreased plasma triglycerides (51% and 42%, respectively) were observed. In the second *ob/ob* mouse study, ALO significantly inhibited plasma DPP-4 (80%), significantly decreased glycosylated hemoglobin (0.9%), and significantly increased plasma insulin (2-fold) and pancreatic insulin content (2.5-fold) after 4 weeks. Despite the lack of measurable DPP-4 inhibition before the OMTT, significantly increased early phase insulin secretion (2.4-fold) and improved glucose tolerance (25% decrease in glucose AUC) were observed in the ALO-treated mice. Immunohistochemical analysis revealed increased insulin staining in the β-cells of ALO-treated mice compared with non-treated mice, suggestive of improved β-cell function with ALO. No significant changes in body weight or food consumption were observed during the 2 studies.

Conclusion: Taken together, these results indicate that ALO is a potent and highly selective inhibitor of DPP-4 that has the potential to improve glycemic control and preserve β-cell function in patients with T2D.

0879

BI 1356, a novel and selective xanthine based DPP-IV inhibitor, exhibits a superior profile when compared to sitagliptin and vildagliptin

L. Thomas, F. Himmelsbach, M. Eckhardt, E. Langkopf, M. Mark;
¹Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany.

Background and Aims: BI 1356 is a novel xanthine based DPP-IV inhibitor with a high potency and a low k_{off} rate in vitro that has been demonstrated to have a long duration of action also in vivo. Here, we compare the in vivo efficacy and duration of action of BI 1356 after single oral dosing with that of sitagliptin and vildagliptin.

Results: All three compounds dose-dependently inhibited plasma DPP-IV activity in HanWistar rats. ED50 values for inhibition of DPP-IV activity 7 hours post dose were 0.3 mg/kg for BI 1356, 0.7 mg/kg for vildagliptin and 3.5 mg/kg for sitagliptin. However, while the inhibitory potency remained high even 24 hours post dose with BI 1356 (ED50 0.7 mg/kg), the ED50 increased to >10 mg/kg for vildagliptin and sitagliptin. The effects of BI 1356, vildagliptin and sitagliptin on glucose tolerance in C57Bl/6J mice were compared after giving the compounds either 45 min or 16 hours before an oral glucose challenge. All three compounds reduced glucose AUC to a similar extent when given shortly before the glucose load (BI 1356 by 45%, sitagliptin by 53%, vildagliptin by 47%; all at 1 mg/kg). In contrast, only BI 1356 still improved glucose tolerance after administration of the same dose 16 hours before the test (AUC by ~25%). While sitagliptin improved glucose tolerance when a 10-fold higher dose (10 mg/kg) was administered, vildagliptin even with that dose was without effect. Thus, the duration of action for enhancing glucose tolerance in vivo follows the order BI 1356 > sitagliptin > vildagliptin.

Conclusion: We conclude that BI 1356 can be preclinically differentiated from vildagliptin and sitagliptin by a longer lasting inhibition of plasma DPP-IV activity and a longer lasting improvement of glucose tolerance at the same doses. These data predict BI 1356 to have a truly once daily dose regimen in humans. This profile of BI 1356 has been confirmed in clinical trials in healthy volunteers and type 2 diabetic patients.

Improvements in β cell function parameters during 52-week treatment with vildagliptin in patients with mild hyperglycaemia

J. E. Foley¹, A. Schweizer², W. A. Scherbaum³, P. M. Nilsson⁴, G. Lalanne⁵, B. E. Dunning⁶, A. Mari⁷;

¹Novartis, E Hanover, United States, ²Novartis, Basel, Switzerland, ³Endo, Diabetes, Rheum, Univ Düsseldorf, Germany, ⁴Med, Lund Univ, Malmö, Sweden, ⁵Medical Group, Mont De Marsan, France, ⁶PharmaWrite, Princeton, United States, ⁷ISIB, National Research Council, Padova, Italy.

Background and Aims: Vildagliptin is a potent and selective DPP-4 inhibitor that improves glycemic control in patients with type 2 diabetes (T2DM) and moderate-to-marked hyperglycemia by increasing α - and β -cell responsiveness to glucose. This study was undertaken to assess the effects of

vildagliptin on model-assessed β -cell function during 52-week treatment of patients with less advanced T2DM.

Materials and Methods: This multicenter, randomised, parallel-group placebo-controlled study enrolled 306 mildly hyperglycemic (A1C 6.2–7.5%) patients with T2DM. Standard meal tests were performed at Week 0 and Week 52 of treatment with vildagliptin 50 mg qd (n = 156) or placebo (n = 150). Insulin secretory rate (ISR) was calculated by deconvolution of C-peptide levels, and β -cell function was evaluated with a model that describes ISR as a function of absolute glucose levels (insulin secretory tone and glucose sensitivity), the rate of change of glucose (rate sensitivity), and a potentiation factor.

Results: At baseline, mean age = 63.1 y, BMI = 30.2 kg/m², FPG = 7.1 mM and A1C = 6.7%. As shown below, vildagliptin significantly increased insulin secretory tone (+17%), glucose sensitivity (+40%) and rate sensitivity (+32%) (Fig. 1)

The excursion of the potentiation factor and total insulin secretion (ISR AUC_{0-240min}) during meals was unchanged. The enhancements of β -cell function were accompanied by a decrease in the glucose AUC_{0-2h} (between-group difference in the adjusted mean change [AM Δ] = -1.7 \pm 0.5 mM·h, P=0.002) and in A1C (between-group difference in AM Δ = -0.3 \pm 0.1%, P<0.001).

Conclusions: In patients with mild hyperglycemia, improved β -cell function is maintained throughout 52-wk treatment and underlies sustained improvement in glycemic control.

Vildagliptin is safe and well tolerated in patients with mild or moderate renal impairment

T. Thuren¹, S. Byiers², P. Mohideen²;

¹Novartis, E Hanover, United States, ²Novartis, Basel, Switzerland.

Background and Aims: Vildagliptin is a potent and selective DPP-4 inhibitor that improves glycemic control in patients with type 2 diabetes (T2DM) by increasing both α - and β -cell responsiveness to glucose. Clinical data have shown that vildagliptin, at doses of 50 or 100mg daily, effectively reduces HbA_{1c} with a tolerability profile similar to placebo. Among patients with T2DM, the prevalence of kidney disease ranges from 20–40%. The purpose of this abstract is 1) to report on the prevalence of mild or moderate renal impairment in the safety database for the vildagliptin global development program and 2) to examine the safety profile of vildagliptin monotherapy in patients with mild or moderate renal impairment in comparison to those with normal kidney function. Metabolism is the major elimination pathway for vildagliptin, with a minority of unchanged drug (23%) excreted in the urine.

Material and Methods: Glomerular filtration rate (GFR) was calculated by the MDRD method: cutoffs of 60 to <90 mL/min/1.73 m² and 30 to <60 mL/min/1.73 m² were used to define mild and moderate renal insufficiency, respectively. Phase 3 safety data from 8 pooled monotherapy and 7 pooled add-on therapy studies with vildagliptin were used.

Results: A total of 1864 patients receiving vildagliptin (either as monotherapy or in combination with other agents) had MDRD-estimated mild (n = 1650)

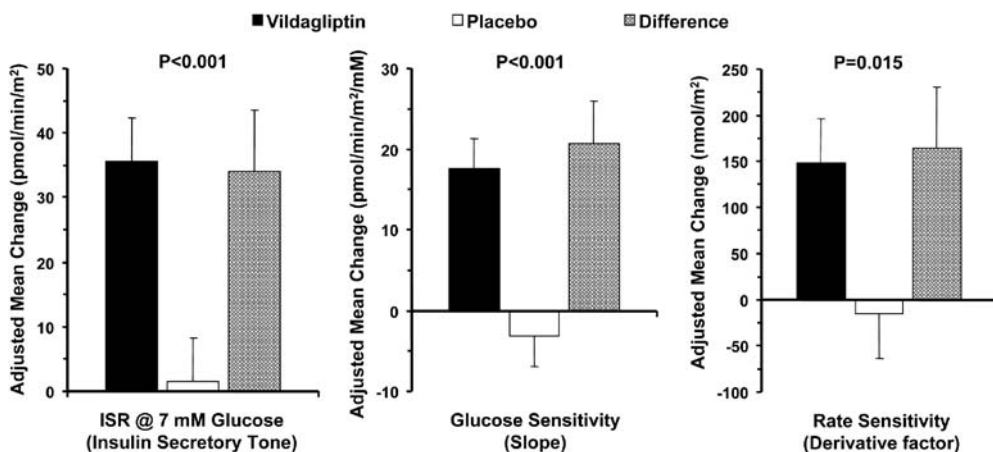

Fig. 1 Abstract 0880

or moderate ($n = 214$) renal impairment, vs. 1913 vildagliptin-treated patients with normal renal function. As shown below, in monotherapy studies the incidence of any adverse event (AE) was similar among patients receiving vildagliptin 50 or 100mg daily, rosiglitazone, pioglitazone or placebo, but lower than that in patients receiving metformin. In patients with moderate renal insufficiency, the incidence of any AE was similar among all active treatment groups, but higher than in the placebo group.

	Vilda 50 mg/d	Vilda 100 mg/d	Met up to 2 g/d	Rosi 8 mg/d	Pio 30 mg/d	PBO
Normal renal function (GFR ≥ 90 mL/min/1.73 m ²)						
n	223	873	67	151	137	160
Any AE	54.3	59.9	74.6	64.9	50.4	63.8
Mild renal insufficiency (GFR 60 – <90 mL/min/1.73 m ²)						
n	163	873	165	104	75	162
Any AE	55.2	63.7	76.4	61.5	48.0	57.4
Moderate renal insufficiency (GFR 30 – <60 mL/min/1.73 m ²)						
n	23	107	20	12	4	25
Any AE	82.6	67.3	70.0	75.0	75.0	44.0

In monotherapy studies, the overall incidence of serious AEs and discontinuations due to AEs showed generally similar levels between mild and moderate renal impairment groups. Subjects with normal renal function tended to have somewhat lower incidences of these events, as would be expected, since renal impairment is generally associated with more comorbid illness.

Conclusions: Nearly half of all patients exposed to vildagliptin (50mg and 100mg daily doses) during its global development program had mild or moderate renal impairment. Assessment of safety in these renally-impaired subjects reveals a safety profile versus (placebo or active) control, similar to that observed in patients with no renal impairment.

Antidiabetic action of nateglinide includes augmentation of glucagon-like peptide-1 activity mediated partly through inhibition of DPP IV mediated degradation

A. M. McKillop, N. A. Duffy, B. D. Green, N. Irwin, V. A. Gault, F. P. M. O'Harte, P. R. Flatt;
School of Biomedical Sciences, University of Ulster, Coleraine, United Kingdom.

Background and Aims: Dipeptidyl peptidase (DPP IV) inactivates glucagon-like peptide-1(7–36)amide (GLP-1) by removing the dipeptide His⁷-Ala⁸ from the N-terminus. Due to the rapid enzymatic degradation of GLP-1, recent diabetic therapeutic approaches have focussed on the inhibition of DPP IV to ameliorate insulin release and metabolic control. This study examined the effect of a range of antidiabetic drugs on DPP IV activity and incretin hormone degradation in type 2 diabetes.

Materials and Methods: The effects of rosiglitazone, troglitazone, glibenclamide, tolbutamide, nateglinide, repaglinide and BTS 67582 on DPP IV activity were investigated in pooled normal human plasma over a range of drug concentrations. Reverse-phase HPLC and electrospray ionisation mass spectrometry (ESI-MS) were used to determine the effects of nateglinide on DPP IV-mediated degradation of GLP-1. Further *in vitro* experiments using clonal beta cells assessed the effects of nateglinide on GLP-1 stimulated insulin release and *in vivo* studies determined the metabolic effects of nateglinide and GLP-1 in obese diabetic (*ob/ob*) mice.

Results: DPP IV inhibitory effects of the thiazolidinediones, troglitazone ($p < 0.001$) and rosiglitazone ($p < 0.001$) were concentration-dependent from 125 to 1000 μM . The strongest inhibitor nateglinide (67% inhibition observed at 200 μM) was effective at low therapeutically relevant concentrations (25 μM ; $p < 0.001$). HPLC and ESI-MS analysis revealed that after 8 h incubation only 14% of GLP-1(7–36)amide remained intact ($t_{1/2}$ 1.4h) in plasma whereas in the presence of 1 mM nateglinide, no GLP-1 degradation was detected ($t_{1/2}$ >8h). Inhibition of DPP IV mediated degradation of GLP-1 by nateglinide was both concentration and time dependent. At a concentration of 62.5 μM , nateglinide inhibited GLP-1 degradation by 45% ($p < 0.001$). Concentration dependent stimulation of insulin secretion was evident with nateglinide (2.0–2.4-fold; $p < 0.001$) in BRIN-BD11 cells and further enhanced up to 3.6-fold

with 10^{-7} M GLP-1 ($p < 0.001$). In obese diabetic *ob/ob* mice, nateglinide (630 $\mu\text{M}/\text{kg}$, ip) improved the glucose-lowering ($p < 0.001$) and insulin-releasing ($p < 0.001$) activity of 25 nM/kg GLP-1 given together with 18 mM/kg glucose. The glucose lowering activity of GLP-1 (53%; $p < 0.001$) was significantly enhanced when administered with nateglinide (67%; $p < 0.001$) in contrast to nateglinide alone (11%; $p < 0.05$). Combined administration of GLP-1 and nateglinide increased insulin levels after 15, 30 and 60 min and AUC values were significantly greater than either glucose alone (529%; $p < 0.001$) or glucose plus GLP-1 (103%; $p < 0.001$). This was accompanied by significantly enhanced circulating concentrations of active GLP-1(7–36)amide (61% increase at 30 min). Similarly nateglinide augmented the glucose and insulin responses to feeding and such actions were abolished by co-administration of 25 nM/kg exendin(9–39) and (Pro³)GIP to block incretin hormone action.

Conclusion: The action of nateglinide as a prandial insulin-releasing agent may partly rely on inhibition of GLP-1 degradation as well as beta cell K_{ATP} channel inhibition.

0883

The correlation among the serum dipeptidyl peptidase IV activity the serum HDL-C and HbA_{1c} levels in patients with type 2 diabetes

T. Varga¹, A. Somogyi¹, G. Lengyel¹, B. Sárman¹, Z. Tulassay¹, L. Selmeci², G. Firneisz²;

¹2nd Department of Medicine,

²Laboratory of Heart and Vessel Surgery Clinic, Semmelweis University, Budapest, Hungary.

Background and Aims: Serum dipeptidyl peptidase IV (DPP IV, CD26) is a cell surface ectoenzyme widely distributed in the human body, that is also detectable in the human serum. The significant efforts from the DPP IV inhibitors enhance the incretin system put the molecule on the map in the treatment of patients (patients) with type 2 diabetes mellitus (T2DM). Although previous studies found correlations between the serum DPP IV activity and the HbA_{1c} furthermore with the fasting glucose levels, no data were available on the potential correlation with other clinically important factors such as the serum lipid profile. We aimed to study the serum dipeptidyl peptidase IV activities in patients with T2DM and compare them with healthy controls. Correlations among the serum DPP IV activity and laboratory data were also evaluated.

Materials and Methods: Serum DPP IV activity was measured by microplate-based (Multiskan-Plus-MKII, Labsystem) kinetic assay in 49 patients with T2DM, and 18 healthy controls. Gly-Pro-pNA (Bachem, Bubendorf, Switzerland) was used as substrate. Results are expressed in nmol/ml/min (U/L) pNA hydrolysed. T-test and Pearson correlation were used for statistical analysis. Glucose, HbA_{1c}, CRP, HOMA-R, TG, LDL-C, HDL-C, Creatinin, Cystatin-C, ALAT, ASAT, gGT, ALP, BI, UA were determined according to the standard methods. Patients with T2DM received a standard test meal (50g CH) to observe postprandial DPP IV activities.

Results: The fasting serum DPP IV activity was not different in patients with T2DM (mean = 25,78 U/L [SD 6,44]) compared to healthy controls (26,05[3,93]). Changes in serum DPP IV activity were neither detectable (0', 60', 180') in patients with T2DM nor in controls after test meal. No correlation was found between DPP IV activity and glucose (0', 60', 120', 180'), HOMA-R index, CRP, LDL-C, TG levels. The serum DPP IV activities correlated positively with HbA_{1c} values at borderline significance (Pearson Corr.: 0,253 $p < (2\text{-tailed signif.}): 0,0797$) in patients with T2DM. Furthermore a significant negative correlation was found between the DPP IV activity and the serum HDL-C levels in type 2 diabetic patients (Pearson Correlation: -0,366, $p < (2\text{-tailed signif.}): 0,0105$).

Conclusion: The serum DPP IV activity remains relatively unwavering. The determination of the serum DPP IV activity probably does not provide clinical benefit in decision making about the initiation of the DPP IV inhibitor therapy in patients with 2TDM. The effect of the DPP IV enzyme is likely to be exerted via a paracrine route, however in the clinical practice this can not be assessed on a routine basis. In this set of type 2 diabetic patients the serum DPP IV activities showed the strongest (negative) correlation with the serum HDL-C levels. Further studies are needed to clarify the exact molecular pathomechanism of the correlation between the serum DPP IV activities and the serum HDL-C levels, that we report here for the first time.

PS 83 DPP-4 inhibitors: session II

0884

Initial combination therapy with sitagliptin, a selective DPP-4 inhibitor, and metformin leads to marked improvement in β cell function in patients with type 2 diabetes

L. Xu, D. E. Williams-Herman;

Clinical & Quantitative Sciences, Merck Research Laboratories, Rahway, United States.

Background and Aims: GLP-1 improves β -cell function in patients with type 2 diabetes. Sitagliptin (SITA) inhibits the degradation of intact (active) incretins, resulting in 2- to 3-fold increases in active GLP-1 levels, and has also been demonstrated to improve β -cell function. Metformin (MF) augments active and total GLP-1 levels. With potentially additive effects on incretins, co-administration of SITA and MF on β -cell function was examined in patients with type 2 diabetes.

Material and Methods: Data were from a 24-week, placebo (PBO)-controlled randomised study in which 1091 patients were randomised to 1 of 6 treatments: SITA 100 mg/MF 1000 mg, SITA 100 mg/MF 2000mg, MF 1000mg, MF 2000mg (all as divided doses administered b.i.d.); SITA 100mg q.d.; or PBO. A subset (n = 500) of patients underwent frequently sampled (10-points collected over 3.5 hrs) meal tolerance tests. β -cell function was assessed using the C-peptide minimal model. Parameters of β -cell function from this model allow for the estimation of the insulin secretion rate (ISR) and the characterisation of the ISR into static (Φ_s ; β -cell responsiveness to above-basal glucose following a meal), and dynamic (Φ_d ; β -cell responsiveness to the rate of increase in above-basal glucose following a meal) components.

Results: After 24 weeks, the changes in static and dynamic β -cell responsiveness (Φ_s and Φ_d) and disposition indices (ISR in the context of changes in insulin sensitivity) were increased with all active treatments relative to PBO and appeared to be approximately additive with co-administered SITA and high dose MF relative to the monotherapies (Table).

Table. Change from Baseline at Week 24 in Indices of Beta-Cell Function

Φ_s ($10^{-9}/\text{min}$)	No MF	MF 1000 mg	MF 2000 mg
No SITA	-1.3	5.9	13.0
SITA 100 mg	10.6	18.4	18.9
Φ_d (10^{-9})	No MF	MF 1000 mg	MF 2000 mg
No SITA	5.2	31.4	54.1
SITA 100	24.2	21.8	132.1
DI _s	No MF	MF 1000 mg	MF 2000 mg
No SITA	-6.9	19.0	48.5
SITA 100 mg	21.7	63.9	90.7
DI _d	No MF	MF 1000 mg	MF 2000 mg
No SITA	-48.5	204.2	483.5
SITA 100	62.2	271.1	1087.9

Data are median change from baseline at Week 24; DI = disposition index

Conclusions: There were marked and approximately additive improvements in β -cell function with co-administered sitagliptin and metformin, consistent with their effects on post-meal active GLP-1 levels.

Achievement of glycaemic targets with vildagliptin

S. Dejager¹, A. Schweizer², A. Couturier¹, R. E. Pratley³;

¹Novartis, E Hanover, United States, ²Novartis, Basel, Switzerland,

³Diabetes Metab Trans Med, Univ Vermont, Burlington, United States.

Background and Aims: The ADA recommends a target A1C <7.0% to minimise risk of microvascular complications in patients with type 2 diabetes (T2DM), but a minority achieve this goal. Vildagliptin is a potent and selective DPP-4 inhibitor that improves glycemic control by increasing both α - and β -cell responsiveness to glucose. The aim of this work is to summarise findings

from the global Phase 3 program regarding the efficacy of vildagliptin in bringing patients to an A1C goal of <7%.

Materials and Methods: Data are reported from two 24-week, placebo-controlled monotherapy trials in drug-naïve patients (pooled), one study of vildagliptin (100mg daily) added to metformin (MET, 2000mg daily) and one study of initial combination therapy with pioglitazone (PIO, 30mg qd). The proportion of patients reaching goal is dependent on the baseline A1C, therefore data are presented for all subjects and for those with a baseline A1C <8%.

Results: As reported below, target A1C was achieved by 40% of patients receiving vildagliptin 100 mg daily vs. 20% of patients receiving placebo; in patients with baseline (BL) A1C \leq 8.0%, more than half of those receiving vildagliptin reached goal. These data were confirmed in a larger pooled analysis of all (5) Phase 3 monotherapy trials; in patients with BL A1C \leq 8.0% (mean \approx 7.6%) 60% of patients receiving vildagliptin 100mg daily achieved A1C <7.0%. When vildagliptin 100mg qd was given as initial combination with PIO 30mg qd, 65% of patients receiving the combination achieved endpoint A1C <7.0% vs. 43% of patients receiving either PIO or vildagliptin alone. As add-on to MET, 4-fold more patients got to goal with vildagliptin 100 mg/d than with placebo; in patients with BL A1C \leq 8.0%, 54% of patients receiving vildagliptin attained the goal vs. 13% of those receiving placebo added to MET.

	Placebo	Vildagliptin 100 mg/d
Monotherapy		
All pts, BL A1C \approx 8.4%	19.8% (36/182)	39.7% ^a (71/179)
BL \leq 8.0%, mean \approx 7.6%	25.7% (19/74)	54.2% ^a (39/72)
Add-on to MET		
All pts, BL A1C \approx 8.4%	9.4% (12/128)	35.5% ^a (50/141)
BL \leq 8.0%, mean \approx 7.5%	13.3% (8/60)	54.1% ^a (33/61)
Initial combination		
	PIO or Vildagliptin alone	Combination
All pts, mean BL \approx 8.7%	43% (62/146 or 67/156)	65% ^a (93/143)
BL \leq 8.0%, mean BL \approx 7.6%	67% or 70% (32/48 or 30/43)	77% (34/44)

^aP<0.001 vs PBO or monotherapy

Conclusions: Twice as many patients achieved the ADA goal A1C of < 7.0% with vildagliptin monotherapy compared to placebo, whereas 4-times more patients reached goal when vildagliptin was added to MET. Two-thirds of patients achieved an endpoint A1C <7.0% when initially treated with the combination of vildagliptin/PIO (100mg/30mg qd).

Sitagliptin, a DPP-4 inhibitor, administered once- or twice-daily, provides improvement throughout 24-hour glucose control in Japanese patients with type 2 diabetes mellitus

K. Nonaka¹, H. Tsubouchi¹, K. Okuyama¹, Y. Fukao¹, P. P. Stein²;

¹Clinical Development Institute, Banyu Pharmaceutical Co., Ltd., Tokyo,

Japan, ²Merck & Co., Inc., Whitehouse Station, N.J., Rahway, United States.

Background and Aims: Sitagliptin is an orally-active, potent and selective DPP-4 inhibitor for the treatment of patients with type 2 diabetes. This 4-week, randomised, double-blind, placebo-controlled, parallel group study evaluated the 24-hour glucose profile with sitagliptin 100 mg/day dosed once-daily (100 mg q.d.) or twice-daily (50 mg b.i.d.) in Japanese patients with type 2 diabetes.

Materials and Methods: Following an 8-week diet/exercise including a 2-week placebo run-in, and wash-off period required for those on oral antihyperglycemic agents, patients with an A1C of \geq 6.5% and <10.0% were randomised to sitagliptin 100 mg q.d., 50 mg b.i.d. or placebo in a 1:1:1 ratio for 4 weeks. Frequent blood sampling over 24 hours was performed at baseline and Week 4 and a weighted average was calculated (the 24 hour weighted mean glucose [24-hr WMG]); change in the 24 hr-WMG was the primary endpoint. Efficacy analysis was based on patients who completed 24-hr sampling at baseline and Week 4.

Results: Seventy-six (of 80 randomised) patients, ages 31–69 years, were analysed for efficacy, including 25, 24 and 27 patients in the sitagliptin 100mg q.d. (mean baseline A1C 7.8%), 50mg b.i.d. (7.5%) and placebo (7.9%) groups, respectively. At Week 4, LS mean change in 24-hr WMG from baseline (95%

CI) was significantly ($p < 0.001$) greater with 100mg q.d. (-34.9 mg/dL [-40.9 , -28.9]) and 50mg b.i.d. (-28.6 mg/dL [-34.7 , -22.4]) compared to placebo (-9.0 mg/dL [-14.8 , -3.2]). No significant difference was observed between sitagliptin groups (i.e., 100mg q.d. vs. 50mg b.i.d.) in the changes of 24-hr WMG ($p = 0.146$). Two-hour postprandial plasma glucose (2-hr PPG) was measured after breakfast, lunch and dinner in this study. The LS mean change in 2-hr PPG from baseline after breakfast was significantly greater with 100mg q.d. (-54.5 mg/dL) and 50mg b.i.d. (-42.6 mg/dL) compared to placebo (-8.2 mg/dL). Similar results were observed in the LS mean change in 2-hr PPG from baseline after lunch and dinner: -43.9 mg/dL, -31.0 mg/dL and -14.8 mg/dL after lunch, and -33.2 mg/dL, -34.1 mg/dL and -12.7 mg/dL after dinner, in 100mg q.d., 50mg b.i.d. and placebo groups, respectively. Fasting plasma glucose was significantly reduced with sitagliptin 100mg q.d. and 50mg b.i.d. compared to placebo with LS mean change from baseline of -22.3 mg/dL, -16.0 mg/dL, and -3.1 mg/dL, respectively ($p < 0.001$ vs. placebo). Glycosylated albumin was also decreased with sitagliptin 100mg q.d. and 50mg b.i.d. compared to placebo: -2.7% , -2.3% , -0.4% , respectively ($p < 0.001$ vs. placebo). For all parameters measured, there was no significant difference between sitagliptin dosing regimens. Moreover, both sitagliptin dosing regimens were well tolerated with no significant between-group differences in the incidence of adverse events and drug-related adverse events. There were neither serious drug-related AE nor events of hypoglycemia reported.

Conclusion: In Japanese patients with type 2 diabetes who had inadequate glycaemic control on diet and exercise, sitagliptin 100mg/day provides substantial glucose lowering efficacy over a 24-hour period following 4 weeks of treatment. No additional efficacy was observed with the twice-daily dose regimen compared to the once-daily dose regimen.

0887

Efficacy and safety of vildagliptin in the elderly: pooled analysis of 5 monotherapy studies

R. E. Pratley¹, J. Rosenstock², F. X. Pi-Sunyer³, A. Couturier⁴, A. Schweizer⁵, S. Dejager⁴,

¹Diabetes Metab Trans Med, Univ Vermont, Burlington, United States,

²Diabetes, Dallas Diabetes Endo Ctr, Dallas, United States,

³Medicine, Columbia Univ, New York, United States,

⁴Novartis, E Hanover, United States, ⁵Novartis, Basel, Switzerland.

Background and Aims: Vildagliptin is a potent and selective DPP-4 inhibitor that improves glycaemic control in patients with type 2 diabetes (T2DM) by increasing α and β cell responsiveness to glucose.

Materials and Methods: Phase 3 trials with vildagliptin enrolled a substantial number of persons age ≥ 65 years, allowing us to examine whether there were any age-associated differences in efficacy or tolerability with this new agent. Data were pooled from the vildagliptin monotherapy arms (100mg daily; 50mg bid or 100mg qd) of 2 placebo-controlled trials and 3 active-controlled trials.

Results: Summarised below are baseline (BL) values and adjusted mean Δ in A1C, FPG and body weight (BW), and the general safety profile of vildagliptin monotherapy.

Efficacy Population	Age ≥ 65 y (mean = 70 y)		Age < 65 y (mean = 50 y)		All (mean = 53 y)	
	N=238		N=1231		N=1469	
BL	$\Delta \pm$ SE		BL	$\Delta \pm$ SE	BL	$\Delta \pm$ SE
A1C (%)	8.3	$-1.2 \pm 0.1^*$	8.7 [†]	$-1.0 \pm 0.0^*$	8.6	$-1.0 \pm 0.0^*$
FPG (mg/dL)	173	$-26.1 \pm 3.0^*$	189 [†]	$-19.3 \pm 1.4^{*†}$	186	$-20.7 \pm 1.3^*$
BW (kg)	83.4	$-0.9 \pm 0.2^*$	92.0 [†]	$-0.2 \pm 0.1^†$	90.6	$-0.3 \pm 0.1^*$
Safety Population	N=270		N=1395		N=1665	
Any AE: n (%)	181 (67.0)		816 (58.5)		997 (59.9)	
SAE: n (%)	13 (4.8)		39 (2.8)		52 (3.1)	
DC due to AE: n (%)	8 (3.0)		34 (2.4)		42 (2.5)	
Hypoglycemia: n (%)	2 (0.7)		4 (0.3)		6 (0.4)	
Death: n (%)	2 (0.7)		1 (0.1)		3 (0.2)	

* $P < 0.05$ vs BL (within subgroup), [†] $P < 0.05$ vs Age ≥ 65 y (between subgroups)

values, and vildagliptin significantly decreased body weight only in the older subgroup. Vildagliptin was well tolerated in older patients, with a low risk of hypoglycemia (and no severe events). Specific AEs occurring in $\geq 5\%$ of older or younger subgroups, respectively, were constipation (5.6%, 2.2%), nasopharyngitis (5.9%, 6.8%), dizziness (6.3%, 5.2%) and headache (3.7%, 6.2%).

Conclusion: Vildagliptin represents a good therapeutic option for treating elderly patients with T2DM.

Dose-response relationship for glycaemic efficacy, safety and tolerability of sitagliptin after 12 weeks of treatment in Japanese patients with type 2 diabetes mellitus

Y. Iwamoto¹, K. Nonaka², A. Okada², K. Okuyama², P. P. Stein³,

¹Diabetes Center, Tokyo Women's Medical University, Tokyo, Japan,

²Banyu Pharmaceutical CO., LTD., Tokyo, Japan,

³Merck&Co., Inc., Rahway, United States.

Background and Aims: Sitagliptin (SITA) is an orally active, potent, selective dipeptidyl peptidase-4 (DPP-4) inhibitor. This randomised, double-blind, placebo-controlled, parallel-group study evaluated the dose response relationship for efficacy and tolerability of SITA in Japanese patients with type 2 diabetes mellitus (T2DM).

Materials and Methods: Japanese patients with T2DM either not on an antihyperglycemic agent or on an antihyperglycemic agent in monotherapy (discontinued at entry into the observation period), entered an 8 week diet and exercise observation period including 2 weeks placebo (PBO) run-in period. Patients with an A1C of 6.5% to 10% after the observation period were eligible to be randomised to 1 of 5 treatment groups (PBO, SITA 25mg, 50mg, 100mg or 200mg q.d.) in a 1:1:1:1:1 ratio for a 12 weeks treatment period. The primary endpoint was the change from baseline of A1C at week 12 and the efficacy analysis was based on a full analysis set with last observation carried forward.

Results: 363 patients, ages 28 to 75 years, were randomised. Mean baseline A1C ranged from 7.49% to 7.74%. LS mean A1C change from baseline was $+0.28\%$, -0.41% , -0.71% , -0.69% , and -0.76% in PBO, SITA 25 mg, 50 mg, 100 mg, and 200 mg groups, respectively. A significant dose-response relationship across PBO to SITA 200 mg was demonstrated ($p < 0.001$). Between group differences compared to PBO in LS mean change from baseline (95% CI) were, -0.69% (-0.85 , -0.52), -0.99% (-1.16 , -0.82), -0.96% (-1.14 , -0.79), and -1.04% (-1.21 , -0.86), in SITA 25mg, 50mg, 100mg, and 200mg groups, respectively. The mean baseline fasting plasma glucose (FPG), ranged from 142.6 mg/dL to 156.5 mg/dL, the LS mean change from baseline was $+6.3$ mg/dL, -9.6 mg/dL, -11.4 mg/dL, -14.6 mg/dL, and -16.9 mg/dL in PBO to SITA 200 mg, respectively. In this study, a meal tolerance test (MTT) was conducted with all randomized patients to assess an effect on postprandial glucose lowering. The LS mean 2-hour postprandial glucose (2hr-PPG) change from baseline was $+1.7$ mg/dL, -38.6 mg/dL, -50.5 mg/dL, -56.6 mg/dL, and -63.4 mg/dL in PBO to SITA 200mg groups, respectively. While the effect of SITA on A1C after 12 weeks plateaued at doses ≥ 50 mg, other key endpoints such as FPG and 2hr-PPG showed numerically better efficacy at doses ≥ 50 mg. During the MTT, glucagon levels were suppressed at all doses of SITA. DPP-4 inhibition rate was also assessed at week 12. On safety, SITA was generally well-tolerated. There were no significant differences between any SITA treatment groups compared to PBO with respect to the incidences of drug-related clinical and laboratory AEs. No drug-related serious AEs were reported. The incidence of hypoglycemia observed in the SITA treatment groups was low and comparable to that observed in PBO group. The effect of SITA on body weight was neutral.

Conclusion: In this study, in Japanese patients with T2DM who were inadequately controlled on a diet/exercise therapy alone, dose-response relationship was established across groups (PBO to SITA 200 mg) in glycaemic control efficacy for both fasting and postprandial glucose. A1C reduction was similar for doses from 50 to 200mg and ranged from 0.96% to 1.04%. SITA up to 200mg was generally well-tolerated without any serious drug-related AEs. The effect on body weight was neutral.

Relative to the younger subgroup, in older patients vildagliptin decreased A1C and FPG to a somewhat greater degree, from significantly lower baseline

0889

Saxagliptin improves glycaemic control as monotherapy in type 2 diabetesJ. List¹, J. Rosenstock², S. Sankoh³, R. Chen¹;¹Global Clinical Research, Bristol-Myers Squibb, Princeton,²Diabetes & Endo, Dallas Diabetes & Endocrine Ctr., Dallas,³Global Biometric Sciences, Bristol-Myers Squibb, Princeton, United States.

Background and Aims: The incretin hormones have a number of beneficial effects on blood glucose regulation, including increasing glucose-stimulated insulin secretion and suppressing glucagon secretion. A new approach to the treatment of type 2 diabetes is to enhance the physiologic actions of incretins by inhibiting the enzyme responsible for their inactivation, dipeptidyl peptidase-4 (DPP-4). Saxagliptin is a potent, oral DPP-4 inhibitor. This phase 2 study evaluated the efficacy and safety of a range of once-daily doses of saxagliptin for the treatment of type 2 diabetes in drug-naïve subjects.

Materials and Methods: Drug-naïve subjects with inadequately controlled type 2 diabetes ($HbA_{1c} \geq 6.8\%$ and $\leq 9.7\%$) were studied in a phase 2, multicenter, randomised, parallel-group, double-blind, placebo-controlled trial. The trial included 2 distinct cohorts: a low-dose cohort (LDC) (2.5, 5, 10, 20, and 40mg once daily vs. placebo), with 338 subjects treated for 12 weeks, and a high-dose cohort (HDC) (100mg once daily vs. placebo), with 85 subjects treated for 6 weeks.

Results: In the LDC (mean baseline HbA_{1c} 7.9%), treatment with saxagliptin led to significant reductions in HbA_{1c} at all doses compared with placebo ($P < 0.007$). The adjusted change from baseline in HbA_{1c} at Week 12 ranged from -0.72% to -0.90% for doses of 2.5 to 40mg daily vs. -0.27% for placebo. Forty-one to 53% of saxagliptin-treated subjects achieved HbA_{1c} of $< 7.0\%$ vs. 20% of placebo-treated subjects. Fasting serum glucose (FSG) decreased by 11 to 22 mg/dL in the saxagliptin treatment arms compared with an increase of 3 mg/dL for placebo. Postprandial glucose 60 minutes after a liquid meal, a major determinant of overall glycemic control, decreased by 24 to 41 mg/dL in the saxagliptin treatment arms compared with a decrease of 1 mg/dL for placebo. Similar overall results were seen in the high-dose cohort (mean baseline HbA_{1c} 7.7%), with an adjusted change from baseline in HbA_{1c} at Week 6 of -1.09% for saxagliptin 100 mg daily vs. -0.36% for placebo. In both cohorts, beta cell function, as measured by HOMA- β , increased in all saxagliptin treatment arms. Saxagliptin had a neutral effect on weight. The incidence of adverse events was similar across all treatment groups, including placebo. The most common adverse events in the LDC were headache, upper respiratory tract infection, and urinary tract infection; the most common adverse events in the HDC were headache, urinary tract infection, and constipation. No cases of confirmed hypoglycemia were observed in the LDC.

Conclusions: Saxagliptin, across a range of doses, improved glycemic control in drug-naïve subjects with type 2 diabetes. Treatment with saxagliptin led to improvements in HbA_{1c} , fasting serum glucose, postprandial glucose, and beta cell function. Saxagliptin was generally safe and well-tolerated.

BI 1356, a novel xanthine-based DPP-IV inhibitor, exhibits high potency with a wide therapeutic window and significantly reduces postprandial glucose excursions after an oGTTK. A. Dugi¹, T. Heise², A. Ring¹, U. Graefe-Mody¹, A. Ritzhaupt¹, S. Huettner¹;¹Boehringer Ingelheim Pharma GmbH & Co KG, Biberach, Germany,²Profil Institut, Neuss, Germany.

Background and Aims: BI 1356 is a novel, orally available, selective inhibitor of DPP-IV in development for the treatment of type 2 diabetes. Safety, tolerability, pharmacokinetics, and pharmacodynamics of BI 1356 were investigated in a single-rising dose trial (SRD, 2.5 to 600mg) in healthy men (47 on BI 1356, 16 on placebo, mean age 38.3 years, BMI 24.8 kg/m²), and in a multiple rising dose trial (MRD, 1 to 10mg) in men with type 2 diabetes (35 on BI 1356, 12 on placebo, age 56.0 years, BMI 28.6 kg/m², baseline HbA_{1c} 6.7%) treated once daily for 12 days.

Materials and Methods: Both trials were double-blind, randomised, and placebo controlled. In the MRD trial, patients entered a 14-day washout period of previous antidiabetic medication before randomisation. DPP-IV activity and BI 1356 plasma concentrations were measured at regular

intervals. An oGTT was performed prior to first drug administration and 24 hours after the last dose to assess postprandial glucose excursions (AUC_{0-2h}) and GLP-1 levels.

Results: In both studies, C_{max} was reached 1–3h post-dose. The exposure of BI 1356 increased less than proportionally in the relevant therapeutic dose range from 1 to 10mg. Time to steady state decreased from 6 to 2 days with increasing doses. Renal excretion was low and does not constitute the main pathway of BI 1356 elimination. In the SRD study, DPP-IV activity was inhibited by $>80\%$ with 5mg BI 1356. After administration of 25–600mg BI 1356, mean plasma DPP-IV activity was still below 10% at 24h post-dosing. In the MRD study, 24h post-dose, the activity of DPP-IV was inhibited by $>50\%$ and $>80\%$ with BI 1356 plasma concentrations as low as 3.2 nmol/L and 5.3 nmol/L, respectively. Compared to baseline, the mean GLP-1 plasma concentrations measured at 24h after the last dose had increased by 12.4 to 14.0 pmol/L for 2.5, 5, and 10mg BI 1356, but only by 2.8 pmol/L with placebo. After 12 days of treatment, postprandial glucose excursions (AUC_{0-2h} after oGTT 24h post-dose) were reduced dose-dependently by -53.0 mg/dL (1mg), -106 mg-h/dL (2.5mg), -82 mg-h/dL (5mg), and -111 mg-h/dL (10mg) for BI 1356 and -25.1 mg/dL for placebo compared with baseline. Despite the small group sizes, the reduction was statistically significant compared to baseline and compared to placebo ($p < 0.05$) for the 2.5, 5, and 10mg dose groups. In both studies, treatment with BI 1356 up to a single dose of 600mg and multiple doses of up to 10mg for 12 days was well tolerated with no signs of hypoglycemia. The overall incidence of adverse events (AEs) in subjects or patients treated with BI 1356 was not higher than with placebo. There were no signs of QTc prolongation in either study. No serious adverse events and no discontinuations due to AEs were observed.

Conclusion: Administration of BI 1356 in single doses of up to 600mg in healthy men and in multiple doses of up to 10mg for 12 days in patients with type 2 diabetes was well tolerated and safe. BI 1356 plasma concentrations correlated well with DPP-IV activity, achieving DPP-IV inhibition of $>80\%$ with a plasma concentration of 5.3 nmol/L. The results confirm the high potency, 24h duration of action, and very wide (>100 -fold) therapeutic window of BI 1356.

Single-rising-dose pharmacokinetics, pharmacodynamics, and tolerability of alogliptin benzoate (SYR-322), a novel, dipeptidyl peptidase-IV inhibitor, in healthy male subjectsR. Christopher¹, P. Covington², M. Davenport³, P. Fleck⁴, Q. Mekki⁴, E. Wann⁵, A. Karim⁴;¹Takeda San Diego, ²Development, Pharmaceutical Product Development,Inc., Wilmington, ³Clinical Pharmacology, Pharmaceutical ProductDevelopment, Inc., Richmond, ⁴Takeda Global Research & DevelopmentCenter, Inc., Deerfield, ⁵Takeda Pharmaceuticals North America, Inc.,

Deerfield, United States.

Background and Aims: Alogliptin benzoate (ALO; SYR-322) is a novel, oral, potent, and highly selective dipeptidyl peptidase-IV (DPP-4) inhibitor under development to improve glycemic control in patients with type 2 diabetes. DPP-4 rapidly degrades glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide, incretin hormones that induce glucose-dependent insulin secretion and play an important role in glucose homeostasis. This study was designed to assess the pharmacokinetics (PK), pharmacodynamics (PD), and tolerability of single rising doses of ALO in healthy male subjects.

Materials and Methods: In this randomised, double-blind, placebo-controlled study, 36 subjects (6 cohorts of 6 subjects each) received either a single rising dose of ALO (25, 50, 100, 200, 400, or 800 mg; $n=5$ per cohort) or placebo ($n=1$ per cohort); all subjects completed the study. Serial PK blood and urine samples were collected up to 72 hours postdose. The PD effects of ALO were determined over 72 hours postdose based on ex vivo plasma DPP-4 inhibition and plasma intact GLP-1 levels.

Results: ALO was absorbed rapidly with a median T_{max} of 1 to 2 hours across all doses. Mean AUC and C_{max} of ALO increased with increasing dose. Mean $T_{1/2}$ of ALO ranged from 12.4 to 21.4 hours across all doses. The fraction of dose excreted unchanged in urine over 72 hours postdose ranged from 60% to 71% across all ALO doses. Alogliptin resulted in rapid, almost complete, and sustained inhibition of plasma DPP-4 activity (Figure). Mean inhibition ranged from 74.3% to 97.0% at 24 hours postdose and from 47.5% to 83.0%

at 72 hours postdose. Peak and total exposure of plasma intact GLP-1 were 2- to 3-fold greater for the ALO dose groups than placebo. Alogliptin was well tolerated across all dose levels. No serious adverse events were reported and no subject discontinued due to an adverse event. The proportion of subjects who experienced at least 1 adverse event did not increase with increasing ALO dose and was similar for all ALO groups combined and the placebo group.

Conclusion: Administration of a single dose of ALO resulted in rapid, potent, and sustained inhibition of plasma DPP-4 activity and increased intact GLP-1 levels in healthy male subjects. The PK and PD profiles of ALO are supportive of a once-daily dosing regimen.

Polymorphisms of the TUB gene are associated with anthropometry and eating behaviour in middle-age women

J. V. van Vliet-Ostaptchouk^{1,2}, N. C. Onland-Moret^{3,4}, R. Shiri-Sverdlov², P. J. J. van Gorp², P. H. M. Peeters⁴, C. Wijmenga³, M. H. Hofker^{1,2}, Y. T. van der Schouw⁴;

¹Department of Pathology and Laboratory Medicine, University Medical Center Groningen, ²Molecular Genetics, Maastricht University,

³DBG-Department of Medical Genetics, University Medical Center Utrecht,

⁴Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, The Netherlands.

Background and Aims: The TUB gene, encoding an evolutionary conserved protein, is highly expressed in the hypothalamus and might act as a transcription factor. Mutations in TUB cause late-onset obesity, insulin-resistance and neurosensory deficits in mice. An association of common variants in the TUB gene with body weight in humans has been reported. The aim was to investigate the relationship of single nucleotide polymorphisms (SNPs) of the TUB gene (rs2272382, rs2272383 and rs1528133) with both anthropometry and macronutrient intake.

Materials and Methods: The association of SNPs in the TUB gene with anthropometrical measurements and self-reported macronutrient intake from a validated food frequency questionnaire was studied in a population-based, cross-sectional study of 1680 middle-aged Dutch women, using linear regression analysis.

Results: The minor allele C of the rs1528133 SNP was significantly associated with increased weight (+1.88kg, $P = 0.022$) and BMI (+0.56 units, $P = 0.05$). Compared with non-carriers, both AG heterozygotes and AA homozygotes of the rs2272382 SNP derived less energy from fat (AG: $-0.55 \pm 0.28\%$, $P = 0.05$, AA: $-0.95 \pm 0.48\%$, $P = 0.047$). However, both genotypes were associated with an increased energy intake from carbohydrates ($0.69 \pm 0.33\%$, $P = 0.04$ and $1.68 \pm 0.56\%$, $P = 0.003$, respectively), mainly because of a higher intake of mono- and disaccharides ($0.86 \pm 0.31\%$, $P = 0.005$, and $1.08 \pm 0.52\%$, $P = 0.038$, respectively). Both these SNPs, rs2272382 and rs1528133, were also associated with a higher glycemic load (GL) in the diet. The GL was higher among those with AG and AA genotypes for the variant rs2272382 than among the wild types (+1.49 (95% CI: $-0.27 - 3.24$) and +3.89 (95% CI: $0.94 - 6.85$) units, respectively). Carriers of the minor allele C of rs1528133 were also associated with an increased GL of 1.85 units compared with non-carriers.

Conclusion: We found that genetic variation of the TUB gene was associated with both body composition and macronutrient intake, suggesting that TUB might influence eating behavior.

Differential gene expression in adipose tissue during weight loss and weight maintenance

L. E. Johansson, H. Parikh, L. Groop, M. Klintonberg, F. Norström, M. Ridderstråle;

Department of Clinical Sciences Malmö, Lund University, Malmö, Sweden.

Background and Aims: Weight loss has previously been associated with a down regulation of inflammatory genes in the adipose tissue. In order to better understand the physiology of weight loss, and also weight maintenance, it is important to identify the pathways involved in these processes. The aim of this study was to investigate the effect on gene expression in adipose tissue after weight loss and weight maintenance after weight loss, respectively.

Materials and Methods: Eleven obese patients referred to the Department of Endocrinology at UMAS were included in the study. Three subcutaneous adipose tissue needle biopsies were collected (at baseline, after $\geq 10\%$ body weight reduction by low calorie diet and after two months of group therapy for weight maintenance) and RNA extracted. The transcriptomes were analysed using HG-U133 Plus 2 GeneChip® from Affymetrix. The robust multi-array

average (RMA) method was used for background adjustment, quantile based normalisation and calculation of expression values. Probe sets for which percentage present calls were less than 50% of all scans were excluded, which left 27,400 probe sets for further analysis. We applied the Patterns from Gene Expression (PaGE) method for log-transformed data with the use of modified *t* statistics to identify differentially expressed probe sets between different groups. We considered only those probe sets as differentially expressed between two groups with a confidence level of at least 0.99. WebGestalt was used for further analysing and visualising the data.

Results: During weight loss 50 genes were upregulated and included mostly ribosomal genes. 185 genes were down regulated during weight loss. These genes were mostly involved in lipid metabolism, oxidoreductase activity genes and cytoplasmic genes. Genes coding for proteins involved in *Wnt* signalling were also among these genes. During weight maintenance 73 genes were upregulated. They were mostly genes participating in lipid metabolism, carbohydrate metabolism and angiogenesis. Interestingly, 330 genes were downregulated during weight maintenance and most of them were inflammatory genes. Between baseline and weight maintenance only two genes were upregulated but 69 were downregulated.

Conclusion: This study indicates that weight loss and weight maintenance after weight loss should be viewed as two separate processes in the adipose tissue. In both cases, more genes were down regulated than up regulated. This may indicate that many genes are up regulated due to resistance to negative regulation in the obese state. Finally, previous findings of a down regulation of inflammatory genes seem to be associated with weight maintenance rather than weight loss.

Factors associated with change in status of non-alcoholic fatty liver disease (NAFLD) in Korea

H.-K. Kim¹, C.-H. Kim², G.-E. Lee¹, S.-H. Chun¹, H.-S. Lee¹, H.-C. Cho¹, K.-R. Kim¹, I.-Y. Pae¹, J.-H. Kim¹;

¹Health Promotion Center, Asan Medical Center, Seoul,

²Endocrinology & Metabolism, Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Republic of Korea.

Background and Aims: Nonalcoholic fatty liver disease (NAFLD) is a common hepatic disorder characterised by fat accumulation in the liver without personal history of heavy drinking. However, there has been little data about long-term changes in status of NAFLD for large number of subjects. To know the factors associated with changing status of NAFLD, we analysed life style factors, biochemical data, and abdominal ultrasonography from subjects who could be followed for 5-years (between 2000 and 2005) at the Health Promotion Center of Asan Medical Center.

Materials and Methods: Among 6096 subjects whose follow-up data were available, 2895 subjects (mean age 47±8.7, range 20–79 years; 1,502 men and 1,393 women) were analyzed after strict exclusion. Subjects who were heavy alcohol consumers, positive for hepatitis B virus surface antigen or hepatitis C virus antibody, had hepatic enzyme concentrations higher than three times the upper normal limit, overt hypo- or hyperthyroidism, any cancer, or sonographic evidence of other chronic liver disease at baseline were excluded.

Results: Fatty liver on ultrasonography was graded into four categories (normal, mild, moderate, and severe) by the degree of echogenicity. At baseline, 1965 subjects were classified as normal, 622 as mild, 288 as moderate, and 20 as severe fatty liver. At follow-up examination after 5 years, 1719 were normal, 690 had mild, 383 had moderate, and 66 had severe fatty liver. After 5 years, 2012 (70%) subjects remained at the same ultrasonographic grade of fatty liver. However, 263 (9%) subjects showed decreased grade of echogenicity and 155 (5%) subjects among them were normalised. In contrast, 583 (20%) subjects were changed into higher grade of fatty liver. Improved group showed 1.6±3.0 kg reduction of body weight from baseline while aggravated group gained 1.7±2.9 kg of weight. Improvement of fatty liver was associated with decrease of serum AST, ALT, triglyceride, cholesterol, and fasting glucose.

Conclusion: In conclusion, mild degree of weight reduction is associated with improvement of NAFLD and related metabolic abnormalities such as dyslipidemia and hyperglycemia in the long-term.

Insulin resistance and insulin secretion in morbidly obese patients after bariatric surgery

M. Promintzer¹, G. Prager², G. Pacini³, C. Anderwald¹, M. Mandl¹, S. Shakeri Manesch², M. Stadler⁴, P. Nowotny¹, M. G. Bischof¹, B. Ludvik¹, A. Luger¹, M. Krebs¹;

¹Department of Internal Medicine III, Division of Endocrinology and Metabolism, Medical University of Vienna, Austria, ²Department of Surgery, Medical University of Vienna, Austria, ³Metabolic Unit, ISIB-CNR, Padua, Italy, ⁴Third Medical Department of Metabolic Diseases and Nephrology, Hospital of Hietzing, Vienna, Austria.

Background and Aims: The increase in the prevalence of type 2 diabetes is closely linked to the rise in obesity. However, severe obesity is a refractory condition and, at present, surgical intervention is the only treatment yielding long term results. Bariatric surgery not only induces lasting weight loss but also leads to improvements or resolution of comorbid diseases, particularly type 2 diabetes. Improvements in insulin sensitivity and insulin resistance might contribute to observed improvements in glucose metabolism. The aim of the study was to assess the effects of bariatric surgery on these parameters.

Materials and Methods: We performed a frequently sampled oral glucose tolerance test (75g, 3h OGTT) and a hyperinsulinemic (40mU/min/m²) isoglycemic clamp test in 12 morbidly obese non diabetic patients before bariatric surgery (OBpre: 10f/2m, age: 38.9±2.8a, BMI: 48.8±1.5 kg/m²) and in 10 matched healthy controls (CON: 8f/2m, age: 41.6±1.3a, BMI: 22.1±0.4 kg/m²). Glucose turnover was determined using DD-[6,6-²H₂]glucose. Adaptation index characterising the relationship between insulin sensitivity and direct β-cell function was calculated. Examinations were repeated ~6 months after surgery in 5 (3 Roux-en-Y gastric bypass, 2 gastric bypass) of these obese patients (OBpost: 4f/1m, age:47.8±2.4a, BMI: 37.7±3.4 kg/m²) and compared to 6 BMI-, age- and sex- matched obese patients without history of gastrointestinal surgery (CONob: 5f/1m, age:50.9±2.7a, BMI:35.3±0.7 kg/m²).

Results: Surgery: Bariatric surgery resulted in a weight loss of 25.9kg (ΔBMI -10.6 kg/m²). OGTT: While fasting plasma glucose concentrations were comparable between OBpre and CON fasting insulin and c-peptide were higher in OBpre. During the oGTT peak plasma glucose and insulin concentrations were significantly higher in OBpre compared to CON.

In OBpost fasting and early postprandial glucose concentrations were unchanged compared to OBpre. However, lower glucose concentrations were observed in the late postprandial period. Fasting insulin and c-peptide concentrations decreased in response to bariatric surgery. However, the postprandial increase in insulin and c-peptide concentrations was markedly augmented in OBpost compared to all other groups (insulin and c-peptide at 60 min.: OBpost vs. OBpre/ CON/ CONob: p<0.001 respectively).

Insulin and c-peptide secretion following glucose load were adapted to insulin resistance prior surgery but were inadequately elevated after bariatric surgery (adaptation index: OBpost:5.0±0.7/ OBpre: 2.6±0.8/ CONob:2.8±0.5/ CON:3.3±0.6; p<0.05 for OBpost vs. OBpre and CONob).

Clamp: As expected the insulin stimulated glucose infusion rate (GIR) was markedly lower in OBpre (M: 2.1±0.5 mg/kg/min) compared to CON (M: 9.5±1.6 mg/kg/min; p<0.001). Despite dramatic weight loss GIR was comparable between OBpre and OBpost (M: 2.8±0.4 mg/kg/min).

Conclusion: Our data indicate that rather augmented insulin secretion than changes in insulin resistance are responsible for the reported improvements in glycaemic control after bariatric surgery.

M.P. is employed on a grant of the Austrian Society of Internal Medicine (Josef-Skoda-Award) which was competitively awarded to M.K.

Bariatric surgery results in a significant decline in sensory nerve function

R. A. Gandhi¹, D. Selvarajah¹, C. N. MacDermott¹, C. J. Emery¹, R. Ackroyd², S. Tesfaye¹;

¹Diabetes Research Unit, ²Department Of Surgery, Royal Hallamshire Hospital, Sheffield, United Kingdom.

Background: Lack of efficacy of conventional treatments of obesity has led to increasing popularity of bariatric surgery as a therapeutic option. Little is known about possible long-term effects. Although an increased incidence of

peripheral neuropathy after surgery has been reported, there is an absence of any prospective studies.

Aims: The aim of this study was therefore to objectively assess peripheral and autonomic nerve function in subjects before and 1 year after bariatric surgery

Methods: 12 subjects (10 females) underwent detailed quantitative sensory testing, nerve conduction studies (radial, sural, common peroneal and tibial nerves), and autonomic function tests.

Results: Sensory nerve conduction velocity (SNCV) fell from 66.7 ± 7.3 to 56.3 ± 4.2 m/s (mean \pm SD) in the radial nerve ($p < 0.001$) and from 51.3 ± 7.0 to 41.9 ± 5.2 m/s in the sural nerve ($p < 0.001$). This was accompanied by a rise in amplitude in both nerves (radial nerve: 42.4 ± 11.0 to 55.1 ± 16.2 μ V, $p = 0.06$; sural nerve: 16.0 ± 4.7 to 22.6 ± 10.4 μ V, $p < 0.05$). No significant changes were seen in parameters of motor nerve function. On quantitative sensory testing, significantly greater numbers of subjects had hyperalgesia during heat-pain testing at 1 year. Autonomic function testing showed a fall in the resting heart rate from 79.7 ± 9.1 to 65.8 ± 9.8 beats/min ($p < 0.01$) and a rise in beat-to-beat variation (R/R ratio) on standing from 1.28 ± 0.19 to 1.56 ± 0.25 ($p < 0.001$). No other significant changes were noted in autonomic function.

Conclusion: This study shows a large decline in SNCV after bariatric surgery. Substantial reductions in body fat may be having an impact on the composition of myelin, a major determinant of SNCV, which consists of 70% lipid. The role of nutritional deficiencies after surgery, as well as inflammatory and immune mechanisms also deserves consideration. The improvements in sensory nerve amplitude are probably due to improved signal detection as a result of reductions in subcutaneous fat. The increase in hyperalgesia is consistent with the development of an early peripheral neuropathy.

Bariatric surgery is increasingly being employed to treat obesity. It is clear, however, that sensory nerve dysfunction is common sequelae and may herald the development of more overt peripheral neuropathy.

Could HbA_{1c} have a role in the diagnosis of type 2 diabetes?

S. E. Manley¹, I. M. Stratton², P. G. Nightingale³, R. A. Round¹, J. M. Smith¹, S. C. L. Gough⁴;

¹Clinical Biochemistry, University Hospital Birmingham NHS Foundation Trust, Birmingham, ²Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, ³Wellcome Trust Clinical Research Facility, University Hospital Birmingham NHS Foundation Trust, ⁴Selly Oak Hospital Diabetes Centre, University Hospital Birmingham NHS Foundation Trust, United Kingdom.

Background and Aims: Diabetes is increasing worldwide, currently 250 million patients, with International Diabetes Federation (IDF) predicting 380 million in 2025, the majority living in the developing world. Diabetes is diagnosed by measurement of fasting plasma glucose (FPG) with the oral glucose tolerance test (OGTT) restricted to those with impaired fasting glucose (IFG). The OGTT is poorly reproducible, time consuming and expensive. The recent IDF clinical guideline suggests HbA_{1c} testing at diagnosis.

Materials and Methods: 700 patients with IFG (WHO criteria) were referred by community physicians in South Birmingham, UK, to a hospital diabetes centre. FPG and HbA_{1c} were measured in capillary blood with 'DCCT aligned' HbA_{1c} reported from an ion exchange, high performance liquid chromatography (IE HPLC) analyser that detects variant haemoglobin. Diabetes (DM) was identified if FPG ≥ 7.0 mmol/L or capillary 2 hour plasma glucose (2hPG) ≥ 12.2 mmol/L on 75g OGTT. A cut-point for HbA_{1c}, for use with FPG to best identify those with DM, was calculated using the first 500 patients' (cohort A) results and subsequently validated in the next 200 (cohort B).

Results: Patients were aged 61(12) years, mean (1SD), 51% male and 11% Asian Indian. FPG from venous blood collected prior to referral was lower than capillary FPG at OGTT, $6.5(0.4)$ mmol/L v $6.7(0.8)$ mmol/L, $p < 0.001$. HbA_{1c} was $6.3(0.7)\%$ with 4 patients in A and 1 in B omitted because of variant haemoglobin. One patient was excluded from B with no 2hPG value. 2hPG on OGTT was $9.8(2.8)$ mmol/L with OGTT not performed in 35% (245/700) since FPG was ≥ 7.0 mmol/L (66/198 for B). There were no significant differences between data from each cohort or for Asian Indians versus the rest. ROC curves derived from cohort A indicated that HbA_{1c} $\geq 6.0\%$ can be used as a cut-point where FPG < 7.0 mmol/L to identify those patients requiring OGTT for diagnosis with resulting sensitivity 96% and specificity 100% for DM. When the algorithm was applied to cohort B, it identified 86/88 cases diagnosed conventionally i.e. sensitivity 98% and specificity 100%. Use of this algorithm would reduce the number of OGTT required in B by 39% from 132 to 81.

Conclusion: Use of this algorithm, HbA_{1c} $\geq 6.0\%$ (by IE HPLC) in combination with FPG < 7.0 mmol/L, to identify IFG patients requiring OGTT would reduce the number of OGTT required by 40%. Such a modification to current diagnostic criteria for DM would not impair sensitivity or specificity but reduce costs and the use of resources. It would simplify procedures for diagnosis of DM in those with IFG, as HbA_{1c} could be measured with FPG prior to referral for OGTT.

VALIDATION – COHORT B

n=198	HbA _{1c} <6% FPG <7 mmol/L	HbA _{1c} $\geq 6\%$ FPG <7 mmol/L	HbA _{1c} <6% FPG ≥ 7 mmol/L	HbA _{1c} $\geq 6\%$ FPG ≥ 7 mmol/L

Population screening for metabolic syndrome – the IJsselstein Screening for Central Obesity studyI. W. G. Bobbink¹, P. L. Salome², K. J. Gorter¹, M. van den Donk¹, G. E. H. Rutten¹;¹Julius Center, University Medical Center Utrecht,²General Practice, Medische Maatschap IJsselstein, The Netherlands.

Background and Aims: Instead of screening for diabetes type 2 in the general population, focussing on groups at high risk for cardiovascular diseases may be preferred. In The Netherlands it is unknown how often cardiovascular risk factors cluster and in how many cases metabolic syndrome (MetS) is present. This study aims to investigate whether GP-mediated population-based screening for central obesity can be used to identify subjects with MetS and to assess the prevalence of MetS.

Materials and Methods: Cross-sectional study among 11,872 adults (20–70 year) on the list of 12 GPs in a city in the center of The Netherlands. Subjects, who were not known with MetS, diabetes, hypertension, or dyslipidaemia, received an invitation from their GP to measure their waist circumference (WC) with an enclosed tape measure. Subjects with a WC >88 cm (women) or >102 cm (men) were invited for further examinations to determine MetS according to the NCEP/ATPIII criteria (WC, blood pressure, fasting glucose, HDL and triglycerides). In addition, a 3% random sample of subjects with a WC ≤ 88/102 cm was invited for further examinations to study the sensitivity of the procedure.

Results: A total of 7253 subjects (61%) responded, 6773 subjects (57%) had measured their WC. 2206 of them (33%) had a WC > 88/102 cm and 1655 of these subjects participated in further examinations. In 450 (27%) of these participants MetS was detected. Additionally, in 4 (3.3%) of the 122 randomly selected subjects with a WC ≤ 88/102 cm who underwent examinations MetS was detected. The prevalence of MetS assessed by screening subjects with central obesity is 7%. The total prevalence of MetS in the source population will be assessed by adding these numbers to the prevalence of MetS in 3500 patients known with MetS, diabetes, hypertension or dyslipidaemia (data available at the EASD meeting). Both the response rate and the participation rate were age-dependent. The sensitivity of the used screening method (MetS in WC > 88/102 group / (MetS in WC > 88/102 group + 33* MetS in WC ≤ 88/102 group)) was 77%. Self-measured WC was overestimated by 76% of the subjects. The mean difference between self-measured and investigator values was 4 cm.

Conclusions: A GP-mediated population screening for central obesity with self-measurement of WC can be used to identify adults with MetS. The prevalence of MetS assessed by such a screening is 7%. This creates possibilities for targeted prevention and treatment of these persons who are at an increased cardiovascular risk.

Abnormal glucose regulation in a community-based population with coronary artery disease; are routine oral glucose tolerance tests necessary?O. A. Mongan¹, A. El-Helali², M. Glacken³, A. W. Murphy⁴, F. Dunne¹;¹Department of Diabetes and Endocrinology, University College Hospital Galway,²Department of Medicine, National University of Ireland, Galway,³Department of Public Health, Merlin Park Regional Hospital, ⁴Department of General Practice, National University of Ireland Galway, Ireland.

Background: Ischaemic heart disease accounts for 25% of all deaths in Ireland. Studies have shown that without an oral glucose tolerance test (OGTT), abnormal glucose regulation (AGR), including impaired fasting glucose (IFG), impaired glucose tolerance (IGT) and diabetes, remains undiagnosed in many people with coronary artery disease. The Heartwatch programme is the national programme in general practice for the secondary prevention of cardiovascular disease in Ireland. A fasting glucose is performed annually as part of this programme, however an OGTT is not routinely recommended.

Aim: This community based study aims to provide reliable evidence of glucose dysregulation, by universal screening, using a 75 gram oral glucose tolerance test, in a defined high risk Irish population with established coronary artery disease.

Materials and Methods: Using the Heartwatch database described, we invited general practitioners (GPs) in the West of Ireland (counties Galway, Mayo and Roscommon) to take part in the study. Participating GPs were asked to invite all of their patients on the database for an OGTT to be carried out in the practice, using a protocol provided by the study group. Training on this protocol was provided to the individual phlebotomists. Informed consent was obtained. To aid recruitment, practices were reimbursed for every OGTT carried out. The OGTT results were classified as normal, IFG, IGT, both IFG and IGT or diabetes according to American Diabetes Association Guidelines.

Results: At the time of the study there were 969 patients enrolled on the Heartwatch database in the selected area. These patients were spread across 33 practices. 23 out of 33 practices agreed to participate. 19 practices comprising of a total of 633 patients on Heartwatch took part in OGTT testing. The baseline prevalence of diagnosed diabetes was 13% (n = 83) leaving 550 people eligible for OGTT. Baseline prevalence of diagnosed IFG was 1% and 2 cases out of 633 had IGT. Of the 550 eligible patients, 56% had an OGTT performed. Of the 305 tests 7.2% had IFG (n = 22), 8.2% had IGT (n = 25), 4.9% had both IFG and IGT (n = 15) and 4.6% were diagnosed with diabetes mellitus (n = 14).

In total we found that 25% of those tested had AGR (N= 76), of these 25 had isolated IGT and 4 of those diagnosed with diabetes had a normal fasting glucose level therefore 37% of those with AGR would have remained undiagnosed without OGTT. This study resulted in the prevalence of abnormal glucose regulation (AGR) increasing from 14.5% to 26.5% in the population of 633 patients.

Conclusion: The baseline prevalence of diabetes and the prevalence of AGR after OGTT are much lower in this study of a high risk Irish population with coronary artery disease, than in similar international studies. Almost 10% of those tested would have remained undiagnosed if an OGTT was done only when indicated by an elevated fasting glucose. We therefore conclude that routine oral glucose tolerance testing, in patients with coronary artery disease, is feasible and necessary.

Intramuscular injection of a vector encoding sRAGE decreases the incidence of diabetes mellitus induced by low dose streptozotocin in rats fed high fat dietB. Su¹, X. Su¹, X. Meng²;¹Endocrinology and Metabolism, Dalian Medical University Second Affiliated Hospital, ²Hematology, Dalian Medical University School of Laboratory Medicine, Dalian, China.

Background and Aims: Studies implicated that dietary AGE could induce body redox and inflammatory cytokines production. We aimed to study if the intramuscular injection of a vector encoding sRAGE could decrease the incidence of diabetes mellitus induced by low dose streptozotocin (STZ) in rats fed on high fat diet.

Materials and Methods: sRAGE was RT-PCR amplified from rat lung total mRNA and cloned to a pLNCX expression vector. Germ-free vectors were injected in hind leg muscles, and transduction was facilitated with electroporation. Mice were grouped into two groups. Mice fed high fat and received sRAGE were designed as treatment group and mice fed high fat that received pLNCX without sRAGE were designed as control group. After 8 weeks of high fat diet, mice were injected with sRAGE or empty vectors. One serial of mice (n=6 in each group) were to observe changes in serum MDA and SOD levels. A second serial (n=10 in each) were to study of STZ-induced incidence of diabetes. One week after injection of vectors, a dose of 30mg/kg STZ was injected intraperitoneally and tail venous glucose was detected one week later.

Results: MDA levels were found decreased one week after injection of sRAGE and lasted for at least three weeks. SOD activities were found increased slowly in the second week and significantly in the third week. As determined with fasting glycemia and random glycemia two mice were in diabetic level (>7.0) in treatment group while 8 mice in diabetic level in control group.

Conclusion: Intramuscular injection of sRAGE decreases the oxygen reactive level and increases anti-reactive activities, and decreases the STZ-induced incidence of diabetes in rats in high fat-diet.

Type 2 diabetes phenotype and progression is significantly different if diagnosed before versus after 65 years of age

H. Kolb¹, B. Schneider², T. Heise³, L. Heinemann³, V. Ludwig⁴, W. Scherbaum¹, S. Martin¹;

¹Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, Germany, ²Institute of Biometrics, Medical University of Hannover, Germany, ³Institute for Metabolic Research, Profil, Neuss, Germany, ⁴IMB, Institute for Medical Informatics and Biostatistics, Basel, Switzerland.

Background and Aims: The incidence of type 2 diabetes is increasing preferentially in younger persons (<65 years of age). It is not known whether disease characteristics in these younger patients are similar to the “classic” late-onset type 2 diabetes.

Materials and Methods: The data base of the German multicentre, retrospective cohort study ROSSO was used to address this question. In ROSSO, 3268 people with type 2 diabetes, from randomly contacted primary care practices, were followed from diagnosis between 1995 and 1999 for a mean of 6.5 years. All newly diagnosed patients of these practices were included, with a lower age limit of 45 years

Results: At diagnosis, 64.2% of the patients had an age between 45 and 65 years. In this younger age group, 57.2% were males, whereas in the age group >65 years only 35.0% were males ($p<0.001$). There was more severe metabolic deterioration at diagnosis and in the following years in the younger cohort, as determined by fasting blood glucose (FBG) and HbA1c levels ($p<0.001$ for both), and by a higher BMI (30.5 vs 28.5, $p<0.001$). Conversely, the prevalence of cardiovascular risk factors (coronary heart disease, heart insufficiency of hypertension, either diagnosed or concluded from the prescription of anti-hypertensives or from increased systolic blood pressure) was significantly higher in the older patient cohort ($p<0.001$, each). Self monitoring of blood glucose (SMBG) was more prominent in the younger cohort (50 vs 36%, $p<0.001$). Both age cohorts experienced a lower risk of the combined endpoint myocardial infarction, stroke and all-cause mortality during the observation period when performing SMBG ($p=0.003$ in the younger cohort, $p=0.039$ in the older cohort).

Conclusion: There are considerable differences in disease characteristics between people diagnosed with type 2 diabetes during 45–65 years of age and patients with diagnosis at later age. Late-onset type 2 diabetes preferentially affects women and is characterised by consistently lower mean BMI, FBG and HbA1c, but exhibits more advanced cardiovascular risk factors. Conversely, younger patients exhibit consistently poorer metabolic but fewer cardiovascular risk factors. The use of SMBG is associated with better clinical outcome in both age cohorts.

Latent autoimmune diabetes in adults as a part of polyendocrine syndrome

M. Bernas, S. M. Zawada-Targoni, A. Czech, J. Taton;
Chair and Department of Internal Medicine and Diabetology, Medical University of Warsaw, Poland.

Background and Aims: Many cases of recently recognized diabetes can have autoimmunological background. Autoantibodies against pancreatic antigens (as it has been proven in the number of studies in diabetes type 1) are not the only one that are present in those patients. It is known that autoimmune thyroiditis is the most common autoimmune disease coexisting with diabetes type 1. Little is known about this problem in subjects with LADA. Latent autoimmune diabetes in adults (LADA) is characterized by clinical features of type 2 diabetes, initial euglycemia (during at least 6 months of treatment) achieved with diet or oral hypoglycemic agents, and presence of autoantibodies.

The aim of the study was to compare the frequency of autoimmune thyroiditis (AT) in adult subjects with newly recognized diabetes type 1, type 2 and LADA.

Materials and Methods: The study included 147 patients with recently recognized diabetes type 1 (29 patients, mean age 46 yrs), LADA (39 patients, mean age 48 yrs) and diabetes type 2 (79 patients, mean age 46.1 yrs). Patients were qualified to the LADA group due to WHO criteria. To assess the type of diabetes the anamnesis was taken, the patients were examined

to BMI, ketoacidosis, concentration of C-peptide (basic and – in the 6th minute after glucagon stimulation) and to autoantibodies: glutamic acid decarboxylase antibodies – GADA, Islet Cell Antibodies –ICA and protein tyrosine phosphatase-like protein IA2-antibodies (ELISA test) at the time of diagnosis. Autoimmune Thyroiditis (AT) was diagnosed using thyroid peroxidase antibodies (TPO), thyroglobulin-antibodies (TG), TSH and fT4 levels.

Results: High titers of autoantibodies were observed in the LADA (ICA: 31%, IA-2: 62.5%/ mean level: 6.69 ng/ml, GADA: 56%/mean: 1082 ng/ml) and type 1 diabetes (ICA: 71.42%, IA-2: 42.85%/ mean level: 1.67 ng/ml, GADA: 100%/mean: 1408 ng/ml). Low levels of GADA were present in 20% of type 2 diabetic patients. Clinically overt hypothyroidisms was estimated in 7 cases of LADA patients (18%), but high levels of anti-thyroid antibodies were observed more common: ATG:15%, mean level 3000 IU/ml (N<180 IU/ml), TPO: in 46%, mean level 1428,5 U/ml (N<100 U/ml) comparing to type 1 where ATG were present in 20%, mean concentration 621.3 IU/ml, and TPO in 33%, mean concentration 1558,5 u/ml and in contrast to type 2 patients, there was no case of overt hypothyroidisms. Anti-thyroid antibodies were present mostly in the presence of more than one diabetic antibodies (58 %).

Conclusion: The study has evaluated that the highest coexistence of antithyroid and antipancreatic antibodies is present in patients with LADA, whereas in type 2 and type 1 is not as common. Thus it seems that there is a need for autoantibody screening for autoimmune thyroiditis especially in patients with LADA.

Transcriptome analyses reveals potential novel biomarkers for the development of type 2 diabetes

P. Ikonomi¹, S. Zangen², Q. Li¹, S. Hacoheh², I. Raz², C. Gelber¹;

¹SCIENCE, ATCC, Manassas, United States,

²Diabetes Unit, Hadassah Hebrew UMC, Jerusalem, Israel.

Background and Aims: The Cohen diabetic (CD) rat is a versatile animal model comprised of 2 rodent strains manifesting many of the common features of type 2 diabetes (T2D) in humans. The sensitive strain (CDs) develops diabetes within 30 days when maintained on a high sucrose/copper poor diet (HSD), whereas the resistant strain (CDr) retains normal blood glucose levels. Neither strain shows any signs of diabetes when provided regular rodent diet (RD). To further characterize the genomic and proteomic changes responsible for either resistance or predisposition to T2D, pancreatic transcriptome changes of these two strains were studied by microarray analyses using the rat expression arrays.

Materials and Methods: Pancreatic RNA extracted for each of the strains was analyzed using the Rat Expression Arrays (Affymetrix) containing oligonucleotide probes for over 30,000 transcripts. The data was analyzed using GeneSpring GX (Agilent, CA) and expression of selected transcripts was confirmed by Real Time PCR.

Results: We have isolated a total of 82 unique transcripts expressed differently in the rat models. Comparisons between the CDs strain and CDr strain when exposed to high sucrose diet, shows that expression of 19 transcripts is reduced by 3 fold or more in CDr-HSD compared to CDs-HSD. These transcripts belong to genes involved in inflammation and immune responses, such as CD38, CD132, CD53 and CCL21. Alternatively, in CDr strain, the expression of 62 transcripts is increased over 3 fold. Regenerating islet-derived 3 gamma (REG3G) and regenerating islet-derived 3 alpha were increased over 20 fold in CDr strain compared to CDs strain, both exposed under a high sucrose diet. These results indicate that both REG3G and REG3A could play protective roles in pancreatic islets. Increased protein and amino acid metabolism was also indicated as shown by the upregulation of methionine adenosyltransferase (MAT1A), glycine amidinotransferase (GATM), phenylalanine hydroxylase (PAH) and asparagine synthetase. Transporter transcripts such as solute carrier family 7 member 3 (SLC7A3), solute carrier family 30 (zinc transporter) member 2 (SLC30A2) and solute carrier family 7 (cationic amino acid transporter member 5 (SLC7A5) as well as the eukaryotic translation initiation factor 4B (EIF4B) were also increased in CDr strain. Sucrose metabolism-related genes including fucosyltransferase 1 (FUT1) were shown to be upregulated by at least 3 fold. Moreover, serine proteinases such as proteinase serine 3, and serine protease inhibitor- kazar type 1 (SPINK1), serine proteinase inhibitor clade I member 2 (SERPINI2),

serine peptidase inhibitor clade A member 10 (SERPINA10) were significantly upregulated in CDr rats. Several unidentified transcripts, whose involvement in T2D remains unknown also show differentiated expression in the resistance and sensitive strains of Cohen Diabetic rat, these transcripts are in the process of further characterization.

Conclusion: Using the Cohen rat models, our microarray analysis indicated the potential involvement of novel pathways in T2D. Quantitative analyses of individual transcripts as well as modifications of their respective proteins will determine the role of such transcripts in the development of the disease and will contribute to the selection of a cluster of predictive markers for the progression of or resistance to T2D.

Liver enzymes and risk of diabetes and cardiovascular disease. Results of the FIBAR Study

C. Lamanna¹, M. Monami¹, G. Bardini², L. Pala², B. Cresci², C. M. Rotella², E. Mannucci¹;

¹Critical Care Medicine and Surgery, Unit of Gerontology, ²Clinical Pathophysiology, Section of Endocrinology, University of Florence, Italy.

Background and Aims: To assess γ -glutamyl-transpeptidase (γ -GT), alanine amino-transferase (ALT), and aspartate amino-transferase (AST) in the prediction of diabetes and cardiovascular disease (CVD) in subjects free from hepatic diseases other than non-alcoholic fatty liver disease (NAFLD)

Materials and Methods: The present analysis was performed on the cohort of subjects enrolled in the FIBAR study, a screening program for diabetes performed between 1st March 2001 and 31st December 2003 in the city of Florence on 3124 subjects who underwent a oral glucose tolerance test. Incident cases of diabetes in nondiabetic subjects (N=2662) were obtained through databases of drug prescriptions, hospital admissions, and lists of subjects eligible for reimbursement. Incident CVD in subjects free of diabetes and CVD at enrolment (N=2617) was identified through hospital admissions and through the register of causes of death. Mean follow-up was 39.6±12.0 months and 39.8±11.4 months for diabetes and CVD, respectively

Results: Yearly incidence of diabetes and CVD was 0.4% and 0.2%, respectively. After adjustment for age and sex, γ -GT>40 U/l was associated with increased incidence of diabetes and CVD (HR [95% CI] 2.54 [1.26–5.11], p<0.05 and 2.21 [0.98–5.43], p<0.10, respectively). Risk of diabetes, but not of CVD, was increased in patients with γ -GT in the 25–40 U/l range. After adjustment for confounders, AST>40 U/l predicted CVD (HR 6.5 [1.5–28.1]), but not diabetes.

Conclusion: Elevated γ -GT or AST are independent predictors of CVD. An increase of γ -GT levels above the normal range, or also in the upper normal range, is an independent predictor of incident diabetes

Body iron stores and the risk of type 2 diabetes

J. Montonen, P. Knekt, A. Reunanen;

Department of Health and Functional Capacity, National Public Health Institute, Helsinki, Finland.

Background and Aims: Epidemiological studies suggest that high body iron stores may be associated with insulin resistance and type 2 diabetes. The aim of this study was to examine serum ferritin concentration and the ratio of the concentrations of transferrin receptors to ferritin in relation to risk of type 2 diabetes.

Materials and Methods: The study design was a nested case-control study within a longitudinal population study. Serum levels of ferritin and transferrin receptors were determined in 234 incident cases with type 2 diabetes identified from the nation wide register of drug reimbursements during the follow-up of 21 years and 464 controls matched for sex, age and study region.

Results: Serum ferritin concentration was associated with an increased risk of type 2 diabetes. The relative risks across the quartiles of serum ferritin concentration were 1.00, 1.76 (95% confidence interval (CI) = 0.92 – 3.35), 2.93 (CI = 1.49 – 5.79) and 2.08 (CI = 1.03 – 4.17; P for trend (P) = 0.08) when adjusted for body mass index, smoking, leisure time physical activity, and

alcohol consumption. The corresponding multivariate relative risks across increasing quartiles of transferrin receptors to ferritin ratio were 1.84 (CI = 0.95 – 3.55), 1.77 (CI = 0.94 – 3.33), 1.17 (CI = 0.63 – 2.18) and 1.00 (P = 0.26). Stronger associations were observed among persons with higher serum concentrations of vitamin E or selenium.

Conclusion: The result of the present study suggest that higher iron stores measured as higher serum ferritin concentration and a lower ratio of transferrin receptors to ferritin are associated with an increased risk of type 2 diabetes.

Fatty liver is associated with risk for development of type 2 diabetes mellitus in Korea

C.-H. Kim¹, H.-K. Kim², K.-E. Lee², S.-H. Chun², I.-Y. Bae², J.-Y. Park³, K.-U. Lee³, J.-H. Kim²;

¹Endocrinology & Metabolism, Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Gyeonggi-do,

²Health Promotion Center, Asan Medical Center, Seoul, ³Endocrinology & Metabolism, Asan Medical Center, Seoul, Republic of Korea.

Background and Aims: Fatty liver is the most commonly found abnormality on liver ultrasonography in general health check-up. Non-alcoholic fatty liver disease is known to be associated with obesity, diabetes, and metabolic syndrome. A limited number of studies have reported associations of markers liver injury, such as alanine aminotransferase (ALT), aspartate aminotransferase (AST), and γ -glutamyltransferase (GGT), with prospective risk of type 2 diabetes. However, it is not established whether hepatic steatosis itself is an independent predictor of incident type 2 diabetes. To investigate the associations of ultrasonographic fatty liver with incident type 2 diabetes, we performed a retrospective longitudinal study.

Materials and Methods: We examined the clinical and laboratory data of 6096 subjects (age, 46.8 ± 8.4, range 20–79 years; 4234 men and 1862 women) who visited the Health Promotion Center at Asan Medical Center for a medical check-up in 2000 and underwent a follow-up examination in 2005. Subjects who had diabetes at baseline, were positive for hepatitis B virus surface antigen or hepatitis C virus antibody, had hepatic enzyme concentrations higher than three times the upper normal limit, or had sonographic evidence of other chronic liver disease (total 724 subjects) were excluded.

Results: Among 5372 included subjects (3670 men and 1702 women), 233 individuals (4.3%) had developed type 2 diabetes after 5 years. In univariate analysis, risk of development of diabetes was associated with male sex, family history of diabetes, smoking, older age, higher BMI, systolic and diastolic blood pressure, fasting glucose, triglyceride, lower HDL cholesterol, and presence of fatty liver on ultrasonography at baseline. In multiple logistic regression models adjusting for age, sex, and alcohol consumption, participants with fatty liver were at significantly increased risk of incident type 2 diabetes compared with those without (risk ratio [RR] 3.92, 95% CI 2.89 – 5.31). After further adjustment for smoking, BMI, triglyceride, HDL, fasting glucose, and GGT, fatty liver remained significantly associated with incident type 2 diabetes (RR 1.84, 95% CI 1.28 – 2.64).

Conclusion: Fatty liver predicts development of type 2 diabetes mellitus independently of classical metabolic syndrome components and markers of hepatic dysfunction in Korean.

In-vitro evaluation of new pharmacodynamic hybrids with insulin secretagogue and NO-donor activity

S. Torri¹, M. Galli¹, V. Calderone², S. Rapposelli³, M. Digiacoio³,

A. Martelli², V. D'Aleo¹, U. Boggi⁴, A. Balsamo³, P. Marchetti¹;

¹Endocrinology and Metabolism, Metabolic Unit,

²Psychiatry, Neurobiology, Pharmacology and Biotechnologies,

³Pharmaceutics Sciences, Faculty of Pharmacy, ⁴Oncology, Transplantation and Advanced Technologies, University of Pisa, Italy.

Background and Aims: Diabetes is associated with beta-cell damage. Vascular alterations are a frequent consequence of the diabetic syndrome, mainly due to endothelium dysfunction. Exogenous nitric oxide (NO) can compensate for the reduced levels of endogenous NO, possibly improving cardiovascular function. Hence we assessed the potential of a molecule combining the properties of insulin secretagogue and NO-donor.

Materials and Methods: Human islets were isolated by collagenase digestion and density gradient purification from the pancreas of 11 multiorgan donors (age 61±15 years; gender 3/8 M/F; BMI 25.0±4.1 Kg/m²). The glibenclamide active metabolite 4-*trans*-hydroxyglibenclamide (M-1) and its nitrooxy derivative DK 315 were obtained through usual synthetic routes. Glibenclamide (GB) was chosen as reference drug. Insulin secretion was studied in response to glucose (G, 16.7 mM), GB (10 and 100 μM), M-1 (10 and 100 μM) and DK 315 (10 and 100 μM). In order to evaluate the vasorelaxing effects, the drugs were also tested on isolated rat aortic rings.

Results: Insulin release at basal glucose (3.3 mM) was 41.0±22.3 μU/ml. Stimulation index (S.I., insulin release in response to a tested compound over basal release) was 4.1±2.5 at 16.7 mM G; 3.8±2.4 and 3.9±2.6 at 10 and 100 μM GB; 4.8±3.0 and 5.7±4.4 at 10 and 100 μM M-1, and 4.9±4.0 and 8.7±5.8 at 10 and 100 μM DK 315, respectively (all N.S. vs 16.7 mM G). GB and M-1 were almost devoid of any significant vasorelaxing effect. DK 315 caused concentration dependent vasorelaxing responses (pIC₅₀=7.240±0.012) which were antagonised by ODQ (1 μM, inhibitor of guanilate-cyclase), indicating that the activity was due to the release of NO.

Conclusion: This study shows that M-1 and DK 315 possess, on human islets, insulinotropic effects comparable to that exhibited by GB. Furthermore, DK 315 showed NO relaxing properties, which can be considered as a complementary pharmacodynamic feature, of potential usefulness for cardiovascular complication associated with the diabetic status.

A novel antioxidant L-2501 ameliorates metabolic disturbances and attenuates weight gain in rats with fructose-induced insulin resistance

N. Gorbenco¹, V. Poltorak², A. Gladkih², O. Ivanova¹, E. Khudyakova¹,

V. Lipson¹, N. Krasova², J. Leschenko², K. Gorbenco¹;

¹Pharmacology, ²Pathophysiology, Institute of Endocrine Pathology Problems, Kharkiv, Ukraine.

Background and Aims: Accumulating evidence suggests a link between increased oxidative stress and insulin resistance. We have previously shown that the low-toxic pyrimido[1,2-a] benzimidazole derivative L-2501 possesses potent antioxidant, anti-inflammatory activity and improves lipid profile in diabetic rabbits. The aim of the study was to explore the impact of L-2501 on metabolic derangements in rats with fructose-induced insulin resistance.

Materials and Methods: Male Wistar rats were divided into three groups: the control group (C, n=8), the high fructose-fed group (F, n=8), which had free access to 250 g/L solutions of fructose for 8 weeks and fructose-fed group treated with L-2501 (F+L) for 8 weeks (50 mg/kg/day per os). At the end of the study fasted rats were subjected to the glucose tolerance test (GTT). Serum levels of non-esterified fatty acids (NEFA), triglycerides (TG) and alanine aminotransferase (ALT) were measured as parameters of insulin resistance. Activities of hepatic glucose-6-phosphatase (G6P), glucose-6-phosphate-dehydrogenase (G6PDH) and liver glycogen content were also measured in all experimental groups. Oxidative status was estimated by plasma thiobarbituric acid reactive substances (TBARS) and total antioxidant activity (TAA).

Results: Fructose feeding induced insulin resistance, as indicated by higher HOMA-IR index (F: 4.52±0.70 vs C: 1.49±0.01, p<0.001) and lower QUICKI

(p<0.01) indexes. The fructose group also developed glucose intolerance, hypertriglyceridemia, significantly elevated fructosamine and NEFA levels, ALT and G6P activities (p<0.01). Administration of L-2501 protected against the forming of fructose-induced glucose intolerance. Area under curve over the GTT was (F+L: 919±34 vs F: 1420±90, p<0.01; C: 851±25 mM x hour). The treatment with L-2501 decreases insulin resistance (HOMA-IR index F+L: 2.29±0.19, p<0.01), triglyceride concentration (F+L: 0.424±0.094 vs F: 0.941±0.97 mmol/l, p<0.01), fructosamine concentrations (F+L: 1.23±0.07 vs F: 1.94±0.17 mmol/l, p<0.01), NEFA levels (2.93±0.13 vs F: 4.20±0.35 mmol/l, p<0.01) and serum ALT activity (p<0.02) in compared with fructose-fed rats treated with placebo. Administration of L-2501 was accompanied by suppression of G6P activity by 44 % (p<0.01), elevation of G6PDH activity (p<0.02) and glycogen content (p<0.01) in liver of fructose-fed animals compared to placebo. In addition, the use of L-2501 was associated with decrease in TBARS concentration 2-fold (p<0.02) and increase in TAA by 75 % (p<0.01) compared to control fructose-fed rats. L-2501 administration resulted in a significant decrease in body weight gain in fructose-fed rats (F+L: 18.9 ± 1.6 vs F: 33.1 ± 2.0 %; p < 0.01).

Conclusion: These data demonstrate that L-2501 administration can ameliorate the deleterious effects of high-fructose diet such as insulin resistance, hypertriglyceridemia, increased gluconeogenesis, oxidative stress and weight gain. These results substantiate the potential of L-2501 as a new therapeutic agent for the correction of multiple risk factors of metabolic syndrome.

0909

Effect of dual (alpha/gamma) peroxisome proliferator-activated receptor activator muraglitazar (MURA) therapy in patients with type 2 diabetes mellitus

M. Fernandez¹, E. Cersosimo¹, A. Gastaldelli², R. A. DeFronzo³;

¹Texas Diabetes Institute, University of Texas Health Science Center, San Antonio, United States, ²Stable Isotope Laboratory, Institute of Clinical Physiology, Pisa, Italy, ³Diabetes Division, University of Texas Health Science Center, San Antonio, United States.

Background and Aims: We evaluated the effect of muraglitazar, a dual (alpha/gamma) peroxisome proliferator-activated receptor (PPAR) activator within the new glitazar class, on glucose and lipid metabolism.

Materials and Methods: A double-blind, randomized controlled trial was performed in 27 patients with type 2 diabetes. Patients received once-daily doses of either 5 mg muraglitazar or placebo plus diet for 16 weeks. Before and after treatment patients underwent: (i) euglycemic hyperinsulinemic clamp combined with tracer infusion to assess endogenous glucose production (EGP) and disposal, and to estimate adipose tissue (Adip-IR=fasting plasma FFA X insulin conc (FPI)) and liver (Hep-IR=EGP x FPI) indices of insulin resistance (IR); (ii) lean and fat body mass quantification by DXA; (iii) liver and visceral fat measurement by MRI/MRS.

Results: MURA treatment improved fasting glycemia (-43 mg/dl, p<0.001), HbA1c (-1.9%, p=0.003), Hep-IR (-37%, p<0.01) and Adip-IR (-50%, p<0.001). Compared to placebo MURA improved total body (primarily reflects muscle) disposal (+2.2 mg/kg.min, p=0.01), increased plasma adiponectin ~2 fold (p<0.0001 vs placebo) and improved insulin-mediated suppression of FFA during the clamp (p<0.002). MURA treatment was associated with a significant increased body weight (+2.5 kg), primarily due to increased body fat (+1.7 kg) but it was associated with significant decreases in both liver fat (-9%, p<0.001) and visceral fat (-1.5%, from 158 to 134 cm², p<0.001); subcutaneous fat increased by +9% (from 393 to 428 cm², p<0.001).

Conclusion: Muraglitazar significantly (i) improved insulin sensitivity in muscle, liver and adipose tissue, despite a modest increase in body fat, and (ii) decreased hepatic and visceral fat content.

0910

CS-917, a fructose 1,6-bisphosphatase inhibitor, combined with a thiazolidinedione or insulin decreases plasma glucose and improves lactate metabolism more effectively than CS-917 monotherapy

T. Yoshida, J. Ogawa, Y. Hagiwara, S. Kanda, K. Takahashi, A. Okuno; Biological Research Laboratories II, Daiichi Sankyo Company, Limited, Tokyo, Japan.

Background and Aims: CS-917 is a novel, oral inhibitor of fructose 1,6-bisphosphatase, a rate-limiting enzyme in gluconeogenesis. We have previously shown that CS-917 reduces plasma glucose (PG) in cynomolgus monkeys and rodent models of type II diabetes such as Zucker diabetic fatty (ZDF) rats and Goto-Kakizaki rats. Elevated plasma lactate (LA) levels have been previously reported following CS-917 administration in old ZDF rats with advanced disease, but not in young ZDF rats. Here, we describe the effect of CS-917 on LA metabolism in rats pretreated with antidiabetic agents.

Materials and Methods: Male, 16-week-old ZDF rats were pretreated for 1 week with rivoglitazone (Rivo; a thiazolidinedione [TZD; 1mg/kg once daily]), insulin (INS [implant]) or acarbose (AC; a glucosidase inhibitor [0.03% in the diet]). Male, 9-week-old streptozotocin (STZ)-treated Sprague-Dawley rats, a model of INS-deficient diabetes, were pretreated with INS, Rivo or dichloroacetic acid (DC; an inhibitor of pyruvate dehydrogenase kinase [50mg/kg, twice daily]). After the pretreatments, CS-917 (100mg/kg) was administered to both ZDF and STZ rats. After administration of CS-917, PG and LA were measured during 8 hours in ZDF rats and LA was measured during 6 hours in STZ rats. The change in the area under the plasma concentration-time curve (Δ AUC) for LA was calculated.

Results: PG and the Δ AUC for LA after CS-917 administration to ZDF and STZ rats with various pretreatments are shown in the table below. CS-917 reduced PG in ZDF rats at 6 hours post administration compared with control. This decrease was more pronounced in ZDF rats that had been pretreated with Rivo, INS and AC compared with non-pretreated ZDF rats. The Δ AUC for LA was increased after CS-917 administration in ZDF and STZ rats. In ZDF rats, pretreatment with INS and Rivo, but not AC, suppressed the increase of Δ AUC for LA after CS-917 administration. In STZ rats, pretreatment with INS and DC, but not Rivo, suppressed the increase in Δ AUC for LA observed after CS-917 administration.

PG and Δ AUC for LA after CS-917 administration in pretreated ZDF and STZ rats

	ZDF rats			STZ rats	
	n	Δ AUC ₀₋₈ LA (h•mg/dL)	PG at 6 hours post CS-917 administration (mg/dL)	n	Δ AUC ₀₋₆ LA (h•mg/dL)
Control (non-CS-917)	8	-9.0 ± 2.6	448 ± 13	8	-9.8 ± 2.9
Pretreatment					
None	8	54.6 ± 5.1 ^a	311 ± 40 ^a	8	415.8 ± 44.0 ^a
INS	8	24.4 ± 5.8 ^{ab}	128 ± 16 ^{ab}	8	0.4 ± 7.7 ^b
RIVO	7	28.2 ± 5.5 ^{ab}	149 ± 16 ^{ab}	8	395.1 ± 53.4 ^a
AC	8	61.4 ± 5.9 ^a	246 ± 14 ^a	-	ND
DC	-	ND	ND	7	150.0 ± 25.1 ^{ab}

a = P<0.05 versus control; b = P<0.05 versus non-pretreated control (t-test). Mean ± standard error, ND = not determined.

Conclusion: These results suggest that enhancement of INS signalling, but not insulin sensitisation, improves LA metabolism. The combination of CS-917 with a TZD or INS may decrease PG and improve LA metabolism more effectively than CS-917 monotherapy in patients with type II diabetes.

0911

A novel glucagon antagonist inhibits glucagon-stimulated glucose production in human hepatocytes and lowers blood glucose in animal models of type 2 diabetes

P. D. van Poelje¹, S. C. Potter¹, J. Hou¹, R. Wu¹, J. M. Fujitaki¹, D. W. Reeder¹, J. Gomez¹, D. L. Linemeyer¹, M. D. Erion¹

¹Metabasis Therapeutics Inc., San Diego, United States.

Background and Aims: Elevated levels of circulating glucagon contribute to fasting and postprandial hyperglycemia in patients with T2DM by inappropriately increasing hepatic glucose production. The aim of these studies was to assess the antidiabetic potential of a novel, small molecule glucagon antagonist (Cpd G) by determining its potency and efficacy in relevant cellular and in vivo models.

Materials and Methods: Receptor antagonism studies were performed with mouse or rat liver cell membrane or recombinant human glucagon receptor-containing cell membrane preparations by ¹²⁵I-glucagon (125 pM) displacement. Extracellular glucose and/or intracellular cAMP levels were determined in cultured human or rat hepatocytes exposed to glucagon (1 nM) and varying concentrations of Cpd G. Expression of the PGC-1 α and PEPCK genes was assessed by the real time-polymerase chain reaction. Blood glucose was measured in freely feeding db/db mice (n=8/group) or overnight fasted Zucker fa/fa (ZF) rats (n=6/group) following IP administration of Cpd G for 1 or 7 days. Pharmacokinetic parameters were determined in Sprague Dawley rats (n=8/group) following PO and IV administration of 30 and 5 mg/kg doses of Cpd G, respectively.

Results: The IC₅₀ values of Cpd G in the mouse, rat and human glucagon receptor assays were 75 nM, 260 nM and 45 nM, respectively. In human hepatocytes, Cpd G fully inhibited glucagon-stimulated glucose production with an EC₅₀ value of 230 nM. Inhibition of glucose production was reversed by increasing concentrations of glucagon. Cpd G also inhibited (EC₅₀ 300 nM) the ~7-fold increase in PGC-1 α and PEPCK mRNA levels elicited by glucagon in human hepatocytes. In rat and human hepatocytes, Cpd G inhibited glucagon-stimulated cAMP production with EC₅₀ values of 550 nM and 210nM, respectively. Single administrations of Cpd G (3, 10, or 30 mg/kg) to db/db mice lowered blood glucose in a dose-dependent manner with a reduction from ~450 mg/dL to ~300 mg/dL observed at the highest dose, while an increase in blood glucose levels in vehicle-treated mice. In ZF rats, administration of Cpd G lowered blood glucose from ~100 mg/dL to levels observed in lean controls, ~70 mg/dL, within 3 hours following a single dose (30 mg/kg), and to a similar extent following 7 days of treatment (30 mg/kg, b.i.d.). Blood glucose levels in vehicle-treated animals were unchanged. The 7-day treatment with Cpd G did not alter body weight, food consumption, or plasma glucagon levels. Plasma Cpd G concentrations were similar on Day 1 and Day 7. Key pharmacokinetic parameters of Cpd G in rats were as follows: oral bioavailability, 21%; terminal half-life, 1.6 h; clearance, 6.4 L/h/kg.

Conclusion: Cpd G demonstrated all the expected effects of a potent glucagon antagonist in rodent and human hepatocytes: inhibition of glucagon-stimulated cAMP production, glucose production, and gluconeogenic gene expression. Moreover, Cpd G markedly lowered fed and fasting blood glucose levels in animal models of overt or mild T2DM. Sub-chronic administration to ZF rats did not result in tachyphylaxis or elevation of plasma glucagon levels. Pharmacokinetic optimization of the Cpd G series may lead to a promising new antidiabetic agent.

0912

Pramlintide improved glycaemic control and reduced weight without increased hypoglycaemia in patients with type 2 diabetes inadequately controlled with insulin glargine ± oral agents

M. Riddle¹, C. Brown², B. Zhang², H. Maier², K. Lutz², D. Maggs², O. Kolterman²;

¹School of Medicine, Oregon Health & Science University, Portland,

²Amylin Pharmaceuticals, Inc., San Diego, United States.

Background and Aims: When type 2 diabetes (T2DM) is inadequately controlled with basal insulin ± oral agents, the usual options are increasing basal insulin and/or adding mealtime insulin. Limitations of these options include weight gain and increased risk of hypoglycemia. Pramlintide, an analog of the beta-cell hormone amylin, has been shown to reduce HbA_{1c},

postprandial glucose (PPG), and body weight in patients with T2DM using basal + mealtime insulin. In the current study, we examined the efficacy and safety of pramlintide as an alternative, rather than an addition, to mealtime insulin.

Materials and Methods: In this 16-week, randomised, double-blind study, 211 patients with T2DM using insulin glargine ± oral agents were treated with pramlintide or placebo with major meals. Patient demographics at baseline (age 55±9 y, diabetes duration 11±6 y, HbA_{1c} 8.5±0.9%, BMI 35±5 kg/m²; mean ± SD) were well balanced between treatment groups. Baseline insulin doses (mean ± SD) were 48±25 U (pramlintide) and 54±42 U (placebo). After optimisation of pramlintide dosage (60 or 120 µg), insulin was titrated weekly, targeting a fasting glucose concentration of 70–100 mg/dl.

Results: Week 16 insulin doses (mean ± SD) were 61±32 U (pramlintide) and 70±50 U (placebo). Reductions in HbA_{1c} and PPG increments from baseline (mean ± SE) were greater in pramlintide- vs. placebo-treated patients (HbA_{1c}: -0.7±0.1% vs. -0.4±0.1%, P<0.05; PPG increments: -24.4±3.6 mg/dl vs. -0.4 ± 3.0 mg/dl, P<0.0001). Improvements in glycemia were accompanied by progressive weight loss with pramlintide and weight gain with placebo (-1.6±0.3 kg vs. +0.7±0.3 kg, P<0.0001). More patients reached a composite outcome measure at Week 16 (HbA_{1c} ≤7.0% or HbA_{1c} reduction ≥0.5% AND no weight gain AND mean PPG increments ≤40 mg/dl AND no severe hypoglycemia) with pramlintide than with placebo (25% vs. 7%, P<0.001). To further explore treatment responses, the study population was divided into two subgroups according to the mean baseline HbA_{1c} (≤8.5% or >8.5%).

Post-hoc patient stratification according to baseline HbA_{1c}

Δ from baseline to	Baseline HbA _{1c} ≤8.5%		Baseline HbA _{1c} >8.5%	
	Placebo (N = 58)	Pramlintide (N = 63)	Placebo (N = 48)	Pramlintide (N = 42)
Week 16				
Δ HbA _{1c} (%)	-0.1 ± 0.1	-0.4 ± 0.1	-0.7 ± 0.1	-1.2 ± 0.1
Δ PPG increments (mg/dl)	-3.6 ± 3.7	-24.9 ± 4.4	3.2 ± 4.6	-23.7 ± 5.9
Δ weight (kg)	0.4 ± 0.4	-2.0 ± 0.4	1.1 ± 0.4	-1.0 ± 0.3

Data are reported as mean ± SE

Regardless of baseline HbA_{1c}, pramlintide + basal insulin titration produced benefits not provided by basal insulin titration alone. Pramlintide was generally well tolerated, with the most frequent adverse events being mild-to-moderate hypoglycemia (pramlintide 44%; placebo 47%) and nausea (pramlintide 31%; placebo 10%). No treatment-related severe hypoglycemia occurred.

Conclusion: In summary, pramlintide + basal insulin titration improved HbA_{1c} and PPG without weight gain or increased hypoglycemia compared to placebo + basal insulin titration in patients with T2DM. These findings support pramlintide as a potential option for the next therapeutic step when patients with T2DM are not achieving glycemic targets with basal insulin therapy.

0913

Metabolic responses to a sodium-glucose transporter-2 inhibitor, GW869682, assessed by whole-genome transcript profiling

S. Ghosh¹, Y. Shen¹, W. W. Harrington¹, J. Schroeck¹, R. Boyle¹, T. Fox¹, T. DeBruin¹, C. D. Smith¹;

¹GlaxoSmithKline Research, Research Triangle Park, United States.

Background and Aims: Enhanced urinary glucose excretion by selective inhibition of the sodium-glucose transporter 2 (SGLT2) in the proximal tubules of the kidney represents a novel therapeutic approach in the treatment of type 2 diabetes. However, it is unclear whether direct removal of glucose by this mechanism improves sensitivity to insulin. We investigated the effects of the SGLT2 inhibitor GW869682 on the transcription of genes involved in key metabolic tissues in the Zucker Diabetic Fatty (ZDF) rat.

Materials and Methods: We profiled whole genome transcripts from adipose tissue, muscle (soleus), liver and kidney of ZDF rats. Eight groups, comprising five animals each, were treated with either a single dose of GW869682 at 30 mg/kg or vehicle for 1, 3, 7 and 14 days. Amplified RNA was hybridised to Affymetrix rat RAE230A chips according to standard procedures. Gene signals were computed using the MAS5.0 software and normalised by the

global scaling method in MAS5.0. Genes with an ANOVA p<0.05 were retained for additional analysis. Statistical comparisons were by 2-sample, heteroscedastic t-tests followed by estimation of false discovery rates.

Results: In the adipose tissue, gene expression by principal components analysis from Day 0 to Day 14 suggested a delay in the progression from glucose intolerance to frank diabetes in drug-treated animals compared with vehicle-treated controls. Analysis of relevant biological pathways in muscle, liver and white adipose tissue indicated statistically significant (p<0.05) upregulation of several genes involved in glucose transport and glucose utilization in drug-treated animals, with concomitant reductions in the expression of genes regulating fatty acid utilization in liver and adipose tissue. The expression of genes encoding key bypass enzymes of gluconeogenesis – glucose-6-phosphatase and fructose-1,6-bisphosphatase – was reduced in the kidney (p<0.05). No changes were observed in the expression of genes normally used as markers for renal damage.

Conclusion: Treatment with GW689682 regulated the expression of key genes involved in glucose and fatty acid metabolism in several metabolic tissues. The patterns of gene expression point to an overall enhancement of insulin sensitivity and better glucose utilization in animals treated with GW689682. Confirmatory *in vivo* physiologic data are needed to support the findings from this transcriptomics study.

Clinical studies to assess safety, pharmacokinetics and pharmacodynamics of sergliflozin, a novel inhibitor of glucose reabsorption

L. Kler¹, E. K. Hussey², R. L. Dobbins², R. L. O'Connor-Semmes², A. Kapur³, S. C. Murray⁴, R. V. Clark², R. R. Stoltz⁵, N. L. Stockman⁵, D. M. Amin⁶, M. S. Kipnes⁷, E. C. O'Driscoll⁸, J. Leong³, D. J. R. Nunez⁹;

¹Clinical Pharmacology and Discovery Medicine, GSK, Greenford, United Kingdom, ²Clinical Pharmacology and Discovery Medicine, GSK, RTP, United States, ³Clinical Study Sciences and Operations, GSK, RTP, United States, ⁴Clinical Pharmacology Statistics and Programming, GSK, RTP, United States, ⁵Clinical Operations, Covance-Evansville, Evansville, United States, ⁶Global Medical Services, Quintile Global CRO, Bracknell, United Kingdom, ⁷Endocrinology, DGD Research Inc, San Antonio, United States, ⁸Clinical Pharmacology and Discovery Medicine, GSK, King of Prussia, PA, United States, ⁹Metabolic Experimental Medicine, GSK, RTP, NC, United States.

Background and Aims: Sergliflozin (S; GW869682) is a novel selective inhibitor of the renal low-affinity sodium-glucose cotransporter (SGLT2). S causes dose-dependent urinary glucose excretion (UGE) in animals and may provide a new treatment for type 2 diabetes (T2D) independent of insulin secretion and sensitivity. Clinical studies have been undertaken to evaluate the effects SGLT2 inhibition in humans.

Materials and Methods: Two double-blind, randomised, placebo-controlled, single-dose escalation crossover studies were conducted. In Study 1, S doses ranged from 5–500mg in 14 healthy males. In Study 2, doses ranged from 50–500mg in 8 subjects with T2D. A 14-day repeat-dose study in 18 healthy overweight and obese subjects (BMI 25–35kg/m²) was also conducted. Subjects received S 500mg, 1000mg or placebo (n=6 for each) three-times daily. Efficacy endpoints included UGE and glucose response during OGTT.

Results: Following single doses, dose proportionality was observed for pharmacokinetic (PK) parameters with no differences observed between healthy and T2D subjects. There was a dose-dependent increase in UGE which plateaued, suggesting that glucose reuptake was maximally inhibited at higher S doses. Duration of UGE paralleled plasma concentrations of the active moiety. S 500mg decreased plasma glucose concentrations over 4h from 18.3 to 11.2mmol/h/L following OGTT in T2D subjects. There were small transient increases in urinary excretion of electrolytes, but no overall increase over 24h. The most common adverse effects (AEs) were headache and sore throat in healthy subjects, and headache and dyspepsia in T2D subjects.

Multiple dosing was well tolerated; most frequently reported AEs were headache, dizziness, flatulence and nausea. PK parameters were stable with no accumulation of S or its major metabolites in plasma. S caused a considerable dose-dependent UGE increase. High doses of S did not provoke hypoglycemia in nondiabetic subjects. There was a ~1.5kg body weight reduction in S-treated subjects from baseline to Day 15 vs. placebo. S caused increases in urine electrolyte levels on Day 1 which resolved by Day 14

without an effect on serum electrolytes or calculated creatinine clearance. S caused a dose-dependent negative fluid balance on Day 1 which had resolved by Day 14 in the 500mg group and was less marked in the 1000mg group.

Conclusion: Single and multiple doses of S were well tolerated, resulted in pharmacodynamic changes consistent with renal SGLT2 inhibition and lowered plasma glucose concentrations in T2D subjects. These are the first clinical data to support SGLT2 inhibition as a unique mechanism for glycemic control.

***Acacia catechu* aqueous bark extract stimulates insulin secretion and insulin action and inhibits starch digestion**

Y. H. A. Abdel-Wahab, G. C. Clarke, P. R. Flatt;
School of Biomedical Sciences, University of Ulster, Coleraine,
Northern Ireland, United Kingdom.

Background and Aims: Higher plants such as *Acacia catechu*, also known as Cutch tree or Indian liquorice root, provide therapeutic opportunities and represent a possibly rich source of potential antidiabetic agents. The aim of the present work was to investigate at the cellular level the antidiabetic activity of *Acacia catechu* on insulin secretion using clonal pancreatic BRIN-BD11 cells, glucose uptake using adipocyte differentiated 3T3-L1 fibroblasts and starch digestion using *in vitro* model.

Materials and Methods: Dried bark/wood was homogenised to a fine powder and a decoction was prepared by bringing 25 g/L of material to the boil in water. The suspension was filtered and 1mL aliquots of the filtered plant solution were brought to dryness under vacuum. Aliquots were reconstituted in incubation buffer for subsequent experiments as required.

Results: An aqueous extract of *Acacia catechu* stimulated insulin secretion 2–4 fold in a dose dependent manner from BRIN-BD11 cells at 5.6mM glucose (1–25 mg/ml, $P<0.001$, $n=8$). Removal of extracellular calcium reduced insulin secretion at both 1 and 5 mg/ml *Acacia catechu* by 57% ($P<0.001$) and 32% ($p<0.05$), respectively. Incubation with verapamil (50 μ M) and diazoxide (300 μ M) abolished *Acacia catechu* (1 mg/ml) induced insulin secretion. Furthermore, the extract significantly increased insulin secretion in depolarised cells (30 mM KCl). Addition of extract (5 mg/ml) to BRIN-BD11 cells produced a sharp rise, which was followed by a gradual sustained increase in intracellular calcium compared to cells incubated with 5.6 mM glucose alone. Furthermore, the extract induced a transient rise in BRIN-BD11 membrane polarization which was reduced by addition of diazoxide (300 μ M). Exposure of adipocyte differentiated 3T3-L1 fibroblasts to *Acacia catechu* (1mg/ml for 20 min) produced a 1.8-fold increase ($P<0.001$) in glucose uptake compared to unsupplemented controls ($P<0.001$, $n=4$). Incubation of insulin (10^{-9} M) with plant extract (1mg/ml) induced a 141% increase in glucose uptake compared to insulin alone (29800 ± 1663 vs. 14420 ± 421.5 DPM, $P<0.001$, $n=4$). This effect was significantly greater than the actions of either alone ($P<0.001$). Incubation of aqueous extract of *Acacia catechu* (1–50 mg/ml) with starch produced a 2–16 % decrease ($P<0.001$) in carbohydrate digestion *in vitro*.

Conclusion: The study has revealed that aqueous extract of *Acacia catechu* contains natural molecules that stimulate insulin secretion, insulin action and inhibit starch digestion *in vitro*. Future work directed at the purification and characterization of active components may reveal new agents for type 2 diabetes therapy.

Antidiabetic effect of a plant material *Murraya koenigii* on nondiabetic and diabetic model rats

S. Sarma¹, S. Khan², B. P. Sarma¹, N. Nahar³, M. Mosihuzzaman³,
B. Rokeya²;

¹Dept of Pharmacology, Govt Ayurvedic College, Assam, India,

²Dept of Pharmacology, BIRDEM, Dhaka,

³Dept of Chemistry, Dhaka University, Bangladesh.

Background and Aims: *Murraya koenigii* (popularly known as Curry leave plants) is available in South India, Bangladesh, Sri-Lanka and Tropical Asia. It is being used extensively in Indian cuisine as special sauces. It has been claimed by the Ayurvedic physicians that curry leaves may control hyperglycemia in type 2 diabetic subjects with special reference to obese type 2 diabetics. We screened the hypoglycemic activity of *Murraya koenigii* in nondiabetic and diabetic model rats following a standardised approach. *Murraya koenigii* leaves were collected from around Dhaka city and identified in the Bangladesh National Herbarium.

Materials and Methods: Freeze-dried 80% ethanol extract of *Murraya koenigii* leaves was used for the study at a dose of 1.25mg/kg body weight.

Male Long-Evans rat bred at BIRDEM Animal House, weighing between (180–200) grams were used to carry out the experiment. Type 1 and type 2 model rats were produced with intraperitoneal injection of streptozotocin using conventional methods and following the procedures standardized in BIRDEM. Acute experiments were done in nondiabetic and in both diabetic model rats with a single feeding in different prandial states. Blood was collected by cutting the tail tips under mild ether anesthesia. Glucose was measured by Glucose-Oxidase (GOD-PAP) method. Statistical Analysis was done by using one-way ANOVA.

Results: Screening result for hypoglycemic activity of 80% ethanol extract of PE075 leaves in nondiabetic rats showed no effect in the fasting state. On the other hand, the extract showed significant hypoglycemic effect ($p=0.03$) in the fasting state in type 2 model rats. Moreover the extract significantly lowered serum glucose level of type 2 diabetic rats in both prandial states (simultaneously with oral glucose load $p=0.002$ and 30 minutes prior to oral glucose load $p=0.002$). Reduction in glucose level was comparable with Glibenclamide treated group. In type 1 diabetic model rats ethanol extract (80%) significantly ($p=0.03$) opposed the rise of serum glucose when the extract was fed simultaneously with glucose load.

Conclusion: The data suggest that 80% *Murraya koenigii* leaves extract has significant hypoglycemic effect in normal rats and significant anti-hyperglycemic effect in both types of diabetic model rats. Therefore, the plant merits further exploration both chemically and biologically to identify the active principle(s) and mechanism of action.

DC250188, a natural compound isolated from Chinese herb with potent efficacy on the treatment of type 2 diabetes and metabolic syndrome in animal models

Y. Leng¹, J. H. Chen², Y. Feng¹, Z. Zhou¹, H. Zhang¹, Y. Shen¹, J. H. Shen²; ¹Pharmacology Department I, ²DDDC, Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai, China.

Background and Aims: Type 2 diabetes mellitus (T2DM) is a major cause of morbidity and mortality worldwide. Current pharmacological therapies are insufficient and new strategies to treat and prevent T2DM are urgently needed. The aim of present study is to investigate the anti-diabetic effect of DC250188, a natural compound isolated from Chinese herb on obese diabetic ob/ob and diet induced obese (DIO) mice. The possible mechanisms of anti-diabetic effect of DC250188 were also explored.

Materials and Methods: DC250188 was administered orally to ob/ob or DIO mice at different doses for 26 or 45 days. Metformin and rosiglitazone were used as positive control. Blood glucose level, body weight and food intake were measured regularly, and insulin, lipid profiles, fructosamine, uric acid and other blood chemistry were analysed after treatment. OGTT, ITT and 2-deoxyglucose uptake assay were also performed on ob/ob mice. The phosphorylation of AMPK in liver and skeletal muscle of ob/ob mice after DC250188 treatment was evaluated by Western Blot. The effects of DC250188 on phosphorylation of AMPK and ACC were also studied on 3T3-L1, L6 and HepG2 cells.

Results: DC250188 dose dependently reduced the hyperglycemia of ob/ob and DIO mice. The hypoglycemic efficacy of DC250188 is similar with metformin and rosiglitazone. The serum fructosamine level in DC250188 treated group is much lower than that of metformin or rosiglitazone treated group, which suggested it had more beneficial effect on the long term glycemic control. In ob/ob mice, DC250188 showed significant reduction in serum triglyceride, free fatty acid, total cholesterol and LDL-C level, whereas metformin and rosiglitazone were less potential in lowering those lipid profiles. The triglyceride deposit in liver and serum uric acid level were reduced significantly after DC250188 treatment, suggested its beneficial effect in the T2DM associated with fatty liver and hyperuricemia. DC250188 could improve OGTT and ITT, and increase insulin stimulated glucose uptake in isolated EDL muscle, which suggested its insulin sensitising effect. DC250188 could also decrease the body weight of both ob/ob and DIO mice. Treatment with DC250188 on ob/ob mice for 26 days could increase the phosphorylation of AMPK in liver and skeletal muscle. DC250188 could also stimulate the phosphorylation of AMPK and ACC in 3T3-L1 adipocyte, L6 myotube and HepG2 cells.

Conclusion: DC250188 exerts potent and efficacious antidiabetic and hypolipidemic effect, and improves metabolic abnormalities such as fatty liver and hyperuricemia, which suggested it would be an excellent therapeutic

candidate for treatment of T2DM and metabolic syndrome. Activation of AMPK might be one of the possible mechanisms of this effect.

0918

Effects of a plant material PE053 on glycaemic and lipidaemic status of type 2 diabetic Long-Evans rats

T. Bandara¹, E. R. Jansz¹, S. Ekanayeka¹, K. Balasubramaniam², B. Rokeya³; ¹Dept. of Biochemistry, University of Sri Jayawardhanapura, Colombo, Sri Lanka, ²Dept. of Biochemistry, University of Jaffna, Sri Lanka, ³Dept. of Pharmacology, BIRDEM, Dhaka, Bangladesh.

Background and Aims: The use of the leaves of the plant PE 053 has a long folkloric history in the treatment of diabetes all over the South Asian countries. Due to its proven hypoglycemic activity on various diabetic animals and humans PE053 has become increasingly popular as a supportive treatment for diabetes. Recent reports have indicated that in addition to hypoglycemic effect the plant PE053 has got beneficial effects on dyslipidemia. The present study evaluates the effect of PE053 on glycaemic and lipidemic status of type 2 diabetic rats.

Materials and Methods: Male Long -Evans rats, bred at BIRDEM animal house and weighing between 150–200g, were used in the study. Type 2 diabetes was induced by a single intraperitoneal injection of Streptozotocin to 48 h old pups and experiments were carried out three months later. Leave powder of PE053 was prepared from mature leaves obtained from Jaffna, Sri Lanka. Acute experiment was done in type 2 model rats with a single feeding. For chronic experiment type 2 rats were divided into 3 groups: 1) Vehicle (receiving only water, $n=6$); 2) Treated with PE 053 leave powder (once daily for 28 consecutive days at a dose of 1.25g/kg body weight, $n=6$) and 3) Treated with standard drug glibenclamide (5mg/kg body weight, $n=6$). Body weight was checked every week. Blood was collected by cutting the tail tip at the beginning and on the days 7, 14, 21, and by decapitation on the 28th day. The parameters measured were serum glucose (by glucose oxidase), serum insulin (by ELISA), lipid profile (enzymatic-colorimetric), serum creatinine (by picric acid-colorimetric) and serum ALT (by enzymatic-colorimetric methods).

Results: Results of the acute experiment showed no significant blood glucose lowering effect of PE053 in type 2 diabetic model rats. On the other hand, chronic and ministration of PE053 leave powder caused a gradual fall of serum glucose level on day 14 (15.45%). A significant reduction in serum glucose level was noticed on the 28th day (serum glucose in mmol/l; $M\pm SD$, 8.95 ± 1.36 vs. 5.56 ± 0.72 , $p < 0.001$). Reduction in glucose level was comparable with the glibenclamide treated group. Fasting serum insulin content did not change in the PE 053 treated group whereas 26.3% increase was observed in glibenclamide treated group. Serum total cholesterol level of the treated group was reduced significantly ($p < 0.05$). Serum TG, and LDL-cholesterol were reduced by 23.5% and 12.3% respectively and HDL-cholesterol level increased by 39.42%. Serum ALT and creatinine level remained unchanged throughout the study period among the Control and as well as PE053 treated groups. ALT level decreased significantly ($p=0.01$) in the glibenclamide treated group. Body weight did not change significantly in any of the groups during the treatment period.

Conclusion: PE053 leave powder improves the glycemic and lipidemic status of type 2 diabetic model rats.

0919

Impact of cinnamon vs. placebo on surrogate markers of metabolic control in patients with type 2 diabetes mellitus

R. Weitgasser¹, A. Pfützner², B. Kerschgens², H. Drexel³, R. Prager⁴, B. Ludvik⁴, T. Wascher⁵, F. Hoppichler⁶, S. Berger⁷, T. Forst², P. Grafinger⁸; ¹Diabetes, University Hospital, Salzburg, Austria, ²R&D, IKFE Institute for Clinical Research and Development, Mainz, Germany, ³R&D, Institute for vascular research, Feldkirch, Austria, ⁴Diabetes, University Hospital, Vienna, Austria, ⁵Diabetes, University Hospital, Graz, Austria, ⁶Diabetes, General Hospital, Salzburg, Austria, ⁷Diabetes, Rehabilitation Hospital, Aflenz, Austria, ⁸Diabetes, Public Hospital, Linz, Austria.

Background and Aims: Preliminary work with cinnamon as nutritional supplement has pointed to a beneficial effect of this spice in reducing

postprandial glucose excursions. However, further evidence is lacking and some potentially carcinogenic coumarin derivatives in the cinnamon formulations have led to some controversy among scientists worldwide about the use of cinnamon in supporting dietary treatment in type 2 diabetes.

Materials and Methods: In order to evaluate these effects further, we performed a randomized double-blind prospective study with a cinnamon extract deprived from all potentially dangerous components (Alsidiabet, Alsitan) vs. placebo, in compliance with the regulations of Good Clinical Practice. In total, 109 patients (treated with diet and exercise) were included (62 men, 47 women, age (mean±SD): 59±9 years, HbA1c: 7.8±0.8 %, BMI: ±xx kg/m²). They were randomised to either receive 360 mg of a cinnamon extract or a similarly shaped and smelling placebo once daily in the morning over a period of 3 months. No change in anti-diabetic medication was allowed during the study. Fasting blood samples were drawn for measurement of HbA1c, glucose, insulin (for calculation of the HOMA_{IR} score), intact proinsulin, hsCRP, adiponectin, Lipids, and oxLDL at baseline and after 6 and 12 weeks.

Results: The HbA1c improved in both groups, but the change was more pronounced in the verum group (verum vs. placebo: -0.6±1.0 % vs. -0.3±1.0 %, p=0.070). Insulin resistance was improved with verum and further deteriorated with placebo (HOMA_{IR}: -0.8±3.1 vs. +0.6±2.5, p<0.05). Almost all other observation parameters showed slight improvement with verum while a further impairment was seen with placebo (adiponectin: +1.1±2.3 vs. +0.1±2.7 mg/l, p=0.052; hsCRP: -0.4±1.6 vs. -0.2±1.2 mg/l, n.s.; intact proinsulin: -2.0±9.4 vs. +1.5±7.4 pmol/l, p<0.05; Cholesterol: -1±26 vs. +9±27 mg/dl, p=0.051; LDL: -1±20 vs. +5±18 mg/dl, n.s.; HDL: +2±4 vs. 0±5 mg/dl, p=0.071; triglycerides: -16±64 vs. +27±87 mg/dl, p<0.005; oxLDL: -7±103 vs. +7±54 nm/ml, n.s.). There were no changes in BMI from baseline to endpoint in both groups. Both treatments were well tolerated and there were no differences between the groups regarding adverse events.

Conclusion: We found a consistent improvement in markers of glycemic control, insulin resistance, β-cell dysfunction and cardiovascular risk when testing cinnamon extract vs. placebo in a double-blind randomized study protocol over three months. Whether this efficacy can be attributed to a direct sensitizing effect of cinnamon on the insulin receptor as postulated in the literature or through other mechanisms (e.g. appetite regulation) needs to be further elucidated. The effects were less pronounced to the results that can be obtained with anti-diabetic drugs, but our study results clearly support the value of cinnamon when used as nutrition supplement in the course of a special diabetes diet.

Supported by Alsitan GmbH

-8, -33%; for JNK: with 500μM EGT: -15, -6, -34% and with 1000μM EGT: -15, -18, -46% all P<0,01). Moreover, EGT prevented PA-induced IL-6 mRNA expression evaluated at the IC50 (500μM) production (P<0.001) both at the transcriptional (-8 and -44% for 500 and 1000μM of EGT) and translational (-0.6 and -1.2ng/mg protein for 500 and 1000μM of EGT) level.

Conclusion: Our results indicate that EGT can effectively protect viability of myoblasts to deleterious metabolic environment such as increase FFA concentration possibly due to inhibition of the activation of the MAPK cascade and reduced inflammatory response.

Ergothioneine protection against lipotoxic effects

I. Laurenza¹, R. Colognato², A. Bertacca¹, S. Del Prato¹, L. Benzi¹;

¹Dept. Endocrinology and Metabolism,

²Dept. of Human and Env. Sciences, University of Pisa, Italy.

Background and Aims: Inflammation and reactive oxygen species (ROS) have been claimed to contribute to the development of micro- and macrovascular diabetic complications. Though this may suggest that use of anti-oxidant agent could provide some protection, so far treatment with classic free-radical scavengers and anti-oxidants has been disappointing. Therefore, more potent agents are under search. We have, then assessed *in vitro* the anti-oxidant capacity of a natural product, Ergothioneine (EGT).

Materials and Methods: To this purpose C2C12 myoblasts have been incubated for 24hrs in presence of 250, 500, 750, and 1000μM palmitic acid (PA), conjugated with 10% (w/v) FFA-free BSA with or without 24-hr pre-incubation with 500 and 1000 μM EGT for assessment of cell viability, p38 and JNK activity by Western blot, and IL-6 both mRNA expression and protein synthesis.

Results: PA incubation led to dose dependent cell viability reduction, while EGT pre-incubation resulted in greater cell viability at each PA concentration (500μM EGT: +5, +16, +17, +23%; 1000μM EGT: +9, +18, +21 and +25%; all P<0,05 or less). Whether this protective effect could be mediated by specific effect on intracellular redox signalling was evaluated by assessment of p38 and JNK activity. As compared to control cells, exposure to PA (250, 500, 750μM) significantly increased p38 (+50, +131, +261% respectively) and JNK (+261%, +396% and +441% respectively) activities (both P<0.001). In contrast, pre-treatment with EGT was associated with reduction of their activity (p38: with 500μM EGT: -12, -13, -31% and with 1000μM EGT: -1,

Treatment with insulin aspart versus human insulin in children and adolescents with newly diagnosed type 1 diabetes

J. Ludvigsson¹, H. Mersebach², K. Kanc Hanzel², H. Holmberg¹;

¹Dept of Clinical and Molecular Medicine, Linköping University, Linköping, Sweden, ²Novo Nordisk A/S, Bagsvaerd, Denmark.

Background and Aims: Rapid-acting modern insulin may offer advantages for the patients but potentially induce antibodies of immunological and clinical interest. Studies of the immunogenicity of modern insulin have mainly been performed in adults. The aim of this study was therefore to compare therapy with IAsp with human insulin (HI) both in combination with NPH insulin in insulin-naive children and adolescents. Insulin antibodies, HbA_{1c}, insulin dose and serious adverse events (SAEs) were investigated.

Materials and Methods: Seventy-two newly diagnosed children and adolescents, aged 2–17 years treated with HI (n = 30) or IAsp (n = 42), both in combination with NPH insulin, were included. IAsp specific antibodies (IAsp-Ab) and antibodies cross-reacting with HI and IAsp (HI-cross-Ab) were analyzed by radioimmunoassay at diagnosis of diabetes and every 3–6 months for 30 months. Data on HbA_{1c}, insulin dose and SAEs were collected retrospectively.

Results: At diagnosis, the mean total daily insulin dose was 1.02 U/kg in the HI group and 0.98 U/kg in the IAsp group. After 18 months treatment the insulin dose was 0.93 U/kg and 0.89 U/kg in the HI and IAsp group, respectively. The total daily bolus doses were 0.58 U/kg of HI and 0.56 U/kg of IAsp at diagnosis and 0.51 U/kg of HI and 0.52 U/kg of IAsp after 18 months treatment. The mean (SD) HbA_{1c} in the HI and IAsp groups were similar at diagnosis, 9.52% (1.97) and 9.57% (1.62), respectively. The HbA_{1c} then decreased to 5.45% (1.40) and 4.81% (0.93) at 6 months and thereafter stabilised at about 6% in both groups for the remaining period. The level of IAsp-Ab remained low throughout the study. The level of HI-cross-Ab increased from a low baseline level at diagnosis to a mean (SD) of 48.75% (21.53) and 40.20% (17.92) after nine months of treatment in the HI and IAsp group, respectively and remained elevated. In a repeated measurement analysis, no statistical significant difference in HI-cross Ab levels was found between treatment groups (p=0.16). HI-cross-Ab were significantly associated with total insulin dose (U/kg) at 18 months (p=0.001), but not with HbA_{1c} at 18 months (p=0.24). Only few SAEs were reported (HI group: n=5, 14 events and IAsp group: n=3, 3 events), the majority being hypoglycemic episodes.

Conclusion: The insulin doses and HbA_{1c} were similar in patients using HI or IAsp from diagnosis. Both treatments were associated with a similar increase in HI-cross-Ab in insulin naive children, but with no influence on treatment efficacy or safety. These results support the safe use of IAsp in children and adolescents with type 1 diabetes.

Low risk of poor metabolic control in pre-pubertal diabetic children treated with insulin pump. The results of the Polish Prospective Pump Study

E. Pankowska¹, A. Szybowska¹, E. Czerniawska², B. Surdej³, L. Lisowicz³, E. Kolender⁴, M. Myśliwiec⁵;

¹Pediatric Diabetology and Birth Defects, Medical University, Warsaw,

²Pediatric, Medical University, Lodz, ³Pediatrics, The Specialist Hospital,

Rzeszów, ⁴Endocrinology, The Specialist Pediatric Hospital, Olsztyn,

⁵Pediatrics Hematology, Oncology and Endocrinology, Medical University, Gdańsk, Poland.

Background and Aims: Epidemiological study has shown that the incidence rate of T1DM increased four times among the youngest children during last decade. Continuous subcutaneous insulin infusion (CSII) as an alternative method is becoming one of the common method uses in pediatric patients; however the best option of replacement insulin therapy in young T1DM is still disputed. To assess the efficacy of pump therapy in pre-pubertal children comparing with multiply daily injection.

Materials and Methods: The cohort, multi center study was conducted in 17 centers in Poland according to the protocol of the Polish Prospective Pump

Study. The data was collected electronically from November 2005 to February 2007 during follow-up visits. HbA_{1c} was assessed in central laboratory using BioRad method (HPLC).

Results: A study group consisted of 538 pre-pubertal children treated with CSII; mean age was 8.03±2.4; ; mean diabetes duration 3.6±2.1 years; mean pump treatment duration was 2.0 ±1.3ys. 245 subjects were enrolled into the control group; there are no significant differences in age and diabetes duration between two groups. HbA_{1c} for study group was 7.38±0.9% vs. 7.33±1.1% ns. The analysis was given in three age related groups: I < 5 years, II 5–9 years; III 9–12 years it shows the best control in preschoolers 7.24±0.7 vs. 7.39±0.9 vs. 7.42±1.0% ns. The risk of poor glycemic control was 23% in individuals treated with CSII. The significant differences were noticed in growth development parameters. In study group the mean BMI in group III (17.57± 2.3 vs. 17.76±2.23kg/m² p<0,05) and in group I (16.43±1.32 vs. 18.16±4.83) were lower, respectively.

Conclusion: Continuous subcutaneous insulin infusion is an effective method of insulin treatment for pre-pubertal children with type 1 diabetes and the risk of high HbA_{1c} is lower if the CSII is used. The growth development consists with physiology was only in patients treated with pump.

0923

Trends in the management of childhood type 1 diabetes in Romania between 1998 and 2006

V. Serban¹, A. Enache², M. Rosu¹, A. Lacatusu³, L. Barna³, A. Sima¹;

¹Diabetes Clinic, University of Medicine and Pharmacy, Timisoara,

²Diabetes Clinic, Clinical Medical Center "Cristian Serban", Buzias,

³Diabetes Clinic, Clinical Medical Center "Cristian Serban" Buzias, Romania.

Background and Aims: In Romania, a country with a low incidence of type 1 diabetes mellitus (DM), the original feature of the management of childhood type 1 DM consists in the existence of a unique modern hospital, specialized in the evaluation and therapy optimization of type 1 DM patients aged between 0 and 30 years, from all over Romania: the Clinical Medical Center "Cristian Serban" from Buzias.

The present paper has two aims: 1) to assess the changes over time (between 1998 and 2006) in insulin strategies 2) to evaluate the variations in glycemic control at the country level before and after admission in the Clinical Center "Cristian Serban", depending on the insulin regimens and age-group, between 1998 and 2006.

Materials and Methods: We enrolled in the study 1191 patients aged between 1 and 18 years, admitted once, twice or three times in the Clinical Center "Cristian Serban" from Buzias, between 1998 and 2006. We investigated the following: a) time trends of insulin regimens using 2, 3 and 4 daily insulin injections b) the quality of glycemic control expressed by glycated hemoglobin (HbA_{1c}) (measured using the turbidimetric method, with a normal range of 4.5–5.7%): mean HbA_{1c} was computed for the first hospital admission (reflecting the glycemic control at home), as well as for the second and the third admission; c) glycemic control depending on age-group (<4 years, 5–9 years, 10–14 years and 15–18 years). Statistical analysis was performed using GraphPad software, a p value of less than 0.05 was considered significant.

Results: Between 1998 and 2006, the percentage of patients using 2 and 3 daily insulin injections decreased from 13.7% to 3.6% (p=0.0041) and from 60.0% to 21.4% (p<0.0001), respectively, while the proportion of patients using 4 insulin injections increased from 26.3% to 75.0% (p<0.0001).

Changes in glycemic control between 1998 and 2006, depending on insulin regimen and on age-group are presented in table 1.

Table 1

	HbA _{1c} (% ,SD) depending on no. of injections*			HbA _{1c} (% ,SD) depending on age group			
	2 inj	3 inj	4 inj	<4 yrs	5–9 yrs	10–14 yrs	15–18 yrs
1998	11.4±2.9	10.8±2.6	10.0±2.4	8.8± 1.7	10.8±2.7	10.7±2.6	11.2±2.9
2006**	9.8± 2.4	9.4±2.6	9.2±2.3	8.4±1.5	8.1±1.8	9.5±2.1	10.2±2.4
p	0.04	0.018	0.06	0.5	<0.0001	0.0005	0.019

* patients at first admission in the center ** for 2 injections group: data from 2001

The analysis of glycemic control depending on age-group has showed a reduction of mean HbA_{1c} as follows (the first figure represents the 1998

value and the second the 2006 value): in children younger than 4 years from 8.8±1.7% to 8.4±1.5% ($p=0.5$); in age-group 5–9 years from 10.8±2.7% to 8.1±1.8% ($p<0.0001$); in age-group 10–14 years from 10.7±2.6% to 9.5±2.1% ($p=0.0005$), and in age-group 15–18 years from 11.2±2.9% to 10.2±2.4% ($p=0.019$).

Conclusion: 1. In Romania, in 2006, most children with type 1 DM use multiple insulin injections regimens. 2. Glycemic control (HbA_{1c}) has improved starting 1998, but remained unsatisfactory, regardless of insulin regimens and insulin types used.

0924

Insulin antibodies correlate negatively with C-peptide levels and positively with insulin sensitivity in young type 1 diabetic patients during the first two years of diabetes

B. Mianowska, A. Szadkowska, O. Wegner, I. Pietrzak, E. Czerniawska, A. Heinrich, W. Młynarski, J. Bodalski;
Department of Pediatrics, Medical University, Lodz, Poland.

Background and Aims: This study was aimed at evaluating the impact of insulin antibodies (IA) on clinical and metabolic characteristics of children and adolescents with type 1 diabetes (T1DM).

Materials and Methods: 33 patients with T1DM (aged 7.6–17.6 years, 24 males) treated with human insulin or human insulin analogs participated in the study. IA (radioimmunoassay, IA-AIA *Cis bio international*, normal value 0–7%), fasting C-peptide (C-pep, radioimmunoassay, C-PEP-CT2 *Cis bio international*), HbA_{1c} (HPLC, Variant *Bio-Rad*) and glucose disposal rate (M-index determined by euglycemic hyperinsulinaemic clamp technique by de Fronzo) were measured at diabetes diagnosis (0–3rd day), 6 months after diagnosis and 24 months after diagnosis. Daily insulin doses were calculated.

Results: IA levels significantly raised within the first 6 months of treatment (6.6+/-1.2% vs. 32.1+/-17.0% at diagnosis and at 6 mths respectively, $P<0.0001$), and remained stable thereafter (33.8+/-18.2% at 24 mths, $P=0.23$ vs. 6 mths). At 6 mths and at 24 mths IA levels correlated negatively with C-pep at diabetes diagnosis ($r=-0.33$, $P=0.05$ at 6 mths, $r=-0.39$, $P=0.04$ at 24 mths). A negative correlation was found between IA levels and C-pep at 6 mths ($r=-0.35$, $P=0.04$) and at 24 mths ($r=-0.39$, $P<0.05$). IA levels positively correlated with insulin sensitivity measured as M-index ($r=0.34$, $P=0.05$ at 6 mths and $r=0.37$, $P<0.05$ at 24 mths). At 6 mths, but not at 24 mths, IA correlated with daily insulin dose per kilogram ($r=0.43$, $P=0.01$). A slight negative correlation between C-pep at diagnosis and daily insulin dose per kilogram at 6 mths ($r=-0.31$, $P=0.06$) and a significant negative correlation between C-pep at diagnosis and daily insulin dose per kilogram at 24 mths were observed ($r=-0.39$, $P=0.03$). No correlation between IA and HbA_{1c} was found.

Conclusion: Currently used human insulin preparations and human insulin analogs induce immune response to exogenous insulin. Patients with lower residual beta cell function at diagnosis require higher insulin doses, and this can promote more intense IA production. The positive correlation between IA and insulin sensitivity can be related either to IA ability to act as a reservoir of free insulin, and can disclose an uncontrolled insulin release from IA-insulin immune complexes, or IA-insulin complexes may not be “inactive” but may participate in total hypoglycemic effects of insulin.

Determinants of insulin resistance development in teenage boys

O. O. Khyzhnyak, T. N. Sulima, E. I. Plekhova;
Pediatric Endocrinology, Scientific Research Institute of Children Health Care, Kharkov, Ukraine.

Background and Aims: It is well known that early onset of adult diseases may be triggered by metabolic disturbances during pubertal development. Nowadays, metabolic disorders such as type 2 diabetes mellitus (DM) and metabolic syndrome keep a leading position in increased prevalence among the world's population. In our studies we were interested in factors that determine predisposition to early onset of metabolic disorders in which resistance to insulin play crucial role.

Materials and Methods: 123 teenage boys with clinical manifestation of the metabolic syndrome were under investigation in the Department of Pediatric Endocrinology. Expanded anamnesis including prenatal and early development period, family history of type 2 DM, hypertension, thyroid dysfunctions, traumas of the head and neck, pediatric infections was collected. Physical examination included height, weight, body temperature and blood pressure measurements, skin, eyes and thyroid gland examination, pubertal (sexual) development (Tanner stage) estimation. Blood samples for insulin, cortisol, thyrotropin (TTH) and leptin measurements were taken in fasting state. Selective participants underwent an OGTT. Blood samples were obtained 0, 30, 60, 90, and 120 minutes after oral glucose administration. Surrogate measure of the insulin resistance – HOMA was calculated according to Matthews et al (1985).

Results: Multiple regression analysis was performed to identify the predictors of the gradually increase in HOMA value from 0.29 to 36.3 in overall sample of subjects. Basic multiple regression model consists of cortisol, TTH and leptin as predictors which explain up to 58.6% of the HOMA dispersion. It was assumed that cutoff point for diagnosis of the insulin resistance divides investigated patients into groups with physiologically derived decrease in insulin sensitivity and genetically predisposed to insulin resistance individuals. In our study HOMA cutoff point was found at the level of 3.9.

In sample with $HOMA<3.9$, combination of cortisol (360.9 ± 260.6 nmol/L; $M\pm SD$) and TTH (2.83 ± 1.17 mIU/L) significantly describe HOMA variability ($R^2=87\%$) in teenage boys with subtle endocrine dysfunctions. As mentioned by several investigators, the fall in insulin sensitivity during puberty is associated with a compensatory increase in insulin secretion. The regulatory purpose of these changes in insulin action and secretion is not clear but is thought to provide a mechanism for increasing the anabolic effects of insulin and growth hormone during a period of rapid somatic growth.

In sample with $HOMA\geq 3.9$ gradual increase in HOMA significantly was associated ($R^2=64.4\%$) with rise in cortisol (434 ± 197.6 nmol/L) and leptin (40 ± 30.59 mkg/L) concentration in fasting blood and serious metabolic disorders. In addition, relative deposit of cortisol to HOMA value is higher in overweight individual ($30\geq BMI\geq 25$), but in obese boys ($BMI>30$) – leptin mainly predetermines HOMA value. These results may be explained by recent finding that leptin modulates glucose homeostasis by acting as an insulin-sensitizing factor in most insulin target tissues.

Conclusion: Positive family history of the type 2 DM and obesity create background for metabolic disorder development, while early puberty and a longer period of maturation may be additional risk factors for early onset of type 2 DM.

A case of type 1 diabetes mellitus with insulin resistance secondary to anti-insulin antibodies treated with plasmapheresis, rituximab and cyclophosphamide

D. R. Franco¹, I. L. Noronha², M. H. B. Kiss³, J. G. H. Vieira⁴,
F. G. Eliaschewitz¹;

¹Clinical research, CPCLIN, ²Laboratory of Molecular and Cellular Nephrology, USP, ³Rheumatology, USP,

⁴Endocrinology, Fleury Laboratory, São Paulo, Brazil.

Aims: To describe a case of type 1 diabetes (T1DM) in whom the presence of anti-insulin antibodies presented a treatment challenge

Case History: Diagnosed at the age of nine, patient R.A.B. was initially well controlled on four shots daily of NPH insulin and Lispro. Two years after the diagnosis the patient was also diagnosed with hypothyroidism and subcutaneous requirements increased reaching 150U/day (3.2U/kg/d). Anti-insulin antibodies [$>20\%$ (normal range $<3\%$)] were identified, and the patient was initially controlled with sc insulin as an outpatient, but presented several episodes of ketoacidosis in the first year of uncontrolled glycemia. His insulin regimen was changed to Glargine, and for 11 months glycemia control improved. However, as insulin requirement again increased and control worsened the patient was switched to i.v. insulin. The patient continued to need more than 1000 IU insulin i.v./day without exhibiting any nocturnal hypoglycemia. We postulated the patient could be producing anti-insulin antibodies, which were rendering him resistant to insulin. Various modalities of immunosuppression were tried out, beginning with 60 mg prednisone daily, which had no effect on the patients' insulin requirements (1200 IU/day). He subsequently received a cycle of gammaglobulin and

methylprednisolone, in an immunosuppressive dose with no effect on insulin requirement. Hospitalisation to perform plasmapheresis for one week was the following step; indeed, glycemia control improved and insulin requirement was reduced to 500 IU/day. However, one week after plasmapheresis insulin requirement increased again and plasmapheresis was repeated concomitant with a new cycle of methylprednisolone and Rituximab. This time, insulin requirement diminished within several weeks and a sustained response to treatment was obtained. The patient was transferred to a s.c. pump receiving 100 IU/day, and remained stable for one year on prednisone and cyclophosphamide. The patient remains now with insulin pump therapy, at 1U/kg/day of insulin requirement and without any immunosuppression.

Conclusion: This unusual case of an adolescent boy with anti-insulin antibodies and T1DM illustrates the use of immunosuppressant therapy and plasmapheresis in improving glycemia control. Rituximab and cyclophosphamide may be considered as an effective means of immunosuppression in patients with markedly raised anti-insulin antibodies with diabetes uncontrollable with insulin alone

0927

Exploratory study on the long-term outcome in children aged up to age 9 years born to mothers with type 2 diabetes mellitus

H. W. de Valk¹, N. H. G. van Nieuwaal¹, W. Lasfar¹, G. H. A. Visser²;

¹Internal Medicine, Univ. Medical Centre,

²Obstetrics, University Medical Centre, Utrecht, The Netherlands.

Background and aims: The number of women with pregestational type 2 diabetes mellitus (PGDM2) is increasing as part of the global diabetes epidemic. Studies have shown that these pregnancies are associated with an increased incidence of adverse outcomes and meticulous obstetric and metabolic care is mandatory. Little is known about long-term outcome of children born to mothers with PGDM2. This study was aimed at exploring evolution of body weight, neuropsychological development and school achievements in a group of these children.

Materials and Methods: Fifty-three children were identified as born to 44 women with PGDM2. Follow-up was available for 41 children (77.4%) ranging from 4 to 156 months; this analysis is limited to data up to 9 years. Development was assessed by attainment of milestones and is expressed as normal or abnormal "van Wiechenscore". This scheme is evaluated at 15 (W15) and 48 months (W48). Weight was assessed monthly during the first year, at 15, 24 and 45 months and at toddler's age (4 years) and at the age of nine years. Differences between groups in continuous data were tested with (non-)parametric tests, in categorical data with X²-test or single proportion test; in longitudinal changes with repeated measures analysis.

Results: Maternal characteristics: mean age at conception is 33±4 years; body mass index: 32.3±7.5 kg/m²; mean HbA1c 6.1%; median duration of disease: 3 years. 51% Caucasian, 34% of Moroccan descent, 15% of other origin. Neonatal characteristics: macrosomia (≥90th percentile) 45.3%, severe hypoglycaemia 58.5%, preterm delivery 18.9%. Maternal and neonatal were similar in Caucasians and Moroccans. W15 was abnormal in 67.5% and W48 in 72.4% with most cases having one abnormal item. Presence of an abnormal score and number of abnormal items were comparable for both sexes and not related to neonatal glucose levels or gestational age at delivery. However, mean HbA1c levels during the first or second trimester were lower with an abnormal than with a normal W15 (6.5±0.8% vs. 5.8±0.7% (p<0.05) and 6.3±0.6% vs. 5.7±0.6% (p<0.05) respectively). The frequency of abnormal W48 was higher in Moroccan compared to Caucasian children (91.7 vs. 50.5%, p<0.05) with no difference in W15. This difference at W48 was not attributable to speech or language problems. From 4 to 9 years, 3 of the 22 children (13.6%) required special education compared to 5.5% in the normal population (p>0.05). Speech therapy was required in 29% compared to 3.7% in the normal population (p<0.05) and specific follow-up examination because of delayed motor-development was required in 26.3% compared to 2.0% in the normal population (p<0.05). Macrosomic neonates retained a significantly higher mean weight percentile during the first six years of age compared to non-macrosomic children (p<0.001, repeated measures analysis).

Conclusion: Maternal pregestational type 2 diabetes is possibly associated with abnormal offspring development to the van Wiechenscore. Surprisingly, abnormal van Wiechenscore at 15 months was associated with lower HbA1c-levels during early pregnancy. Children have a higher mean weight percentile during follow-up. Although this is a relatively small patient group, these

results indicate that the consequences of maternal type 2 diabetes stretch for the developing child further than the immediate neonatal period and that more developmental research in large groups is needed.

0928

Characteristics of adolescents with type 1 diabetes who exhibit adverse outcomes

M. S. Faulkner¹, C. Johns², L. Quinn²;

¹College of Nursing, University of Arizona, Tucson,

²Medical-Surgical Nursing, University of Illinois at Chicago, United States.

Background and Aims: Adolescents with type 1 diabetes are challenged to balance their therapeutic regime of diet, exercise, and insulin management with developmental changes to achieve optimal glycemic control. The goal of this study was to identify characteristics among adolescents with type 1 diabetes who have poor outcomes from their disease. Poor outcomes were defined as inadequate glycemic control, hypoglycemic events, and hospitalizations due to diabetes. A secondary aim of this study examined differences in glycemic control or insulin dose among subjects receiving insulin via pump versus multiple daily injections.

Materials and Methods: Adolescents with type 1 diabetes ages 13–18 years (n = 108; 55% males; 67% Caucasian; 27% Black; 6% Hispanic) were recruited from a diabetes care center in a large urban setting in the United States. Subjects completed a survey quantifying frequency of insulin injections, blood glucose monitoring, hypoglycemic reactions requiring assistance from another person, and hospitalizations within the past year because of diabetes. Parents completed a demographic questionnaire pertaining to income level, marital status, and highest educational level completed. Adolescents kept a 3-day food record that was later reviewed with them by a registered dietician for accuracy and entered into Nutritionist Pro™ software for macronutrient analysis. A lab draw was performed to obtain current HbA_{1c}. Subjects were grouped according to level of glycemic control (< 8 % vs. ≥ 8 % HbA_{1c}), hypoglycemia requiring assistance in the past year (none vs. ≥ 1 episodes), and hospitalizations over the past year (none vs. ≥ 1) to determine differences in the following variables: BMI, insulin dose, self blood glucose checks, HbA_{1c}, total caloric intake, % calories from carbohydrates, protein, and fats, parents' educational level, parents' marital status, annual family income, race, and gender.

Results: Subjects receiving insulin via pump on average had better glucose control (HbA_{1c} 7.9% vs. 9.0%, p < 0.001) and were on lower insulin doses (0.7 u/kg/day vs. 1.1 u/kg/day, p < 0.001). Those with adequate glucose control (HbA_{1c} < 8%) were on a lower insulin dose (0.9 u/kg/day vs. 1.1 u/kg/day, p = 0.005), checked their blood sugar more frequently (4.9 vs. 3.9 times per day, p < 0.001), and had fathers with a higher education level (14.8 years vs. 13.2 years, p = 0.007) when compared to counterparts with poor glucose control (HbA_{1c} ≥ 8%). In addition, those with poor control were more likely to come from a single parent home (p = 0.02), lower income family (p = 0.05), and from an ethnic minority (p = 0.01). No significant differences were found between those hospitalized and those not hospitalized as well as those who experienced hypoglycemic reactions versus those who did not.

Conclusion: Findings from this analysis supports using pump therapy for adolescents when appropriate. It also identifies groups of adolescents who are in need of more guidance and supervision to manage their disease appropriately. Further research is needed to explore what interventions will most likely bring about more favorable outcomes for such groups.

Social disparity in clinical presentation of childhood onset type 1 diabetes in Germany

J. Rosenbauer, A. Icks, G. Giani;

Institute of Biometrics and Epidemiology, German Diabetes Centre, Düsseldorf, Germany.

Background and Aims: Aim of the study was to describe the clinical presentation of Type 1 diabetes at diagnosis in a population-based cohort of children in particular with respect to social status.

Materials and Methods: During 2002–2006, 2735 new cases of Type 1 diabetes under 15 years of age were prospectively registered by the diabetes

register of the German federal state of North-Rhine-Westphalia (completeness of registration $\geq 95\%$). Data on demographics, clinical symptoms preceding diagnosis, and clinical presentation and hospital stay at diagnosis were obtained from hospital records and from parents of diabetic children by means of mailed standardised questionnaires. Social status of families was assessed by the parents' school education (Low: ≤ 9 years, middle: 10–11 years, high: ≥ 12 years). Besides descriptive statistics data were analysed by logistic regression.

Results: Data of 1642 patients (60% of registered cases, 901 boys) could be included in the analysis. The age distribution at onset was 22.7%, 36.1% and 41.2% for the age groups 0–4, 5–9 and 10–14 years, respectively. The most frequently reported symptoms were polydipsia (93.6%), polyuria (92.4%), weight loss (76.6%), fatigue (69.7%), and abdominal pain (37.1%). Mean duration of symptoms before diagnosis was 31.6 days. While the reported frequency of clinical symptoms did not depend on families' social status, lower social status families reported a shorter duration of symptoms. At clinical examination 46.7% of the children presented dehydration, 11.8% impaired consciousness, and 0.7% coma. Mean levels of glucose and glycosylated haemoglobin (relative to upper normal value) at diagnosis was 464.5 ± 193.0 mg/dl and 1.87 ± 0.43 respectively. Ketonuria, bicarbonate values ≤ 10 mmol/l, and severe ketoacidosis ($\text{pH} \leq 7.2$) were present in 79.0%, 14.1%, and 15.6% of the children, respectively. Children of lower social status families presented significantly increased metabolic decompensation than children of upper class families. Prevalence of severe ketoacidosis was 18.2%, 14.6% and 12.8% for low, middle and high social status ($p < 0.05$), respectively. Accordingly, children of low social status were hospitalised for a longer period (in average 15.4 days) than children of middle (13.8 days) or high social status (13.5 days) ($p < 0.05$). 13.6% of deprived children were hospitalised for at least 3 weeks compared to 6.5% and 5.3% of children of middle and high social status ($p < 0.05$). Adjusted for sex, age, familial diabetes and family situation (single parent vs. complete family), relative risk of low social status children compared to high social status children for severe ketoacidosis was 1.78 (95%-CI: 1.21–2.62; $p = 0.003$), and for a long time hospitalisation (≥ 3 weeks) relative risk was 2.89 (95%-CI: 1.72–4.86; $p < 0.001$, additionally adjusted for ketoacidosis).

Conclusion: This population-based survey showed that deprived children present with increased metabolic derangement at onset of type 1 diabetes and stay at hospital for a longer time. Activities aiming at increasing public awareness of presenting characteristics of childhood diabetes in particular in the target group of low social status families might help to reduce the social disparity in clinical presentation of childhood onset Type 1 diabetes.

PS 89 Care and treatment of diabetes in pregnancy

0930

Pre-Pregnancy Care (PPC) in women with diabetes mellitus resident in the West Midlands UK

F. P. Dunne^{1,2}, D. Jenkins², N. Shah², W. MacKenzie², W. Oakley², J. Benn², P. Brydon², C. Shuter², P. McGeown², J. Gardosi²;

¹National University of Ireland, University College Hospital, Newcastle Road Galway, Ireland,

²West Midlands Perinatal Institute, Birmingham, United Kingdom.

Aim: A prospective cohort study as part of the National CEMACH collection to examine pre-pregnancy care in a multi ethnic population of women with established Diabetes Mellitus.

Methods: The study period extended for 12 months between March 2002 and Feb 2003. Information was collected on uptake and location of pre-pregnancy care, uptake of folic acid, achievement of target HbA_{1C}.

Results: Information on 418 women, 269 (type 1) 149 (type 2), mean age 31 was collected. 25.1% overall were of non-European origin rising to 57% in those with type 2 diabetes. 55% of non European women with type 1 and 78% with type 2 disease were associated with the highest quintile of deprivation compared to 45% nationally. 28% of the total group received pre-pregnancy care (PPC), lower in type 2 than type 1 women (24 v 30%). 41% were receiving folic acid, less in type 2 than type 1 (33 v 45%). 41% had a recorded PPC HbA_{1C}, less in type 2 than type 1 (32 v 46%). Only 12.5% had an HbA_{1C} $< 7\%$. 60% of PPC was delivered in the adult hospital diabetes clinic with the other 40% receiving PPC in GP and community services. PPC was significantly associated with achieving a target HbA_{1C} $< 7\%$ in the pre-pregnancy and first trimester periods ($P < 0.01$). Achievement of a HbA_{1C} $< 7\%$ in trimester 1 was significantly associated with infant survival at 28 days ($P = 0.01$).

Conclusion: In the West Midlands we fall well short of achieving the pre-pregnancy goals for women with diabetes. Women with type 2 diabetes appear to have a lower standard of care. Increasing the number of women who achieve these targets is likely to improve their pregnancy outcomes. A combined primary and secondary delivery of a PPC service is likely to have a more successful outcome than either alone.

0931

Continuous subcutaneous insulin infusion (CSII) reduces the rate of hypoglycaemic episodes throughout pregnancy

N. Ignatova¹, N. Arbatskaya¹, E. Melnikova²;

¹Clinical – diagnostic centre, City Clinical Hospital №1,

²Department of Endocrinology and Diabetology, Russian State Medical University, Moscow, Russian Federation.

Background and Aims: Pregnant women with type 1 diabetes mellitus (DM) have an increased risk of experiencing adverse maternal and fetal outcomes. Improving glycaemic control can minimise these risks, but must be balanced against increasing the rate of severe hypoglycaemia, which can prove fatal. The aim of study was to evaluate the effectiveness of CSII therapy in good metabolic control.

Materials and Methods: 41 women with type 1 DM and unplanned pregnancy were divided by two groups. CSII group included 21 women transferred on CSII therapy at 14±9,9 weeks of pregnancy. Group of insulin analog (Ian) included 21 women treated with insulin lispro or aspart and NPH before and during pregnancy. Insulin dose was adjusted based on 8 capillary meter readings daily. Safety and efficacy of CSII vs. Ian was evaluated by HbA_{1C}, maternal hypoglycaemia (major, minor and nocturnal), pregnancy outcomes.

Results: Mean HbA_{1C} values in the start of study were $6,8 \pm 0,7$ (CSII) vs. $7,4 \pm 1,8$ (Ian). At end of study, women in both groups had mean HbA_{1C} values of $6,3\%$ ($p > 0,5$, not significant), however HbA_{1C} was lower in the 3rd trimester of pregnancy in the CSII group. Only one major hypoglycaemic event was recorded throughout the study in Ian group. Rates of minor hypoglycaemia were lower in CSII treatment group in comparing Ian group: $6,1 \pm 1,7$ vs. $11,6 \pm 2,3$ episodes in the 1st trimester of pregnancy; $4,8 \pm 1,4$ vs. $12,2 \pm 2,7$ and $3,4 \pm 1,1$ vs. $10,0 \pm 3,0$ episodes in the 2^d and 3rd trimesters. Night

time hypoglycemia occurs more rarely in CSII group than in I an one in each trimesters of pregnancy: 1,0±0,3 vs. 2,8±0,6 / 1,4±0,4 vs. 1,7±0,3 / 1,8±0,6 vs. 2,5±0,7. Pregnancy outcomes were similar in both groups.

Conclusion: Changing therapy on CSII treatment during pregnancy assists to improve metabolic control and reduce the rate of hypoglycaemic episodes.

0932

Insulin pump therapy in pregnant women with diabetes mellitus type 1: a systematic review

T. W. Gratzner^{1,2}, K. J. Jeitler^{1,2}, A. Berghold³, K. Horvath¹, T. R. Pieber², A. Siebenhofer¹;

¹Dept. of Internal Medicine, EBM Review Center, Medical University,

²Institute of Medical Technologies and Health Management, Joanneum

Research, ³Institute for Medical Informatics, Statistics and Documentation, Medical University, Graz, Austria.

Background and Aims: Due to the need of a more stringent metabolic control during pregnancy continuous subcutaneous insulin infusion (CSII) therapy is thought to have advantages in the treatment of pregnant women with diabetes mellitus type 1 (DMT1). Our aim was to investigate possible clinical benefits of CSII therapy compared to subcutaneous injection therapy (IT) in pregnant women with DMT1 with regard to glycaemic control, insulin requirements and adverse events.

Material and Methods: We systematically searched databases (MEDLINE, EMBASE, CENTRAL) up to March 2007 for randomised controlled trials (RCT). Two reviewers independently evaluated the relevance of studies and their quality after inclusion. Discrepancies were solved by consensus and a systematic review was performed.

Results: The search yielded 608 references of which 6 RCTs were relevant to our question and included in the review. The number of patients ranged from 10 to 89 and publication dates from 1986 to 1993. Methodological quality was judged low for all studies. We did not perform meta-analysis because most of the studies did not provide sufficient data.

HbA1/HbA1c was reported in 4 RCTs. No statistically significant differences between treatment groups were found at any time (one study, Laatikainen 1987, did not report a formal statistical test). The findings on percentage of blood glucose values outside of target range did not provide conclusive data, showing advantages for CSII therapy in some studies and for IT therapy in others.

One investigation found statistically significant lower insulin requirements in the CSII vs. IT group (1.3 vs. 1.6 IU/kg/day; $p=0.041$) at the end of the 3rd trimester.

No statistically significant differences in the incidence of severe maternal hypoglycaemia and the number of maternal ketoacidotic events were reported in any of the studies.

None of the studies found statistically significant differences between CSII and IT groups on intrauterine/perinatal death or birth weight under the 10th and above the 90th percentile.

Summary of Results (Tab. 1)

CSII versus IT

Endpoint		Botta 1986	Burkart 1988	Carta 1986	Coustan 1986	Laatikainen 1987	Nosari 1993
HbA1/HbA1c 1 st trimester	(%)	-	-	7.8 vs. 8.5	-	8.5 vs. 8.2	6.0 vs. 6.2
HbA1/HbA1c 3 rd trimester	(%)	-	-	7.1 vs. 7.0	6.3 vs. 6.4	6.7 vs. 7.1	6.3 vs. 6.2
Insulin dose 1 st trimester	(IU/d)	-	-	34 vs. 30	-	-	40 vs. 36
	(IU/kg/d)	-	-	-	0.7 vs. 1.0	-	-
Insulin dose 3 rd trimester	(IU/d)	-	-	50 vs. 58	-	49 vs. 54	57 vs. 55
	(IU/kg/d)	-	-	-	1.3 vs. 1.6 [†]	-	-
Maternal severe hypoglycaemia	(events)	-	5 vs. 3	0 vs. 1	-	-	3 vs. 1
Maternal ketoacidosis	(events)	1 vs. 0	1 vs. 0	-	0 vs. 0	-	3 vs. 0
Intrauterine / perinatal death		1 vs. 0	1 vs. 2	0 vs. 0	-	-	2 vs. 1
Birth weight <10 th percentile		-	3 vs. 1	0 vs. 0	2 vs. 0	-	0 vs. 2
Birth weight >90 th percentile		-	7 vs. 12	2 vs. 0	1 vs. 0	-	1 vs. 0

† = statistically significant difference; – = not available

Conclusions: No clinically important advantages for CSII therapy in pregnant women with DMT1 can be deduced from the available RCTs. The fact that the majority of the studies were conducted some 20 years ago raises doubts as to their current relevance. Well conducted RCTs employing new CSII systems are needed. (Tab. 1)

Hypoglycaemia in pregnant women with type 1 diabetes: predictors and role of metabolic control

L. Ringholm Nielsen¹, U. Pedersen-Bjergaard², B. Thorsteinnsson², M. Johansen³, P. Damm³, E. R. Mathiesen¹;

¹Department of Endocrinology, Rigshospitalet, Copenhagen,

²Endocrinology Section, Nordsjællands Hospital – Hillerød,

³Department of Obstetrics, Rigshospitalet, Copenhagen, Denmark.

Background and aims: Women with type 1 diabetes (T1DM) are at particular risk of severe hypoglycaemia during pregnancy. We evaluated frequencies of mild and severe hypoglycaemia and analysed influence of strict metabolic control, nausea, vomiting and other potential predictors on occurrence of severe hypoglycaemia in these subjects.

Materials and Methods: Prospective, observational study of 108 consecutive pregnant women with T1DM. At 8, 14, 21, 27 and 33 weeks gestation the women performed self-monitoring plasma glucose (SMPG) (8/day) for 3 days and completed a questionnaire on nausea causing change in diet, vomiting in the previous week, history of mild (managed by the patient herself) and severe hypoglycaemia (requiring assistance from others), and self-estimated awareness of hypoglycaemia.

Results: Forty-nine (45%) women experienced 178 events of severe hypoglycaemia throughout pregnancy, corresponding to an incidence of 5.3, 2.4 and 0.5 events/patient-year in first, second and third trimester, respectively, compared to 1.1 event/patient-year the year preceding pregnancy. Sixty-five (37%) severe hypoglycaemic events occurred at night (0–8 a.m.). Eighty percent of all severe hypoglycaemic events occurred before 20 weeks with a peak (15 events) at 9 weeks. The incidence of mild hypoglycaemia was 5.5, 5.1, 4.2, 3.8, and 3.8 events/patient-week at 8, 14, 21, 27 and 33 gestational weeks, respectively, with a significant decrease from 8 to 33 weeks ($p<0.0001$) and no difference between women with and without severe hypoglycaemia. Biochemical hypoglycaemia (<3.9 mM) was present in 15% of the SMPG throughout pregnancy both in women with and without severe hypoglycaemia. Nausea or vomiting was only reported as a possible provoking cause in 4 (3%) severe hypoglycaemic events. Nor prevalence of nausea and vomiting, median SMPG, fraction of SMPG values ≤ 3.9 mM, HbA1c or insulin dosage differed significantly between women with and without severe hypoglycaemia. SMPG fluctuated significantly more at 8 vs. 33 weeks in women with and without severe hypoglycaemia ($p<0.0001$). Throughout pregnancy, HbA1c and median SMPG decreased and insulin dosage increased with no differences between women with and without severe hypoglycaemia. Women with severe hypoglycaemia

had longer duration of T1DM (median 19 vs. 13 years), more often severe hypoglycaemia in the year before pregnancy (47 vs. 17% of the patients), more often self-estimated impaired awareness (75 vs. 43%), and more frequently SMPG outside the range of 4.0–9.9 mM at 8 weeks (48 vs. 34%), all $p < 0.01$. Logistic regression analysis identified self-estimated impaired awareness at 8 weeks (OR [95% CI]: 3.8 [1.3–8.8]) and history of severe hypoglycaemia during the previous year (OR: 3.1 [1.1–8.5]) as independent predictors for severe hypoglycaemia.

Conclusion: In pregnant women with T1DM, the incidence of mild and severe hypoglycaemia was highest in early pregnancy although the metabolic control was stricter and insulin dosage was higher in last part of pregnancy. Predictors for severe hypoglycaemia were self-estimated impaired awareness and a history of severe hypoglycaemia during the previous year.

Have pregnancy outcomes in type 1 diabetes improved over the past 13 years?

S. Pye¹, S. Gennatas¹, V. Dawson¹, M. Halliday², S. Hodgett², I. Scudamore², M.-F. Kong¹, R. Gregory¹;

¹Diabetes & Endocrinology,

²Obstetrics & Gynaecology, Leicester General Hospital, United Kingdom.

Background and Aims: In 1989 one of the goals of the St Vincent declaration was to achieve pregnancy outcomes in women with diabetes that approximates that of women without diabetes over the next 5 years but this target has not been achieved. The aim of this study was to compare pregnancy outcomes in women with type 1 diabetes mellitus (T1DM) over the past 13 years.

Materials and Methods: We undertook a retrospective survey of all pregnancies complicated with T1DM in our centre between 1994 and 2006. There were 147 pregnancies, 124 were in caucasians. As we were expecting an improvement in outcomes over the years we divided the women into two groups.

Results: There were 61 pregnancies between 1994–2000 (group A) and 86 between 2001–2006 (group B). Mean age was 28.7 ± 4.6 in both groups. Gestational age at booking was 8.6 weeks in group A and 7.9 weeks in group B. 64% received preconception counselling in group A vs. 50% in group B. 43% of women were taking folic acid at booking in group A and 71% in group B. The duration of diabetes was 10.9 ± 7.7 years in group A and 13.9 ± 10.1 years in group B. Mean HbA_{1c} at booking was $7.9 \pm 1.5\%$ in group A vs. $7.6 \pm 1.5\%$ in group B. Mean HbA_{1c} during pregnancy was $6.7 \pm 0.7\%$ in group A vs. $6.5 \pm 0.9\%$ in group B. Mean gestational age was 37.1 ± 2 weeks in group A, 36.5 ± 3.7 weeks in group B. Mean birth weight was 3399.7 ± 714 g in group A and 3441.4 ± 850 g in group B. 49.2% in group A had induction of labour vs. 31.4% in group B. 24.6% in group A and 27.9% in group B had a normal vaginal delivery. 16.4% had instrumental delivery in group A vs. 9.3% in group B. 23% had emergency caesarean section in group A vs. 36% in group B. 26.2% had elective caesarean section in group A vs. 23.3% in group B. There were 5 miscarriages in group A and 3 in group B. There was one stillbirth and one IUGR in group A. 14.8% had large for gestational age babies in group A vs. 22.1% in group B. No pregnancy was complicated by shoulder dystocia in group A but there were 2 in group B. Eleven women had polyhydramnios in group A and 4 in group B. Eleven babies (18%) in group A had hypoglycaemia and 7 (8%) in group B. 24 women (39.3%) in group A had babies who needed admission to the neonatal intensive care unit (NICU) vs. 14 (16.3%) in group B. Two babies in group B had congenital anomalies but none in group A. There was 1 neonatal death in group B and none in group A.

Conclusion: There were some improvements in a number of key outcomes (more women taking folic acid, reduced admission rate to NICU, reduced neonatal hypoglycaemia and less cases of polyhydramnios) over recent years. However, preconception counselling has not improved; HbA_{1c} at booking was $7.9 \pm 1.5\%$ in group A vs. $7.6 \pm 1.5\%$ in group B, and more women were delivered by emergency caesarean section in group B. The percentage of women delivered by elective caesarean section has not changed. There seems to be an increase in the number of large for gestational age babies over recent years. Women with T1DM of child-bearing age should receive intensified medical treatment during preconception and pregnancy and should be targeted to receive information about the potential impact of poorly controlled diabetes on the outcome of pregnancy.

0935

The effectiveness of glibenclamide in women with gestational diabetes: preliminary experience

R. I. G. Holt¹, P. Clarke², E. Parry², M. A. G. Coleman²;

¹Endocrinology & Metabolism Sub-division, University of Southampton,

²Fetal Maternal Medicine, Princess Anne Hospital, Southampton, United Kingdom.

Background and Aims: Several studies have suggested that glibenclamide may be used safely and effectively in women with gestational diabetes (GDM). The aim of our study was to assess effectiveness and safety of glibenclamide for GDM in UK clinical practice.

Materials and Methods: Women with GDM requiring pharmacological therapy were offered a choice of insulin or glibenclamide. Maternal and fetal outcomes were assessed in women treated with insulin (45) or glibenclamide (44) and compared with those treated with diet alone (55).

Results: Women choosing glibenclamide were more likely to be Asian ($p=0.002$) and had higher fasting (6.3 ± 0.2 v 5.8 ± 0.1 mmol/l, $p=0.04$) and 2 hr glucose (10.9 ± 0.4 v 9.5 ± 0.4 mmol/l, $p=0.02$) at diagnosis than those choosing insulin. There was no difference in maternal age or parity. The gestation at the start of treatment was 31^{+1} v 0^{+3} weeks (range 21^{+5} v 37^{+5}) with no difference between those treated with insulin or glibenclamide. The mean dose of glibenclamide was 7.8 ± 0.8 mg (median 5 mg, range 2.5–15 mg). Ten glibenclamide women switched to insulin (inadequate control (7), unpredictable hypoglycaemia (1), other (2)). These women had higher baseline body mass index than those who continued with glibenclamide (33.2 ± 1.7 vs. 28.8 ± 1.0 kg/m² $p=0.02$).

There was no difference in mode of birth, birth weight or birth weight centile between groups. One unrelated stillbirth occurred with glibenclamide. Despite higher baseline glycaemia in the glibenclamide group, maternal and neonatal outcomes were not significantly different between glibenclamide and insulin treated women except for lower APGAR scores at 1 minute in the glibenclamide group. Neonatal jaundice and hypoglycaemia occurred more frequently in women treated pharmacologically compared with women treated with diet ($p < 0.03$).

Conclusion: The use of glibenclamide in pregnancy is associated with adequate glycaemic control in 77% and equivalent fetal outcomes to women treated with insulin.

0936

How can we improve postnatal glucose tolerance testing in the gestational diabetic population?

M. Wu¹, N. De Mendonca², J. Girling², C. Cotzias²;

¹Clinical Effectiveness/Obstetrics and Gynaecology,

²Obstetrics and Gynaecology, West Middlesex University Hospital NHS Trust, Isleworth, United Kingdom.

Background and Aims: Women with gestational diabetes (GDM) in our unit are managed in a multidisciplinary obstetric endocrine clinic and counselled about the importance of a postnatal glucose tolerance test (GTT) to identify ongoing glucose intolerance. All women with GDM are given a GTT appointment at 6–8 weeks postnatal. Ongoing glucose intolerance in a multi-ethnic population in the United States has been reported to be as high as 36%. The obstetric population in our unit is multi-ethnic with a significant proportion of women of South Asian or Black African/Caribbean background (only 54% White European). The aims of this study are to describe the demographic and clinical characteristics of our GDM population and to determine the association between these and postnatal glucose testing.

Materials and Methods: Women attending the obstetric endocrine clinic for GDM from 2000–2005 inclusive were identified from clinic records and a retrospective case note review performed.

Results: 419/474 (88%) women were included in the analysis. Mean body mass index (BMI) was 29 kg/m² and 160/398 (40%) women were classified as obese (BMI ≥ 30 kg/m²). 300/419 (72%) women were aged 30 years and above and only 105/415 (25%) were of White European background, while 218/415 (53%) were of Asian ethnicity, 64/415 (15%) of Black African/Caribbean ethnicity, and 28/415 (7%) of Oriental or other ethnicity. 221/419 (53%) required insulin to achieve target glucose levels during pregnancy and 240/419 (57%) were induced. 172/419 (41%) women delivered by caesarean section.

254/419 (61%) women attended for postnatal GTT: Of those, 55/254 (22%) women had an abnormal result; (36 women had impaired glucose tolerance or impaired fasting glucose and 19 had diabetes mellitus). There was no difference in ethnicity, age, or BMI between women who attended for postnatal glucose testing and those who did not. More women who required insulin in addition to dietary modification to control glucose levels during pregnancy attended for a postnatal GTT 147/221 (66.5%) vs. 107/198 (54%), $p=0.006$. Not only did women on insulin therapy have a greater likelihood of attending for their postnatal GTT (OR 1.69, 95% CI, 1.14–2.50), they were also more likely than those managed by diet alone to have an abnormal result 46/147 (31%) vs. 9/107 (8.5%), $p<0.000$.

Conclusion: The association between insulin therapy during pregnancy and rate of postnatal GTT attendance is consistent with health behaviour that is motivated by the belief that one is genuinely ill and that the consequences of the illness will impact one's well being. Given that nearly one-quarter of our GDM population who return postnatally for a GTT have an abnormal result, with reported incidences of more than one-third in the literature, it is crucial to encourage women to attend for postnatal glucose testing. Women with GDM in our unit need to be informed that almost 1 in 3 needing insulin treatment during pregnancy and 1 in 10 managed with diet alone will have ongoing abnormal carbohydrate metabolism. This counselling strategy should be implemented to improve our postnatal glucose testing rates.

PS 90 Diabetes in pregnancy: education and diet

0937

Gestational diabetes mellitus: advantages of an intensive educational programme using E-consulting

J.-J. Altman¹, M. M. Agarwal², S. Parat³, R. Ducloux¹, M. Duval¹, A. Yamgnane⁴, Y. Dumez⁴, M. F. Safradou¹;

¹Diabetology – Nutrition – Endocrinology, Hopital Européen Georges Pompidou, Paris, France, ²Pathology, Faculty of Medicine, UAE University, Al-Ain, United Arab Emirates, ³Pediatrics, Hopital Necker, Paris, France, ⁴Obstetrics and Gynecology, Hopital Necker, Paris, France.

Background: Despite four decades of research, there is still no consensus on the optimal screening, diagnosis and follow-up strategy for gestational diabetes mellitus (GDM). However, there is agreement that strict control of maternal hyperglycaemia results in better outcome for both, the mother and her neonate in the index pregnancy.

Aim: To optimise the control of maternal hyperglycemia using an educational program via E-consulting for GDM.

Materials and Methods: One hundred consecutive pregnant women were followed prospectively. Fasting plasma glucose (FPG) and post prandial glucose (PPG) were performed at booking and at 24–28 weeks, if the initial testing was normal. If the FPG was ≥ 90 mg/dl and/or PPG ≥ 120 mg/dl, women were educated for self monitoring capillary glucose (SMPG). Six SMPG per day, an appropriate diet and physical therapy were recommended. The SMPG results were reported weekly to the physician who advised her within 24 hours, both being done via E-mail.

Results: Of the 100, 30 women were followed by this intensive E-consulting program while the remaining 70 women were managed by the traditional hospital approach. Overall, 27 (27%) women from the entire cohort needed insulin therapy. The women undergoing e-consulting were treated earlier by 10 +/- 2 days. Optimal glycemic targets were obtained in 95% women.

Conclusion: E-consulting is a reliable, quick and good approach to achieve glycemic control for GDM. Moreover, these women being at high-risk for type 2 diabetes mellitus, can be better motivated for long-term follow-up after delivery.

0938

Gestational diabetes mellitus (GDM): a comparison between women who achieve target capillary blood glucose levels (CBG's) with education, diet and exercise alone and those who also require insulin

R. Kaushal¹, N. I. M. De Mendonca², T. J. J. Bracewell-milnes², M. Wu³, J. C. Girling⁴, C. S. Cotzias²;

¹Diabetes and Endocrinology, ²Obstetrics and Gynaecology, ³Clinical Governance and Risk, ⁴Obstetrics and Gynaecology, West Middlesex University Hospital, Isleworth, Middlesex, United Kingdom.

Aim: To identify demographic and pregnancy outcome differences between women who achieve target CBGs with diet and exercise alone and those who need insulin to enable accurate risk counselling for women with GDM.

Introduction: Gestational diabetes is a common, poorly characterised condition. The method of screening, criteria for diagnosis, and the target CBG's to be achieved are not universally agreed.

Methods: All women with GDM managed in our combined obstetric diabetes clinic between 2000–2005 inclusive were identified and a retrospective case note review performed.

Women with the following risk factors;

- 1st degree family history of diabetes
- Non-Caucasian
- Age or Body Mass Index (BMI) > 30 years or kg/m²
- Poor obstetric history – previous; unexplained SB, NND, congenital abnormalities
- Previous large baby (>4.5 kg)

In Current pregnancy:

- Large fetus
- Polyhydramnios
- Fasting glycosuria x 2
- Multiple pregnancy

• Hyper / hypothyroidism were identified and offered a 50gm oral glucose challenge test (OGCT) at 28 weeks gestation. If the blood glucose at 1 hour \geq 7.8mmol/l a formal 75g glucose tolerance test (OGTT) was undertaken. GDM was diagnosed with fasting blood glucose $>$ 6mmol/l or $>$ 9mmol/l at 120min. Women were counselled about fetomaternal implications of GDM, importance of postnatal (PN) OGTT and implications of GDM on long-term health and subsequent pregnancies. All received formal diabetes lifestyle and CBG monitoring education, with target levels of $<$ 6mmol/l fasting and $<$ 8mmol/l 2hr post-prandially. Women unable to achieve these targets with diet and exercise were commenced on insulin.

Results: From 2000–2005, of 474 women with GDM, 419 (88%) notes were reviewed: (47.3%) achieved target BMs with diet and exercise alone and (52.7%) required insulin. No differences were observed in age, ethnicity or parity, but women requiring insulin had a higher BMI. Demographic and pregnancy outcome data are shown in Table 1. Discussion: We have demonstrated that women requiring insulin to control GDM are more obese and carbohydrate intolerant at diagnosis. These women have high caesarean section rates (almost 50%) and almost 10% of those achieving a vaginal delivery will have an associated shoulder dystocia, a potential cause of serious perinatal complications. Such data have not been reported extensively before. This robust information will allow more focussed counselling of our women with GDM according to their treatment needs.

	Diet Group, N= 198	Insulin group, N= 221	P value
BMI m/kg 2 *	27 (24–31)	29 (26–33)	0.001

Gestational diabetes in a multiethnic London population; the demographics, treatment requirements and pregnancy outcomes and the implications of the ACHOIS trial for them

N. I. M. De Mendonca¹, T. J. J. Brace-well-Milnes¹, R. Kaushal², J. C. Girling¹, M. Wu³, C. S. Cotzias¹;

¹Obstetrics and Gynaecology, ²Endocrinology and Diabetes,

³Clinical Governance, West Middlesex University Hospital, Isleworth, Middlesex, United Kingdom.

Aim: To compare the demographic and pregnancy outcomes of our GDM population with our general antenatal population and consider the relevance of the ACHOIS trial for these women.

Introduction: ACHOIS recently showed that treating GDM significantly reduces serious perinatal morbidity. Our unit differs from ACHOIS in terms of diagnostic criteria for GDM and target Capillary Blood Glucose (CBG) levels. The screening and Diagnostic Criteria of ACHOIS suggest Risk identification – refer for 75gm Oral Glucose Tolerance Test (OGTT) Or selective 50gm Oral Glucose Challenge Test (OGCT) – refer for 75gm OGTT if \geq 7.8mmol/l at 1hr. Diagnostic values are fasting $<$ 7.8 mmol/l, 2hour 7.8 – 11.0 mmol/l. CBG monitoring targets are $<$ 5.5mmol/l fasting/ pre-prandial and $<$ 7 mmol/l 2hrs post prandial. In our unit, if risk factor positive, a 50gm OGCT is performed (refer for 75gm OGTT if $>$ 7.8mmol/l at 1 hour). Diagnostic values at OGCT are: Fasting $>$ 6 mmol/l, 2hr $>$ 9 mmol/l. CBG monitoring targets are $<$ 6 mmol/l fasting/ preprandial and $<$ 8 mmol/l 2 hour post prandial.

Methods: A retrospective review of all women with GDM in our unit from 2000–2005 inclusive was performed. Demographic, treatment and outcome data were collected.

Results: During the study period, there were 474 women with GDM (2.6% incidence). Our GDM population was older, more obese, more insulin resistant and had an Asian and Afro Caribbean representation almost 75% and 50% respectively, greater than in the ACHOIS group. Furthermore, 53% of our GDM population required insulin compared with 20% in the ACHOIS intervention group despite lower target BMs. Our GDM group were more likely to need an induction of labour, have a caesarean section, suffer from shoulder dystocia and have a baby $>$ 4kg at birth. (Tab. 1)

Conclusion: The ACHOIS trial demonstrated that treating GDM reduces serious perinatal complications. The data presented highlight the higher risk in our women with GDM compared with the general population and the disparity between them and the women in the ACHOIS study. In view of this the outcomes achieved by ACHOIS should only be extrapolated with caution to such multi-ethnic populations. The screening and diagnostic criteria of ACHOIS are not without significant economic and clinical implication and it must be considered that the outcome improvements demonstrated may not be replicated in other populations.

Fetal outcomes and improved HbA_{1c} values in pregnant women with type 1 diabetes using real-time continuous glucose sensors

M. Voelmlé, S. L. Ellis, L. Gerard, P. Gottlieb, S. Garg;
Young Adult Clinic, Barbara Davis Center for Childhood Diabetes, Aurora,
United States.

Background and Aims: Optimising glucose control in pregnant patients with diabetes continues to be a challenge. Intensive insulin management that includes increased glucose monitoring improves glycemic control.

Materials and Methods: The purpose of this retrospective pilot study was to evaluate the glycemic control of pregnant patients with Type 1 DM who used Real-time Continuous Glucose Monitors (RTCGM) in addition to self monitored blood glucose (SMBG) as compared to women who only preformed SMBG. Secondary outcomes included fetal size.

Results: A total of 6 patients used either a DexCom STS or Medtronic Paradigm RT for approximately 50% of the time during the remainder of the pregnancy after mean initiation at 16.8 weeks (12–24 weeks gestation) gestation. A computer matched control group for age, gender, duration of diabetes, ethnicity, and normal AERs (<20 ug/min) was used for data analysis. Mean (\pm SD) age and duration of diabetes was 32.2 \pm 5.4 yrs and 17.8 \pm 3.2 yrs for the study group. The baseline characteristics were similar in the two groups. Baseline A1C values were 6.6 \pm 1.1 % and 6.8 \pm 0.5% in the sensor and control groups respectively (p >0.05). Significant reductions in mean A1C values were seen at all time points in the sensor group (Fig 1.). There was a tendency towards worsening of A1C at 7 months of gestation (p =0.08, figure 1) in the control group. All babies born to the women in the sensor wearing group were average for gestational age. The mean birth weight was 3309 grams and matched in the 50–90th percentile for gestational age. The women in the sensor group wore the sensors at least 50% of the time since initiation and throughout gestation. The mean weight of the babies in the control group was 3688 grams and included 2 large for gestational age (LGA) babies.

Conclusion: We conclude that use of real-time continuous glucose monitors in pregnant moms with diabetes can improve A1c values with improved fetal outcomes. This pilot study supports the need for larger randomized control trials to evaluate the significance and clinical implications of RTCGM in the management of pregnant women with Type 1 DM. (Fig. 1)

0941

Nutritional beliefs and practices among diabetic pregnant mothers in a tertiary care hospital in Bangladesh

U. S. Munn¹, S. Hossain¹, T. Khan¹, K. R. Ahmed²;
¹Dept of Human Nutrition, BIRDEM, ²Health Economics Unit,
Diabetic Association of Bangladesh, Dhaka, Bangladesh.

Background and Aims: Food beliefs and practices in a particular society are crucial for the dietary management of diabetic patients. Pregnant mothers with diabetes, specially in developing countries, are particularly prone to suffer from dietary imbalances due to superstitions and irrational beliefs and practices. This may, consequently, have deleterious effect on the health of both mother and child. The present study was designed to explore the existing beliefs and practices related to food intake during pregnancy among a group of Bangladeshi diabetic pregnant mothers.

Materials and Methods: One hundred diabetic pregnant mothers (age in yrs, M \pm SD, 30 \pm 4) were purposively selected from the Out-Patient Department of BIRDEM (the tertiary care hospital of the Diabetic Association of Bangladesh). Majority of the diabetic pregnant mothers were literate (96%) and by profession, housewives (86%). A pre-designed, pretested, interviewer-administered questionnaire was used to explore the beliefs and practices about the time of intake and the nature of food. χ^2 - test was done for performing significant test.

Results: Forty three percent of the pregnant mother believed that food should not be taken during the 'call for prayer' and 91% of these mothers practiced it. For 'eclipse' the percentage of such kind of belief was much higher (80%) and 90% of these mothers practiced it. Mentally and physically abnormal child and different kinds of child illness were among the reasons for these beliefs. With varying proportion for particular fishes 44–58% respondents believed that some fishes like *Macrognathus aculeatus* (local name Baim), *Cirrhinus mrigala* (Mrigal) and *Wallago attu* (Boal) should be avoided due to the increased movement of child, fetal malformation and disease. Many of them (93%) actually practiced it. Twenty eight percent had adverse beliefs about *Anas platyrhynchos* (Duck), 78% about *Ananas spp* (Pineapple), 4% about *Rubus fruticosus* (Black berry), 8% about *Cocos nucifera* (Coconut), 10% about 'Tea & coffee'. The corresponding percentages for practice were 82%, 99%, 75%, 50% and 90%. The reasons included maternal and fetal abnormality, appearance of the child (like eye spot with pineapple, black skin with black berry and tea/coffee, and white eyes with coconut) and threat of abortion.

Conclusion: There are a number of nonscientific beliefs and prejudices among diabetic pregnant mother of Bangladesh regarding the intake of food.

Dietary habits during pregnancy and their influence on glucose challenge test

A. Bertolotto¹, A. Calianno², M. C. Pugliese², G. Pucci², S. Vignali², C. Lencioni¹, L. Volpe¹, L. Benzi², G. Di Cianni¹;

¹Department of Endocrinology and Metabolism, University of Pisa, ²Department of Endocrinology and Metabolism, Section of Clinical Nutrition, University of Pisa, Italy.

Background and Aims: Dietary therapy during pregnancy, is the cornerstone to maintain normal weight gain in order to decrease risk of maternal morbidity and adverse perinatal outcomes. The nutritional counselling needs informations on dietary and lifestyle habits. The Glucose Challenge Test (50 g–1 h GCT) is recommended as a screening test for gestational diabetes (GDM). The aims of the present study were to: 1. evaluate energy and nutrient content of diet of pregnant women; 2. verify whether dietary patterns could affect the result of the GCT test.

Materials and Methods: A cohort of pregnant women were interviewed before the execution of GCT to obtain their dietary habit informations. A food frequency questionnaire that included a list of 85 foods was performed by three trained dieticians. Photographs were used to compare different servings for each item. Women were asked to report how often a day and how many days each food was used during the week before GCT. The energy intake and the nutrient content of their diets were calculated using a nutritional analysis program based on data of the European Institute of Oncology.

Results: We studied 166 pregnant women that underwent a GCT at 26±1.5 weeks of gestation; their clinical characteristics were: age 32.4±3.7 years; pre-pregnancy BMI 22.5±4.3 Kg/m²; weight gain 7.4±3 Kg; positive family history of diabetes mellitus 13.2%; primiparous 56%; smokers 8%. GCT was found positive (GCT + if blood glucose concentration ≥ 140 mg/dl after 1 hour of glucose load) in 42 (25.3%) and negative (GCT -) in 124 cases (74.7%). No difference in demographic and clinical data resulted between GCT+ and GCT- cases. The mean daily energy intake of the cohort was 2136±555 Kcal : carbohydrates (CHO) 47% (complex CHO 32%; refined CHO 15%), total fats 38% (saturated fatty acids (FA) 7%; monounsaturated FA (MUFA) 28%; polyunsaturated FA (PUFA) 3%), proteins 15%. The cholesterol intake resulted 267±78 mg/d and that of fibers was 21.6±9.5 g/d. All parameters referring energy and macronutrient intake were not different between GCT + and GCT-. Only fiber intake resulted significantly higher in GCT- (22±8.4g/d vs. 18.9±6.5g/d, p=0.03) than in GCT+ women.

Conclusion: This study gives informations about dietary habits in Mediterranean pregnant women. A diet with low fiber intake could be associated with an increased risk of minor abnormalities of glucose metabolism during pregnancy.

PS 91 Causes and consequences of gestational diabetes

0943

Suitability of the new diagnosis criteria of the American Diabetes Association for gestational diabetes in Maresme area (Barcelona).**Is it adequate to apply these criteria to our population?**

E. Ballestar¹, E. Pizarro¹, J. Solé², J. Sargatal², E. Palomera³, C. Monfort⁴;

¹Endocrinology and Nutrition, ²Obstetrics and Gynecology, ³Research Unit, ⁴Diabetes Education Unit, Hospital of Mataró, Barcelona, Spain.

We present the results of a Gestational Diabetes Mellitus (GDM) Program in the Maresme area (215,000 inhabitants) of Barcelona (1994 – 2004).

Aims: Evaluation of: (a) GDM prevalence according to National Diabetes Data Group (NDDG) criteria, (b) clinical, obstetrical and neonatal results in GDM global group and GDM with pregravid body mass index (BMI) ≥ 30 and (c) insulin therapy in GDM 100-g glucose tolerance test (GTT) with basal plasmatic glycemia (BPG) ≥ 95 mg/dL (new American Diabetes Association BPG criterion).

Method: 1 or 2 screenings with 1hour-50 g of glucose loading test at the beginning of gestation, selective screening initial and/or between 24–30 weeks of gestation. If positive (glycemia ≥ 140 mg/dL), GTT fasting and 1-, 2-, 3-hour postprandial was indicated. GDM was diagnosed by NDDG criteria. Diet and self-monitoring of capillary blood glucose (CBG) at home (1 fasting and 3 postprandial / 1 hour) were required. Optimum control: fasting CBG < 95 mg/dL and postprandial < 130 mg/dL. If ≥ 2 CBG in a week were elevated, insulin therapy was indicated.

Results: 12,705 pregnancies were screened for GDM over 11 years. 962 had GDM (prevalence 7.6 %). Age was higher in GDM group (31.6±4.9 y.) compared with non-GDM (27.8±4.8 y.). Insulin therapy was required in 23.4% of GDM, being more frequent when BPG was ≥ 95 mg/dL (51.1% vs. 15.5%), and when pregravid BMI was ≥ 30 (40.2% vs. 20.5%, p< 0.001). Weight increase was similar in GDM treated with only diet (9.45±4.5 kg) vs. insulin therapy (9.50±4.55 kg). Gestational age at delivery (39.2±1.6 vs. 39.5±1.5 weeks) and neonatal weight (3210±490 g vs. 3206±436 g) were similar in GDM and non-GDM. Cesarean and macrosomia were more frequent in GDM (23.5% vs. 19% and 5% vs. 3%, respectively), particularly when pregravid BMI was ≥ 30 (cesarean: 39% vs. 20.6%, p < 0.001; macrosomia: 9.1% vs. 4.3%). In GDM global group, 5 minutes Apgar ≤ 6 and neonatal hypoglycemia were observed in 0.3% and 5.4%, respectively.

Conclusions: Our Gestational Diabetes Mellitus Program was successfully applied during 11 years. According to our results, we can conclude that : (a) because of 50% of GDM with BPG ≥ 95 mg/dL of GTT required insulin therapy, a reduction of BPG level (95 instead of 105 mg/dL), maintaining the rest of NDDG criteria would be appropriate in our area, and (b) the elevated rate of insulin therapy, cesarean and macrosomia in GDM with pregravid BMI ≥ 30 suggest that obesity prevention programmes before pregnancy should be implemented.

0944

The effect of paternal and maternal history of diabetes mellitus on the development of gestational diabetes mellitus (GDM)

A. G. Tabák¹, G. Tamás¹, A. Péterfalvi², Z. Bosnyák², E. Madarász¹, J. Szánthó⁴, I. Rákóczi⁴, Z. Kerényi²;

¹1st Department of Medicine, Semmelweis University, Faculty of Medicine,

²Diabetology, Health Service of Csepel,

³Outpatient Clinic, Health Service of Ferencváros, ⁴Department of Obstetrics and Gynaecology, Szent Imre Hospital, Budapest, Hungary.

Background and Aims: Previously several studies reported an excess of maternal diabetes among type 2 diabetes patients. Much less is known about the differential role of paternal or maternal diabetes on the development of gestational diabetes mellitus (GDM). Our aim was to explore the risk of GDM associated with paternal and maternal diabetes, and to describe the unique characteristics of GDM women with maternal diabetes.

Materials and Methods: A nested case-control study was performed using data of a population-based screening program of GDM (75g oGTT, WHO criteria) in an urban area of Hungary between May 2002 and October 2003. All Caucasian women with GDM (n=134) and an age-matched control group

(n=134) was selected. Family history data was ascertained during a direct interview with the patient.

Results: GDM women were more obese (BMI 25.4 ± 6.4 vs. 23.0 ± 4.7 kg/m², $P = 0.001$), and had a higher fasting (5.3 ± 3.4 vs. 4.5 ± 0.4 mmol/l, $P = 0.016$) and postload blood glucose (8.6 ± 0.8 vs. 5.5 ± 1.0 mmol/l, $P = 0.0001$) compared to controls. Neither paternal history nor the father's ancestry with diabetes mellitus was a risk factor of GDM. Mothers (and the mothers' ancestry) of the GDM women had diabetes mellitus more frequently than those of the control group (odds ratio [OR] = 3.252 95% confidence interval [CI] 1.147–9.222, OR = 2.92 95% CI 1.455–5.859). Using a logistic regression the only significant and independent predictors of GDM were higher BMI ($P = 0.003$) and a positive maternal history of diabetes mellitus ($P = 0.077$). Positive maternal history of diabetes mellitus of GDM women was independently associated with higher post-load blood glucose (120 min) (9.0 ± 1.0 vs. 8.5 ± 0.9 mmol/l, $P = 0.004$), higher weight (76.0 ± 18.1 vs. 67.9 ± 14.7 kg, $P = 0.087$), and higher systolic blood pressure (117 ± 21 vs. 110 ± 13 mmHg, $P = 0.086$) compared to GDM women without a maternal history of diabetes mellitus.

Conclusion: Maternal history of diabetes mellitus seems to be a stronger predictor of gestational diabetes than paternal history. This association was independent of the effect of age and BMI. GDM women with a maternal history of diabetes mellitus might have a more severe disease than those GDM cases without.

0945

Circulating visfatin in women with gestational diabetes

B. Telejko¹, A. Zonenberg¹, K. Niedziolko-Bagniuk¹, M. Kuzmicki², A. Nikolajuk¹, J. Szamatowicz³, M. Gorska¹;

¹Department of Endocrinology, Diabetology and Internal Medicine,

²Department of Pathophysiology of Pregnancy, ³Department of Gynecology, Medical University of Białystok, Białystok, Poland.

Background and Aims: Visfatin – a new adipokine exhibiting insulin – like activity – has been shown to be increased in patients with type 2 diabetes and long – standing type 1 diabetes, whereas in women with gestational diabetes (GDM) the opposite results, namely increased and decreased levels have been demonstrated. In this study we compared visfatin concentrations between pregnant women with normal glucose tolerance (NGT), GDM and non-pregnant healthy women.

Materials and Methods: The group studied consisted of 61 patients with GDM at 28.8 ± 3.8 week of gestation, 63 pregnant women with NGT at 29.7 ± 3.2 week of gestation and 36 non-pregnant healthy women. Serum visfatin concentration was measured using an enzyme – linked immunosorbent assay.

Results: Median visfatin concentrations did not differ significantly between women with GDM (median 14.8 [interquartile range 10.8–17.3] ng/ml) and NGT (15.3 [11.8–19.4] ng/ml), but were markedly higher than those found in non-pregnant women (11.4 [8.6–15.2] ng/ml, $p = 0.0008$ vs NGT and $p = 0.0083$ vs. GDM group). Visfatin levels correlated slightly with insulin ($R = 2001$, $p = 0.0111$) and HOMA-IR values ($R = 0.1783$, $p = 0.0241$). No association with glucose, gestational age or body mass index was observed. Stepwise multiple regression analysis revealed that visfatin concentrations were significantly predicted only by HbA1c values (Beta=0.2630, $p = 0.0046$)

Conclusion: Elevated visfatin levels in pregnant women may be connected with increased insulin or insulin resistance but not with GDM.

0946

Visfatin response to glucose is reduced in women with gestational diabetes mellitus

A. Handisurya¹, D. G. Haider^{1,2}, A. Storka², E. Vojtassakova², A. Luger¹, M. Wolzt^{1,2}, A. Kautzky-Willer¹;

¹Department of Internal Medicine III, Division of Endocrinology and Metabolism, ²Department of Clinical Pharmacology,

Medical University of Vienna, Austria.

Context: The insulin-mimetic adipocytokine visfatin has been associated with insulin resistance and is regulated by glucose. Recently, retinol binding protein-4 (RBP-4) was related to the development and progression of insulin resistance.

Objective: We hypothesized that glucose-induced plasma visfatin and RBP-4 regulation are different in women with gestational diabetes mellitus (GDM).

Design and Patients: Plasma visfatin and RBP-4 concentrations were investigated in 10 women with GDM and 10 age-matched healthy women in pregnancy week 24–28 during a standard oral glucose tolerance test (OGTT).

Results: There was no difference between fasting plasma RBP-4 or the appetite-regulating peptide obestatin, which remained unchanged during OGTT. In contrast, women with GDM had lower systemic visfatin concentrations than controls (1.9 ± 0.8 ng/ml vs. 5.2 ± 4.4 ng/ml, respectively, $p < 0.05$), which were associated with fasting glucose ($p < 0.05$). The glucose-induced increase in plasma visfatin over baseline was smaller in GDM, with an area under the curve of 409 ± 106 ng*min/ml versus 780 ± 345 ng*min/ml in controls ($p < 0.05$).

Conclusion: Glucose-induced increases in circulating visfatin are reduced in women with GDM. This mitigated response may be associated with impaired glucose tolerance. RBP-4 or obestatin plasma levels are not acutely affected by changes in plasma glucose concentrations.

0947

Early development of cardiovascular risk in women with prior gestational diabetes

L. Volpe¹, I. Cuccuru¹, C. Lencioni¹, V. Napoli², A. Ghio¹, C. Fotino¹, F. Romero¹, G. Penno¹, S. Del Prato¹, G. Di Cianni¹;

¹Department of Endocrinology and Metabolism, University of Pisa,

²Department of Radiology, University of Pisa, Italy.

Background and Aims: We have previously shown that both the Metabolic Syndrome and low-grade inflammation are common findings in women with previous gestational diabetes (pGDM) suggesting these women may have not only greater risk for diabetes but also for cardiovascular disease (CVD). As such they are expected to have earlier signs of sub-clinical atherosclerosis as compared to women without pGDM. The aim of present work was, then, to verify such a hypothesis.

Materials and Methods: 28 clinically healthy women with pGDM and 24 controls women with a history of normal pregnancy were evaluated at 36 months after delivery. A 75g-2h oral glucose tolerance test (OGTT) was performed to determine area under glucose curve (AUC_{gluc}), insulin sensitivity index (ISI) and resistance (HOMA-R). Moreover, blood pressure (BP), BMI, waist circumference, lipid profile, oxidised LDL (Ox-LDL), C-Reactive Protein (CRP), and fibrinogen were determined. In all women Intimal Media Thickness (IMT) was measured at 4 segments of left and right carotid, and mean carotid IMT value calculated.

Results: Family history of type 2 Diabetes (61.3 vs 8.1%, $p < 0.0001$), and cardiovascular diseases (54.8 vs. 20.8 %, $p < 0.001$) was more common amongst pGDM than control women. The former also were older (37.75 ± 4.4 vs. 34.12 ± 3.2 years, $p < 0.001$), had larger waist circumference (85.9 ± 9.3 vs. 79.9 ± 9.7 cm $p < 0.03$), and higher diastolic BP (70.6 ± 7.3 vs. 66.6 ± 5.7 mmHg $p < 0.03$), while there was no difference in BMI (24.22 ± 3.2 vs. 23.1 ± 3.5 Kg/m²). Fasting plasma glucose levels (84.3 ± 9.6 vs. 79.5 ± 4.3 mg/dl), AUC_{gluc} (873.5 ± 147.4 vs. 690.6 ± 114.4 mg/dl*min), triglycerides (91.28 ± 67.7 vs. 62.7 ± 21.4 mg/dl), fibrinogen (356.7 ± 69.2 vs. 298.45 ± 60 mg/dl), CRP (3.4 ± 1.8 vs. 0.8 ± 0.9 mg/L), and HOMA-R (1.9 ± 1.08 vs. 1.39 ± 0.7) were all greater ($p < 0.05$ or less) in pGDM, while ISI (6.4 ± 4 vs. 11.7 ± 10 , $p < 0.01$) was lower than controls. Mean common carotid IMT value was higher in pGDM women than in control women (0.57 ± 0.058 vs. 0.51 ± 0.051 mm, $p < 0.01$) with no difference in the values at the artery bulb level. On simple regression IMT was related with age ($r = 0.43$, $p < 0.0009$), BMI ($r = 0.37$, $p < 0.0043$), waist circumference ($r = 0.32$, $p < 0.019$), systolic ($r = 0.36$, $p < 0.007$) and diastolic BP ($r = 0.3$, $p < 0.0013$), HOMA R ($r = 0.29$, $p < 0.037$), AUC_{gluc} ($r = 0.28$, $p < 0.004$), Ox-LDL ($r = 0.34$, $p < 0.004$) and CRP ($r = 0.33$, $p < 0.001$). However when all latter variables were introduced in a multiple regression analysis only Ox-LDL (f-test 5.3, $p < 0.02$) remained significantly associated with IMT.

Conclusion: Our results show that sub-clinical carotid artery atherosclerosis is present three years after delivery in pGDM women. IMT is associated with multiple CVD risk factors, but independently associated only with Ox-LDL. Therefore our data suggest that pGDM women are at greater CVD risk and indicate Ox-LDL as a target for early preventative intervention.

0948

Women with pregnancy-induced hypertension have an increased incidence of subsequent diabetesA. Dhawan¹, P. Baker², S. Dissanayake³, S. Khan¹, P. Lewis¹;¹Cardiology, Stepping Hill Hospital, Stockport,²Maternal foetal health, CMMC, United Kingdom,³Diabetes, Stepping Hill Hospital, Stockport, United Kingdom.

Introduction: Studies have shown that hypertension in pregnancy is associated with a higher incidence of hypertension in the later life. We investigated whether there is a relationship between hypertension in pregnancy and the subsequent incidence of diabetes.

Methods: The current diabetic status of 200 women with a history of pregnancy-induced hypertension was compared with that of 100 women delivered during the same period in the past. Data from this index pregnancy including age, family history of diabetes, gestational diabetes, BMI and blood pressure was collected. Current diabetic status was established by direct contact, questionnaire and general practitioner and hospital records.

Results: These women were followed up over a mean period of 15 years (range 11–20 years). There was no significant difference between the mean age of the women (43 years, range 37–50 Years) in the two groups. Incidence of diabetes was significantly higher in women with pregnancy-induced hypertension compared with normotensive pregnancy (39/200 vs. 7/100, $p < 0.001$). Using a multivariate binary logistic model (age, hypertension in pregnancy, gestational diabetes, family history of diabetes and BMI), pregnancy induced hypertension (OR 3.904, 95% CI: 1.41–10.79, $p = 0.009$) and gestational diabetes (OR 6.06, 95% CI: 2.39–15.36, $p = 0.0001$) were sole significant independent predictors of future diabetes.

Conclusion: Pregnancy induced hypertension is associated with increased future risk of developing diabetes.

Efficacy of continuous subcutaneous insulin infusion in type 1 diabetes: a 2-year perspective under the established guidelines and indications for funding from a national health service

M. Giménez, I. Levy, M. Jansà, M. Vidal, G. Chiganer, I. Conget; Endocrinology and Diabetes Unit, Hospital Clínic i Universitari/IDIBAPS, Barcelona, Spain.

Background and Aims: To determine the 2-year efficacy of CSII following the current established indications and guidelines of the Catalan National Health Service compared to previous conventional MDI therapy.

Materials and Methods: Longitudinal, prospective, observational unicenter study. 153 T1D subjects previously treated with MDI in whom CSII was indicated following the guidelines of the Catalan National Health Service Authorities were included in the study. At baseline, we registered data on age, gender, duration of the disease, BMI, insulin dose and indications for CSII. HbA_{1c} and the frequency of hypoglycaemic events, classified into mild and severe, assessed the quality of glycaemia control. For evaluation of the quality of life, three different self-report questionnaires were assessed. After 24 months of follow-up all subjects were evaluated including the same items measured before the initiation of CSII. Serious adverse events and injection site complications were also recorded.

Results: In 96% of subjects, CSII indication included inability to obtain optimal glycaemic profile using MDI. HbA_{1c} fell from 7.9 ± 1.3 at baseline to 7.3 ± 1.1 ($p < 0.001$) after 24 months of CSII, and this diminution depended on the initial value of HbA_{1c} and the number of severe hypoglycaemia episodes reported during the year before CSII initiation. Insulin requirements were significantly lower at the end of follow-up (0.55 ± 0.21 U/kg·body weight) in comparison to before using CSII (0.70 ± 0.20 , $p < 0.001$). BMI increased from 24.1 ± 3.1 kg/m² at baseline to 24.4 ± 3.2 after 24 months of CSII treatment ($p = 0.024$). The rate of diabetic ketoacidosis episodes per year remained unchanged during follow-up. Mild and severe hypoglycaemic episodes were significantly reduced. The overall DQoL scores significantly improved in all aspects after 24 months of CSII.

Conclusion: The use of CSII improves metabolic control and quality of life outcomes with fewer hypoglycaemia episodes in T1D subjects previously conventionally treated with MDI under indications for funding from National Health Service guidelines.

Insulin pump therapy in adults allows metabolic control at lower rates of hypoglycaemia along with reduced insulin doses – results from the nationwide DPV-survey among German diabetes centersW. Quester¹, W. Kerner², E. M. Fach³, K. Edel⁴, S. Wüchner⁵, K. Badenhoop⁶, T. Klaes⁷, H. R. Engels⁸, A. Gordalla⁹, H. J. Ziegelasch¹⁰, H. R. Henrichs¹¹, R. W. Holl¹²;¹Heart- and Diabetes Center NRW, Bad Oeynhausen, ²Klinikum Karlsburg,³Schwerpunktpraxis, Stephanskirchen, ⁴Klink Hermannsborn, Bad Driburg,⁵Diabetes Center, Klinikum Darmstadt, ⁶University Clinic, Frankfurt,⁷Gemeinschaftsklinikum Koblenz-Mayen, ⁸Krankenhaus Hellersdorf,Berlin, ⁹Abt. Endokrinologie Stoffwechselekrank., Klinik für InnereMedizin Universität Rostock, ¹⁰Innere Medizin, Klinikum Schwerin,¹¹Diabetes Zentrum, Christliches Krankenhaus Quakenbrück, ¹²Institut für

Epidemiologie, Universität Ulm, Germany.

Background and Aims: In adult patients with type 1 diabetes, intensified insulin therapy and insulin pump therapy are options for insulin substitution. Data on pump therapy under real-life-conditions in large multicenter databases are rare.

Materials and Methods: The DPV diabetes documentation system allows prospective documentation of parameters relevant for the process of diabetes care, as well as outcome indicators. For each individual patient, records during the most recent year were averaged. HbA_{1c} values were mathematically standardised to the DCCT normal range. The SAS 9.2 analysis software was used for nonparametric comparisons, using Holm adjustment for multiple testing, and generalised mixed models.

Results: By March 2007, data on 8483 adult subjects with type 1 diabetes (mean age 36.1 ± 0.2 years, range 18–88 years) were available for analysis.

Gender ratio was 51% males and 49% females, the mean age at onset of diabetes was 20.2±0.2 years (mean diabetes duration 15.9±0.1 years). 6245 patients (73.6%) used multiple daily injections, while 2238 (26.4%) used CSII. Diabetes duration was longer in pump patients (20.1 versus 14.3 years, $p<0.0001$), and more women opted for CSII (57.5% versus 45.8%, $p<0.0001$). Daily insulin requirement was lower in pump patients (43.9±0.4 Units compared to 53.6±0.3 Units, $p<0.0001$). 50.4% of subjects on multiple injections used insulin analogs, compared to 72.7% of CSII patients ($p<0.0001$). Mean HbA_{1c} was 7.8% in both groups, and no difference was present after adjustment for age, duration of diabetes, gender, insulin dose, insulin preparation, degree of overweight and center heterogeneity. In contrast, the rate of severe hypoglycaemic episodes was lower in CSII patients (4.1 events per 100 patients·years) compared to MIT patients (6.6 events, $p<0.0001$). This difference remained significant after adjustment for potentially confounding variables ($p<0.02$). CSII patients were slightly more overweight with a BMI of 25.7 compared to 24.9 kg/m² in MIT patients. Micro- and macroalbuminuria were more prevalent in MIT compared to CSII patients ($p<0.0001$ and $p<0.01$, respectively, after adjustment for confounders).

Conclusion: Insulin requirement is significantly lower in CSII patients compared to MIT and the rate of severe hypoglycemia is significantly lower, while BMI is slightly higher. No significant difference in HbA_{1c} values was detected, but the rate of micro- and macroalbuminuria were lower in CSII-patients.

0951

Long-term results of continuous subcutaneous insulin infusion (CSII) treatment – national register in the Czech Republic

Z. Jankovec, D. Cechurova, M. Krcma, S. Lagicova, M. Zourek, Z. Rusavy; Medical Department, University Hospital, Plzen, Czech Republic.

Background and Aims: National Register of patients treated by insulin pump are available during treatment period 1998–2007 obtained from nearly 2.550 patients from 52 departments of diabetology in the Czech Republic. The aim of our study is to present the current results of data evaluation.

Materials and Methods: The data was collected continuously utilising special database software and evaluated in regular intervals. For statistical evaluation the common statistical methods, Wilcoxon rank-sum test, Spearman rank correlation coefficient and Kruskal-Wallis analysis were used.

Results: The average age of patients was 40,6±15,66 years, the average history of diabetes at the start of CSII treatment was 13,0±9,42 years, and the average duration of insulin pump treatment was 4,9±3,55 years, BMI 35,2±15,76 kg/m². Main reasons for the treatment by CSII: 63% for bad control, 18% for hypoglycemia, 22% for neuropathy, 19% for dawn Phenomenon, and 14 % for other chronic complications (each of the patients could state multiple reasons). The results have shown a significant improvement of values of HbA_{1c} in the insulin pump treatment compared to the values before the start: 9,60±2,12% vs. 8,47±1,71 after 1 year ($p<0,001$). Simultaneously, the average daily insulin dose was reduced: 49,6±18,2 vs. 40,2±14,4 IU/day ($p<0,05$). During the CSII treatment a permanent and statistically significant increase of basal doses while bolus doses do not change. Likewise, there has been a significant weight increase (BMI) after the 2nd year of treatment ($p<0,05$). The values of HbA_{1c} during CSII treatment have been directly proportional to the HbA_{1c} values at the start of the treatment. The predictive factors of success of the CSII therapy seem to be bad control of diabetes and hypoglycemia as reasons for the start of CSII treatment.

Conclusion: Our results show an enduring character of improvement of monitored parameters from a long-term point of view. CSII treatment has been effective especially in very badly controlled diabetic patients.

Insulin requirement profiles of type 2 diabetic patients after achieving stabilised glycaemic control with short-term continuous subcutaneous insulin infusion

Y. H. Noh¹, S. Y. Park¹, J. H. Lee¹, D. Y. Kim¹, S. B. Choi²;

¹Biochemistry,

²Internal Medicine, Konkuk University, Chungju, Republic of Korea.

Background and Aims: Large prospective studies have demonstrated that optimum glycemic control is not routinely achieved in clinical practice. Recently CSII therapy for T2DM patients have emerged as a promising therapeutic strategy, for several studies have reported a better glycemic control, fewer complications and more remission cases with CSII in T2DM patients. However, barriers to optimal insulin therapy including fear of hypoglycemia, suboptimal initiation and dose titration have kept physicians from initiating CSII therapy for T2DM patients who have endogenous insulin secretion with wide spectrum. Moreover, few studies have reported the actual insulin dose requirement profiles of T2DM patients in CSII therapy. In the present study, to find predicting factors for determining the insulin dose requirement profiles of T2DM patients to be used on the initiation of CSII therapy, we analysed clinical parameters and laboratory data at baseline and total daily dose (TDD) infused in T2DM patients after achieving stabilised glycemic control with CSII treatment.

Materials and Methods: We analysed insulin requirement profiles of 300 T2DM patients [male 50%, age 57.9±11.4, duration of T2DM 11.0±7.9 years, fasting plasma glucose (FPG) 155±54.4 and postprandial plasma glucose (PP2) 236±81.7 mg/dl, HbA_{1c} 9.1±2.2%] after stabilisation of blood glucose level achieved (FPG 110±21.2 mg/dl and PP2 121±17.4 mg/dl) by two weeks of CSII therapy and performed statistical analyses including *t*-tests, Pearson correlation, and multiple linear regression tests. Carbohydrate to insulin ratio [CIR, carbohydrate intake amount (g/day) divided by insulin bolus dose (IU/day)] was calculated.

Results: Insulin requirement profiles and CIR data from 300 T2DM patients are summarised in Table 1. Means of TDD, basal insulin dose, CIR, and BMI were significantly different between male and female patients ($p<0.01$). TDD was associated with sex, height, BMI, HbA_{1c}, FPG, PP2, fasting C-peptide, and HOMA-IR ($p<0.05$). CIR was associated with age, sex, duration of DM, height, BMI, HbA_{1c}, FPG, PP2, fasting C-peptide, and HOMA-IR ($p<0.05$). After adjustment for age, sex, and BMI, TDD was associated with HbA_{1c}, FPG, PP2, fasting C-peptide, and HOMA-IR ($p<0.05$). After adjustment for age, sex and BMI, CIR was associated with weight, height, HbA_{1c}, PP2, HOMA-IR ($p<0.05$).

Conclusion: From these analyses we could make equations to predict TDD, CIR, bolus and basal profiles using clinical and laboratory data before the initiation of CSII therapy. These equations may give more practical guidelines for the initiation and dose titration of CSII therapy on T2DM patients than the present guideline based on weight in determination of insulin dosage. (Tab. 1)

Table 1. Insulin Requirement Profiles of 300 Type 2 Diabetic Patients 2 weeks after CSII therapy

	TDD (IU/day)	Bolus (IU/day)	Basal (IU/day)	Carbohydrate intake (g/day)	CIR (g/IU)	BMI (kg/m ²)	HbA _{1c} (%)	Fasting C-peptide (ng/ml)

Insulin pump treatment in the elderly: a closer look at its feasibility and effectivenessR. Hoogma¹, S. Matthaei², M. A. Schweitzer³, S. Grunder³, A. Bühr³;¹Interne Geneeskunde/Diabetes, Groene Hart Ziekenhuis, Gouda,The Netherlands, ²Diabetes Zentrum Quakenbrueck, Germany,³Roche Diagnostics GmbH, Mannheim, Germany.

Background and Aims: Insulin pump therapy is considered the gold standard for optimised glucose control and increasingly the preferred way to intensified treatment for the younger patients for whom the long-term benefits are of utmost importance. There might be a number of patients getting older with the pump and others looking for the short-term benefits CSII offers to them. However, not much data is available for this age group on pumps.

Materials and Methods: A structured questionnaire was distributed to 36,450 CSII patients with T1 and T2 diabetes from Europe and North America to determine patient characteristics, medical data, complication rates and treatment satisfaction. In total, there were 25 structured questions with additional information on socio-demographic background, insulin pump indication, initiation and follow-up of treatment. We report the analysis of the sub-set of data of patients older than 65 years and compare them with the younger ones.

Results: 902 (6.4%) of the 14,015 respondents were ≥ 65 years old. Overall, elderly patients on CSII had a longer duration of diabetes (29.6 ± 14.4 vs. 20.2 ± 11.4 years) and their time on insulin treatment was longer (26.3 ± 15.6 vs. 19.5 ± 11.5 years), the difference to the duration of diabetes most likely explained by the higher percentage of T2 patients (21.6% vs. 4.2%). Remarkably, the mean age at start of CSII was 63.6 ± 6.5 vs. 35.2 ± 12.8 years; on average they were 5.5 ± 5.1 vs. 4.7 ± 4.3 years on CSII. Reasons for starting CSII therapy differed between the two groups mainly in: neuropathy (30.8 vs. 13.3%), diabetic complications (22.2 vs. 13.0%) and bG fluctuations (59.5 vs. 39.8%), whereas more flexible lifestyle (44.5 vs. 67.5%), variable nature of work (16.2 vs. 31.3%) and Dawn phenomenon (32.6 vs. 49.3%) were less important reasons in the elderly. Both groups reached good glycaemic control with a mean HbA_{1c} of $6.9 \pm 1.1\%$ vs. $7.0 \pm 1.1\%$. All patients reported equally high treatment satisfaction levels for CSII therapy.

Conclusion: Whereas elderly patients on CSII differ in their indication for this form of intensified insulin therapy, they reach equally good glycaemic control and high treatment satisfaction based on self-reported figures in this observational study. Improvement in symptoms of diabetic complications is important indications for CSII in patients ≥ 65 years and can be addressed successfully. Higher age therefore should not be a contra-indication to start diabetic patients on pumps.

0954

Pharmacokinetic and pharmacodynamic effects of an s.c. infusion of insulin lispro by a disposable basal insulin pump in healthy volunteersK. Rave¹, L. Heinemann¹, P. Gravesen²;¹Profil, Institute for Metabolic Research, Neuss, Germany,²Danfoss A/S, Microtechnology, Nordborg, Denmark.

Background and Aims: Basal infusion of insulin with a constant rate over a period of at least 3 days is an attractive option for patients with type 2 diabetes. In comparison to a subcutaneous (sc) injection of a long-acting insulin analogue once daily a continuous infusion of a fast-acting insulin analogue should lead to a more constant metabolic effect. A novel disposable Microfluidic Elastomer Patch Pump (MEPP) was developed to allow a high accurate insulin infusion at a constant flow rate.

Materials and Methods: By means of the glucose clamp technique we measured the pharmacokinetic and pharmacodynamic responses to a continuous sc infusion of insulin lispro (IL) either applied via a MEPP or by a commercially available insulin pump (Accu-Chek Spirit, A-CS, Roche Diagnostics). This study was conducted in an open-labelled cross-over design. Eight healthy male volunteers (mean age 36 years (range 30–44); BMI $26.7 \text{ kg}\cdot\text{m}^{-2}$ (23.0 – 29.9)) were enrolled. Insulin lispro was infused at a rate of 2 U per hour for 24 hours, using the MEPP for 3 out of 4 experiments performed in each volunteer; the A-CS was used during the other experiment. Blood glucose of volunteers was kept constant at a target value of $4.5 \text{ mmol}\cdot\text{l}^{-1}$ by a glucose clamp procedure. Blood samples were taken in regular intervals for specific measurement of serum IL

levels. Twentyseven individual MEPPs were employed during the 24 glucose-clamps, among which 21 constantly delivered IL and 6 failed.

Results: When taking data from the successful experiments only, total serum insulin lispro area under curve (AUC-INS_{0-24h} 44.7 ± 11.7 vs. $38.8 \pm 7.5 \text{ mU}\cdot\text{min}\cdot\text{ml}^{-1}$ (mean \pm SD, n=19 for MEPP and n=8 for A-CS)), fractional serum IL AUC (AUC-INS_{0-6h} 7.6 ± 2.5 vs. $7.3 \pm 1.4 \text{ mU}\cdot\text{min}\cdot\text{ml}^{-1}$), peak serum IL levels (INS_{max} 43.1 ± 11.7 vs. $36.4 \pm 6.0 \text{ }\mu\text{U}\cdot\text{ml}^{-1}$) and time to peak levels (T-INS_{max} 853 ± 253 vs. $559 \pm 308 \text{ min}$) were comparable after infusion with MEPP or A-CS. Likewise, total glucose infusion rate AUC (AUC-GIR_{0-24h} 5533 ± 2233 vs. $5499 \pm 1865 \text{ mg}\cdot\text{kg}^{-1}$), fractional GIR AUC (AUC-GIR_{0-6h} 755 ± 505 vs. $845 \pm 520 \text{ mg}\cdot\text{kg}^{-1}$), maximum GIR (GIR_{max} 5.7 ± 2.0 vs. $5.7 \pm 2.1 \text{ mg}\cdot\text{kg}\cdot\text{min}^{-1}$) and time to maximum GIR (T-GIR_{max} 933 ± 462 vs. $978 \pm 472 \text{ min}$) were similar during infusion of IL via the MEPP or the A-CS. Mean weight difference of insulin pumps after 24 h of insulin pumping was $0.63 \pm 0.07 \text{ g}$ for the MEPP and $0.49 \pm 0.01 \text{ g}$ for the A-CS, which is well the theoretical amount of pumped insulin. Analysis of failing MEPPs revealed that remains from the production process obstructing the flow capillary were responsible for pump failures. Neither adverse events or adverse device effects were observed during the study, and there were no adverse findings of safety laboratory tests and vital sign measurements which could be attributed to the study treatment. Examination of the application site revealed no noticeable skin reactions.

Conclusion: In summary, continuous sc infusion of the fast-acting insulin analog insulin lispro by means of a disposable pump result in a pharmacokinetic and pharmacodynamic response comparable to that observed with a commercially available pump. Given that a more reliable performance of this functional model is possible, this Microfluidic Elastomer Patch Pump is an attractive alternative to conventional insulin pumps.

Reduction of HbA_{1c} using the “bolus wizard” in patients with type 1 diabetes on CSII therapy

J. Ferri, F. J. Ampudia-Blasco, L. Sorribes, C. Argente, R. Carmena;

Endocrinology, Clinic University Hospital Valencia, Valencia, Spain.

Aims: To assess the benefit of using the “bolus wizard” (BW) in the metabolic control of patients with type 1 diabetes on continuous subcutaneous insulin infusion therapy (CSII).

Methodology: Observational, prospective study conducted on a group of patients with type 1 diabetes who were using the BW, after a variable period of CSII therapy and/or multiple dose insulin (MDI). A comparison was made by means of mean HbA_{1c} values during the 6 months before and after using this pump utility. All patients used a pump model with a BW (Paradigm[®] 512/712 or 515/715, Medtronic Inc., USA). To draw comparisons, the Wilcoxon test was performed with SPSS 12.0. Data were expressed using mean \pm SD.

Results: 38 patients, of a total of 49 users (77.5%), used the BW routinely (27 women, aged 35.3 ± 6.9 years (X \pm DE), BMI $24.3 \pm 3.7 \text{ kg}\cdot\text{m}^{-2}$, diabetes since 18.7 ± 8.9 years, on CSII therapy for 2.83 ± 1.89 years, with “bolus wizard” for 8.9 ± 5.2 months). Of these, 60.5% were patients who had been on CSII therapy previously but used earlier models without this function (Minimed 507C and 508B, Medtronic Inc., USA). The difference between the mean HbA_{1c} before and after using the BW, was -0.31% (CI 95%: -0.03% , -0.59% , $p=0.031$). However, when an analysis was made only of patients who had been on CSII previously, the incorporation of the BW did not lead to a significant reduction in HbA_{1c} (difference in HbA_{1c} of -0.12% (CI 95%: -0.50% , 0.26% , $p=0.432$).

Conclusions: Use of the BW in patients with type 1 diabetes on CSII therapy leads to improved metabolic control, and this is more significant in patients who had been on MDI prior to starting the new therapy.

0956

Insulin detemir provides superior glycaemic control compared with NPH insulinJ. J. Larsen¹, S. Heller², C. B. Pedersen¹;¹Novo Nordisk A/S, Bagsvaerd, Denmark, ²School of Medicine and

Biomedical Sciences, University of Sheffield, United Kingdom.

Background and Aims: To investigate the glycaemic control achieved with the long-acting analogue insulin, detemir (detemir) and intermediate-acting

NPH insulin (NPH), using a meta-analysis based on three randomised, multinational, parallel, open-label trials that included 1555 men (60.5%) and women (39.5%) with type 1 diabetes.

Materials and Methods: Subjects received detemir or NPH once-daily plus human soluble insulin (HSI) at meals in one 26-week trial, and received detemir or NPH twice-daily plus insulin aspart at meals in two 16-week trials. At baseline, subjects had a mean (SD) duration of diabetes of 16.3 (10.6) yrs, with a mean age of 40.3 (12.2) yrs. Average HbA_{1c} was 8.4% and 8.3%, FPG was 11.4 and 11.5 mmol/L, body weight was 75.9 and 76.0 kg and BMI 25.1 and 25.3 kg/m², for subjects randomised to detemir and NPH, respectively.

Results: Glycaemic control, as measured by HbA_{1c} and FPG, and change in body weight were analysed across the three trials. There was a significant improvement in HbA_{1c} after treatment with detemir superior to that seen with NPH, with an estimated mean difference of -0.13%, 95% CI [-0.22, -0.04], *p*=0.006 and mean reductions from baseline to end of trial of 0.4 and 0.2 percent points, respectively. FPG also decreased in both groups, with an estimated mean difference of -1.53 mmol/L, 95% CI [-1.99, -1.07], *p*<0.0001 in favour of detemir. When using detemir, no increase in body weight was observed, whereas use of NPH resulted in weight gain, with an estimated mean difference between treatments of -0.64 kg, 95% CI [-0.94, -0.34], *p*<0.0001. In each trial, these results were obtained with similar basal and bolus insulin doses for the detemir and NPH groups. Over the 24-hour period, the relative risk of hypoglycaemia was similar between the detemir and NPH groups in each of the three trials. Reduced risk of minor nocturnal hypoglycaemia was observed with detemir in the 26-week trial and in one of the 16-week trials. The safety profiles, described by the incidence of adverse events in each trial, were similar with detemir and NPH.

Conclusion: Use of detemir resulted in a modest improvement in glycaemic control and a beneficial effect on weight compared with NPH in subjects with type 1 diabetes treated on a basal-bolus insulin regimen.

Supported by Novo Nordisk A/S

For the patient subgroup who switched from RHI to LIS at randomisation, there was an additional reduction of HbA_{1c} at endpoint (-0.14%, *p*<0.05 vs. run-in). Overall, OD GLA+LIS showed a greater improvement in HbA_{1c} (-0.41% vs. NPH insulin at baseline; *p*<0.001). FBG were similar at endpoint in both arms (RHI=9.1±2.4 mmol/L [164.6±42.4 mg/dL] vs. LIS=9.4±2.3 mmol/L [169.2±41.8 mg/dL]; *p*=NS). The incidence of nocturnal severe hypoglycaemia was similar in both groups at endpoint (RHI=0.015±0.009 vs. LIS=0.016±0.008 episodes/patient/month; *p*=NS).

Conclusion: These results suggest that the OD GLA+LIS regimen is more effective in achieving good glycaemic control when switched from NPH insulin+RHI using a stepwise approach of changing basal insulin first followed by bolus insulin.

Italian experience trial for the implementation of insulin glargine in basal-bolus regimen in patients with type 1 diabetes

P. Brunetti¹, M. Muggeo², L. Cattin³, A. Arcangeli⁴, P. Pozzilli⁵, V. Provenzano⁶, A. Francesconi⁷, P. Calatola⁸, F. Santeusano¹;

¹Department of Internal Medicine, University of Perugia, ²Division of Endocrinology and Metabolic Disease, University of Verona, ³Department of Clinical, Morphological and Technological Sciences, University of Trieste, ⁴USL 4, Diabetes and Metabolic Disease Unit, Prato, ⁵Division of Diabetes and Metabolic Disease, University Campus Bio-Medico, Rome, ⁶Division of Diabetes and Metabolic Disease, Hospital of Partinico, Palermo, ⁷Diabetologia and Metabolic Disease Unit, Hospital of Santa Maria Annunziata, Florence, ⁸ASL SA/2, Diabetology Centre, Salerno, Italy.

Background and Aims: Once-daily (OD) basal insulin glargine can be used as part of a multiple daily injection regimen in patients with type 1 diabetes mellitus (T1DM). This randomised, multicentre study compared OD glargine (GLA)+prandial regular human insulin (RHI) with OD GLA+prandial lispro (LIS) in reducing the incidence of severe nocturnal hypoglycaemia at endpoint.

Materials and Methods: Patients with T1DM (n=489) previously on a basal-bolus regimen (NPH insulin+RHI or LIS) were switched to OD GLA as basal insulin. The daily dose of OD GLA was titrated (Fasting blood glucose [FBG]=5.0–6.7 mmol/L [90–120 mg/dL]) for 8 weeks (run-in) prior to randomisation; patients continued with their previous bolus insulin. Patients (n=395) were randomised to LIS (n=193) or RHI (n=202) and treated for 16 weeks. Data are mean ± standard deviation.

Results: Both OD GLA+RHI and OD GLA+LIS regimens reduced HbA_{1c} from baseline (with NPH insulin) to the end of run-in (both *p*<0.01) and were similar at endpoint, although the LIS arm tended towards a lower value (Table).

HbA _{1c} (%)	RHI arm	LIS arm
Baseline (with NPH insulin)	7.39±0.88	7.39±0.97
8 weeks with GLA (run-in)	7.10±0.82*	7.00±0.88*
16 weeks with GLA (endpoint)	7.10±0.83†	6.95±0.78†

**p*<0.01; †*p*<0.001, both vs baseline

PS 93 Pharmacokinetics and physiology of insulin therapy

0958

Long-term follow-up of patients on U-500 Human Actrapid

V. Nayyar, I. Lawrence, M.-F. Kong, A. Gallagher, R. Gregory, S. Hiles, S. Jackson, P. McNally, M. Davies;
Diabetes & Endocrinology, University Hospitals Of Leicester NHS Trust, Leicester, United Kingdom.

Background and Aims: Patients with severe insulin resistance need to inject large volumes of insulin, the discomfort of which may lead to poor concordance. In addition the absorption of insulin may be erratic. U500 Human Actrapid is available on 'named patient' basis directly from the manufacturer, and has been used in insulin-treated diabetic patients who are severely insulin resistant.

Materials and Methods: We undertook retrospective case record review of 81 patients who had received U500 Human Actrapid and looked at ethnic background, changes in weight, amount of insulin injected, HbA1c, lipid profile and blood pressure. These were analysed in pre group (parameters before initiation of U500 insulin) and post group (latest parameters till February 2007).

Results: Eighty-one patients received U500 Human Actrapid (73 type 2 DM and 8 type 1 DM). U500 insulin used for a mean duration 30±22.6 months (range 1–98months). Sixty one patients were White European, (36 male, 25 female), 17 Asian (11 male, 6 female) and 3 patients Afro-Caribbean (2 female, 1 male). Twenty-five patients were also receiving metformin, 5 were receiving a thiazolidinedione, 2 on combination of metformin and thiazolidinedione, and 2 were on a combination of metformin and acarbose. The mean insulin dose was 311.3±111.5 vs. 368.4±179.9 units/day. The mean HbA1c improved from 10.0±1.8% to 8.9±2.0% ($p<0.0001$). However, the number of patients achieving an HbA1c <7.5% increased from 5.1% (4 patients) to 27.5% (23 patients), $p<0.0001$. Similarly more patients achieved a target HbA1c <7%: 0% vs. 22.5% (18 patients), $p<0.0001$. Patients who were on U500 insulin for a longer period (>36 months) showed a greater reduction in HbA1c compared to those who had taken U500 insulin for a shorter period (<36 months): 1.8%±1.5% vs. 0.99%±1.8%, $p<0.05$. There was also a reduction in Total Cholesterol (4.9±1.4 vs 4.3±1.0mmol/l, $p<0.0001$) and Triglycerides (4.3±4.5 vs. 3.0±3.0mmol/l, $p<0.001$). However, there was no significant change in the systolic blood pressure (139.9±20.7 vs. 137.3±21.8), diastolic blood pressure (76±14.5 vs. 74±12.2), LDL -cholesterol (2.7±1.3 vs. 2.3±1.0mmol/l) and HDL-cholesterol (0.9±0.3 vs. 1.0±0.3mmol/l). There was significant weight gain: 116.2kg±27.1 kg vs. 121.3kg±29.3kg ($p<0.001$). Two patients received U500 Human Actrapid via an insulin pump. 11 patients have died (4 from sepsis, 3 from myocardial infarction, 1 due to opiate overdose, 1 from an acute exacerbation of COPD, 1 from post operative pneumonia & 1 cause of death was unknown). U500 insulin was discontinued in 14 patients (6 due to improved glycaemic control, 1 following bariatric surgery, 2 at patient's requests, 2 due to poor compliance and 3 due to unclear reasons).

Conclusion: Long-term glycaemic control improved with the use of U500 Human Actrapid in all ethnic groups ($p<0.05$). There was also an improvement in lipid parameters, but most patients were on a statin. However, there was associated increased weight gain and patients were taking larger insulin doses. U500 Human Actrapid is a valuable treatment option in insulin-treated diabetic patients who are severely insulin resistant.

Self-association of insulin glulisine in solution – results of a comparative circular dichroism study

R. H. A. Becker¹, A. Wollmer², G. Seipke¹;

¹sanofi-aventis, Frankfurt, Germany,

²Biochemistry, RWTH Aachen University, Germany.

Background and Aims: Pure monomeric insulin analogues are vulnerable to denaturation and require zinc for shelf-life stability. This promotes self-association that compromises the gain in rapid absorption, compared with regular human insulin. This study compared the association state of insulin glulisine in pharmaceutical solutions with insulin aspart and insulin lispro using Circular Dichroism (CD) spectroscopy.

Materials and Methods: Pure insulin glulisine, insulin aspart, insulin lispro and wild-type human insulin were dissolved in 25 mmol/L Tris/HCl buffer, pH 7.8 with or without phenol (10 mol/monomer), with or without ZnCl₂ (0.4 mol/monomer) and thus included insulin solutions that simulated the 'marketed' formulations (SMF) of insulin lispro, insulin aspart and wild-type insulin (all with added zinc) and insulin glulisine (zinc-free). The association state of each insulin at concentrations of 0.02–1.00 g/L was assessed by CD spectroscopy as mean residue weight ellipticity at 275 nm, which reflects the quaternary structure of insulin complexes in solution.

Results: In the absence of zinc with or without phenol (Figure), insulin lispro and insulin aspart remained mainly monomeric whereas insulin glulisine (SMF) and, to a greater extent, wild-type insulin assemble as dimers and/or higher-order aggregates at increasing concentrations. In the presence of ZnCl₂, both insulin lispro and insulin aspart, to a greater extent insulin glulisine and, above all, wild-type insulin formed higher-order aggregates. The addition of phenol further promotes formation of higher-order aggregates of all insulins (SMF), except insulin glulisine.

Conclusions: The results show that pure insulin glulisine is less dissociated than pure insulin lispro and insulin aspart in solution, while showing less higher-order aggregates when compared with insulin lispro and insulin aspart formulated with zinc and phenol (Figure). This may help to explain why insulin glulisine without zinc meets the stability criteria for a viable product, while concomitantly presenting with a more rapid early deployment compared with other monomeric insulin products.

Insulin glulisine improves postprandial metabolism and microvascular blood flow compared with regular human insulin in type 2 diabetic patients

C. Hohberg¹, M. Larbig², A. Pfützner¹, B. Jenke¹, C. Hartmann¹, M. Weber³, T. Forst^{1,3};

¹Institute for Clinical Research and Development, Mainz,

²sanofi-aventis Deutschland GmbH, Berlin,

³Johannes Gutenberg University, Mainz, Germany.

Background and Aims: Increasing attention is being directed on the causal association between the postprandial state and the development of micro- and macrovascular complications. Several studies have demonstrated associations between postprandial metabolism, endothelial function and microvascular blood flow. The aim of our study was to compare the effect of insulin glulisine with regular human insulin on postprandial metabolism and microvascular function in patients with type 2 diabetes (T2DM).

Materials and Methods: Fifteen T2DM patients treated with oral antidiabetic drugs (9 male, 6 female; mean±SD age 57.9±8.2 years; HbA_{1c} 7.1±0.5%; duration of diabetes 11.2±10.9 years) received insulin glulisine immediately

prior or regular human insulin 15 minutes before consuming a standardised liquid meal (Ensure Plus[®], 56% carbohydrates, 29% fat, 15% proteins) in a randomised sequence on two different study days. At baseline and after 30, 60, 120, 180, and 240 minutes, blood was taken for the measurement of glucose, insulin, intact proinsulin, asymmetric dimethylarginine (ADMA) and the peroxidative status using enzyme-linked or chemiluminescent immunoassays. In addition, microvascular skin blood flow was measured using laser doppler fluxmetry. Exploratory statistical analyses were conducted to compare insulin glulisine with regular human insulin, with calculation of two-sided 95% confidence intervals for between-group differences.

Results: Insulin glulisine resulted in significantly higher insulin levels for the first 120 minutes following the meal (Table), and glucose levels and intact proinsulin were significantly lower over the entire 240-minute postprandial observation time compared with regular human insulin. A suppression of ADMA levels by $-15 \pm 6\%$ (mean \pm SEM; $p=0.02$) was observed during insulin glulisine treatment, while regular human insulin was associated with a non-significant (n.s.) increase of $14 \pm 8\%$. In addition, insulin glulisine increased postprandial microvascular blood flow by $38.2 \pm 21.9\%$ ($p=0.008$), whereas no change was observed with regular human insulin. The peroxidative status remained unchanged with both insulins.

Conclusion: Prandial treatment with insulin glulisine resulted in improved postprandial metabolic control including suppression of postprandial intact proinsulin secretion. In addition, treatment with insulin glulisine reduced postprandial endothelial stress and improves microvascular blood flow compared with regular human insulin.

	Insulin glulisine	Regular human insulin	p value
AUC-Insulin ₀₋₁₂₀ min (mU/L)	51.0 \pm 6.8	38.2 \pm 5.4	0.004
AUC-Glucose ₀₋₂₄₀ min (mg/dL)	158 \pm 8.8	180 \pm 8.9	0.03
AUC-Proinsulin ₀₋₂₄₀ min (pmol/L)	26.2 \pm 3.5	31.1 \pm 4.3	0.002

The use of rapid-acting insulin analogue as the baseline infusion during glucose clamping improves pharmacokinetic evaluation

J. Cassidy¹, R. Baughman¹, G. Tonelli¹, A. Boss¹, B. Hernandez², S. Schwartz²;

¹MannKind Corporation, Danbury, ²Clinical Research, Diabetes & Glandular Disease Clinic, San Antonio, United States.

Background and Aims: In the glucose clamp technique, a glucose infusion maintains concentrations within a target range and an i.v. insulin infusion is used to suppress endogenous insulin secretion and/or provide basal insulin. However, separating endogenous from exogenously administered regular human insulin remains problematic. A potential solution uses lispro insulin (lispro) as the insulin infusate. An insulin analog-specific assay enables the independent quantification of the infused lispro (Lispro Insulin RIA Kit, Linco) and regular human insulin (E170 RHI Assay, Roche Diagnostics).

Materials and Methods: This procedure was used in a euglycemic clamp study evaluating a pulmonary regular human insulin formulation (PI) in type 1 diabetes mellitus. Subjects received an i.v. insulin infusion to establish glucose concentrations of 90–110 mg/dL.

Results: The insulin infusion rate was fixed 1 hour before dosing with PI at $t=0$, and remained constant thereafter. Regular human insulin concentrations from PI dosing were established by 3 methods (see figure): 1) lispro infusate (circle, no correction); 2) regular human insulin infusion, corrected by subtracting the $t=0$ value from all values (triangle); or 3) regular human insulin infusion, corrected by subtracting the mean of the 240–360 minute values from the preceding data (square). A fixed insulin infusion can still generate $t=0$ insulin concentrations that are higher (see figure) or lower than the end-of-study values (240–360 min), and using either correction method will generate erroneous kinetics.

Conclusion: The data demonstrate that the use of lispro as the insulin infusate allows for direct regular human insulin determination and reduces data variability. This modified procedure can also be used to suppress endogenous insulin in type 2 diabetes mellitus, avoiding the commonly used

discontinuation of the baseline insulin infusion at dosing, a situation that often generates regular human insulin concentrations <0 when normalized.

Comparing within-patient blood glucose variability in analog vs human insulin self-prepared mixture regimens (insulin lispro + insulin lispro protamine suspension vs regular human insulin + NPH)

S. D. Beattie, L. N. Kerr, S. J. Jacober, C. A. Jones, M. H. Tan; Eli Lilly and Company, Indianapolis, United States.

Background and Aims: Day-to-day variability in glucose response to the same subcutaneously delivered insulin dose can challenge insulin-requiring diabetes patients (pts). This analysis examined intra-subject variability (ISV) of mean BG values in a clinical trial, rather than PK/PD, setting.

Materials and Methods: These post-hoc analyses were conducted on data from a published, randomized 12-month, open-label, 2-arm parallel study of 166 pts with type 1 or 2 diabetes mellitus (102 T1DM, 64 T2DM). In that study, after a 2–4 wk lead-in with self-mixed regular human insulin+NPH [RI+NPH] before breakfast and dinner, pts were randomised to insulin lispro+insulin lispro protamine suspension [LP+ILPS] or RI+NPH bid for 12 mos; insulins were titrated to achieve premeal BG ≤ 7.8 mM and postprandial (pp) BG ≤ 10 mM. At 3 mos, investigators could intensify treatment if needed. In the post-hoc analyses, ISV was defined as day-to-day BG variability within pts at different time points during the day or across different time points during the day among 3 reading days. To compare variances between treatments in the ISV analyses at different time points during the day, a likelihood ratio (LR) test was based on an analysis of variance (ANOVA) model for BG values incorporating fixed effects for treatment and random effects for pts within treatment and measurements within pts. To compare variances between treatments in the ISV analyses across different time points during the day, a LR test was based on an ANOVA model for BG values incorporating fixed

	LP+ILPS (mM) Endpoint SD N=85	RI+NPH (mM) Endpoint SD N=80	P-value (LR test)
Intra-subject variability (among 3 BG reading days)			
8-pt BG Profile Time Points: *			
Pre-breakfast (FBG)	2.67	3.17	0.03
2-h post-breakfast BG	3.19	3.78	0.03
Pre-lunch BG	2.40	3.11	0.001
2-h post-lunch BG	3.31	3.55	0.38
Pre-dinner BG	3.28	3.51	0.39
2-h post-dinner BG	2.91	3.62	0.007
Bedtime BG	3.07	3.28	0.41
3 AM BG	3.08	2.91	0.50
All Pre-meal BG [†]	2.80	3.29	<0.001
All Post-meal BG [†]	3.16	3.57	0.03
Overall BG [‡]	3.00	3.25	0.02

*3 measurements per subject contributed to the analysis

[†]9 measurements per subject contributed to the analysis

[‡]24 measurements per subject contributed to the analysis

effects for treatment, time points, and their interaction and random effects for pts within treatments, time-by-patient interaction, measurements across days within pts, and measurements across times within days.

Results: From the published results, at endpoint the analog insulins group showed lower HbA_{1c} (7.5±0.1 vs. 7.9±0.1%, $p=0.02$), lower BG levels 2-h post-breakfast and post-dinner, pre-dinner, and at bedtime, and no difference in FBG (8.4 vs. 8.5 mM) or hypoglycemia rate (1.1 vs. 1.1 episodes/pt/30 days) vs the human insulins group. Additionally, 16% of the LP+ILPS group and 6% of the RI+NPH group intensified treatment at 3 mos. The present post-hoc analyses demonstrated the analog insulins resulted in lower BG ISV pre-breakfast, 2-h post-breakfast, pre-lunch, and 2-h post-dinner and lower all pre-meal, all post-meal, and overall BG ISV (table 1).

Conclusions: Analog insulin regimens (lispro+IPLS) provided better HbA_{1c} control than human insulins (RI+NPH) with lower pp BG and no difference in FBG or hypoglycemia rate. BG ISV was also lower with the analog insulins (including all pre-meal and all post-meal BG), however the relative contributions of lispro and IPLS to lower ISV could not be identified.

Clear differentiations in onset and duration of action are shown with different premixed ratios of biphasic insulin aspart (BIAsp)

U. Eckers¹, T. Heise¹, K. Kancz², J. N. Nielsen², L. Nosek¹;

¹Profil Institut für Stoffwechselforschung, Neuss, Germany,

²Novo Nordisk A/S, Bagsvaerd, Denmark.

Background and Aims: Most diabetes mellitus patients can achieve good glycaemic control using once-, twice- or three times daily biphasic insulin aspart (BIAsp 30), but some may benefit from a higher proportion of fast-acting insulin aspart to reduce prandial glucose levels. We investigated the time-action profiles of different premixed ratios of 0.4 U/kg BIAsp (BIAsp 30, 50 and 70; containing 30%, 50% and 70% insulin aspart [IAsp], respectively) and IAsp in people with type 1 diabetes.

Materials and Methods: This was a randomised, single-centre, four-period crossover trial comprising 32 type 1 diabetes patients (11 female, 21 male); mean (± SD) age 37±8 years; HbA_{1c} 7.6±0.7; BMI 25±3 kg/m². Each patient took part in four glucose clamp experiments, one for each insulin (clamp level 5 mmol/l, with a clamp duration of 28 h [12h for IAsp]). Each experiment was 7–14 days apart.

Results: Higher 'early' metabolic activity (area under the glucose infusion rate curve from 0–6h [AUC_{GIR}, 0–6h]) correlated with a higher percentage of soluble IAsp (BIAsp 30: 1155, BIAsp 50: 1448, BIAsp 70: 1718, IAsp: 1968 mg/kg; $p<0.01$ for each neighbouring ratio comparison). A higher proportion of soluble IAsp also correlated with a faster onset of action. Protaminated IAsp was inversely correlated to the lower 'late' metabolic activity (AUC_{GIR}, 12–28h: BIAsp 30: 159, BIAsp 50: 84, BIAsp 70: 18 mg/kg; $p<0.05$ for each neighbouring ratio comparison). Peak metabolic activity, inferred from maximum glucose infusion rate GIR_{max}, increased linearly with higher ratio of soluble IAsp (BIAsp 30: 4.7, BIAsp 50: 6.0, BIAsp 70: 7.1, IAsp: 8.9 mg/kg/min; $p<0.01$ between insulin ratios) (Figure), although

** $p<0.01$; *** $p<0.001$; † $p<0.05$ (excluding IAsp)

Fig. 1

time to GIR_{max} was comparable between formulations. The duration of action (time until blood glucose exceeded 8.9 mmol/l) decreased as the proportion of soluble IAsp increased (70.2 vs. 57.4 vs. 55.4 vs. 35.2 min, respectively; between-treatment differences for each neighbouring ratio comparison: $p<0.05$). Pharmacokinetic endpoints supported the pharmacodynamic data; higher early IAsp levels (AUC_{IAsp} 0–6h) correlated with increasing proportion of IAsp, and significant differences were observed between the preparations ($p<0.001$). Late levels decreased with increasing soluble IAsp. Maximum serum IAsp concentrations (C_{max}) were higher in formulations with a higher proportion of IAsp (BIAsp 30: 67, BIAsp 50: 98, BIAsp 70: 152, IAsp: 212 mU/l), though time to C_{max} was not notably different.

Conclusion: Supporting previous research, greater early-phase metabolic effects and a shorter duration of action were shown with increasing ratios of rapid-acting IAsp in BIAsp preparations. A longer metabolic effect was observed with an increased proportion of protaminated IAsp. The differences in action profile between BIAsp preparations should help physicians to optimise insulin therapy according to individual patients' needs. (Fig. 1)

The modest weight gain observed in the Belgian and French ADAPT™ Study correlates with the mealtime bolus insulin dose but not with the basal insulin detemir

J.-P. Le Floch¹, M. Lévy², H. Mosnier-Pudar³, R. Mira⁴, F. Nobels⁵,

S. Laroche⁶, S. Gombert⁶, E. Eschwege⁷, P. Fontaine⁸;

Aaslt, Belgium, ⁶Novo Nordisk, La Defense Puteaux, France,

⁷U780, INSERM, Villejuif, France, ⁸Diabetology Dept, clinique Marc

Linquette, Lille, France.

Background and Aims: Treatment guidelines emphasise the importance of achieving HbA_{1c} targets using intensified insulin therapy in type 1 diabetes. However, this type of treatment can result in weight gain. This study is based on data from a French and Belgian multicentre randomised, parallel-group study (ADAPT™) comparing once- with twice-daily insulin detemir, and using insulin aspart before meals, in type 1 diabetic patients over a 7 month period (including 1-month run-in). These analyses aimed to investigate possible reasons of weight gain for these patients

Materials and Methods: The study was completed by 457 out of 520 randomised patients. Completers comprised men 52% aged (mean ±SD) 42 ±13 years, with a diabetes duration of 17±11 years, 42% with degenerative complications. Weight change was analysed as a quantitative and qualitative value. Factors associated with weight change were screened using linear regression, ANOVA and chi-square tests. Multivariate analyses were performed using multiple linear regression and logistic regression models.

Results: End-of-study HbA_{1c} was 7.9±1.0% (an improvement of 0.6±0.8%) and the BMI was 25.6±4.1 kg/m². Over 6 months, weight increased by 1.1±3.1 kg and BMI increased by 0.4±1.1 kg/m², with 55% of patients gaining weight. Similar results were shown in the patient subgroups receiving once- or twice-daily detemir injections (1.0±3.0 versus 1.1±3.2 kg, 0.4±1.1 versus 0.4±1.1 kg/m², respectively, NS). The weight gain was significantly associated with the absence of diabetes complications (1.9±0.3 versus 1.0±0.3; $p<0.05$), the improvement in HbA_{1c} ($r=0.22$; $p<0.001$), the aspart dose ($r=0.13$; $p<0.01$) and the total insulin dose ($r=0.10$; $p<0.05$), but not with the frequency of hypoglycaemia or with the detemir dose. The multivariate analyses showed that the improvement in HbA_{1c} and the aspart dose were explanatory factors for weight gain (multiple regression: $R^2=0.08$; logistic: $R^2=0.02$; $p<0.001$). Similar results were found with BMI.

Conclusion: These exploratory analyses suggest that the modest weight gain observed in patients treated with a basal-bolus detemir plus aspart insulin regimen can be attributed to the meal time short-acting insulin dose and not to the detemir dose. These analyses did not show evidence of a relationship between weight change and hypoglycaemia.

0965

Contribution of fasting and postprandial hyperglycaemia to haemoglobin A_{1c} levels in insulin-treated patients

H. Shimizu, S. Oh-I, Y. Ariyama, T. Tsuchiya, Y. Uehara, S. Okada, M. Mori; Department of Medicine and Molecular Science, Gunma University Graduate School of Medicine, Maebashi, Japan.

Background and Aims: The relative contribution of postprandial glucose decreased progressively from the lowest to the highest quintile of haemoglobin HbA_{1c}, whereas the relative contribution of fasting glucose increased gradually with increasing levels of HbA_{1c} in non-insulin- and non-carbonyl-treated diabetic subjects. However, the exact contribution of fasting and postprandial glucose concentrations to HbA_{1c} levels remains unclear in insulin-treated patients.

Materials and Methods: Fifty seven insulin-treated, outcoming diabetic patients were included in the present study. We analysed the diurnal glycaemic profiles of diabetic patients conventionally (twice a day; b.i.d., n=24) or intensively treated (basal-bolus; n=33) with insulin. Over 10 % of insulin dose was not changed for at least 8 weeks before the start of the study. Their fasting and postprandial glucose concentrations were determined at home by themselves with glucose self-monitoring apparatus. HbA_{1c} levels were measured by HPLC method on the visit to our hospital. Correlation of HbA_{1c} levels to self monitored blood glucose levels at home were calculated in each measuring point.

Results: The average of HbA_{1c} levels in all subjects included was 7.83 %. In conventionally treated group (b.i.d.), there was a significant correlation between HbA_{1c} levels and fasting glucose levels only before lunch (L), but at 2 hr after all meals (B-PP, L-PP, D-PP). In intensively treated group (basal-bolus), a significant correlation between HbA_{1c} levels and fasting glucose levels was found before breakfast (B), lunch (L) and at 2 hr after breakfast (B-PP) and dinner (D-PP). When we analysed all subjects together, there was no significant correlation between HbA_{1c} levels and fasting glucose levels before breakfast (B) or dinner (D), while only fasting glucose level before lunch (L) was significantly correlated with HbA_{1c} levels. In contrast, postprandial glucose levels were significantly correlated with HbA_{1c} levels in all measuring points (B-PP, L-PP, D-PP). The correlation was highest at 2 hr after breakfast and dinner (B-PP, D-PP). The sum of fasting and postprandial glucose levels was also significantly correlated with HbA_{1c} levels ($\gamma=0.626$, $p<0.001$).

Conclusion: These data indicate that postprandial blood glucose levels are more important determinants of HbA_{1c} levels than fasting glucose levels in insulin-treated patients. It is concluded that postprandial hyperglycaemia after breakfast and dinner should be important to more improve HbA_{1c} levels in insulin treated diabetic patients.

Influence of treatment with insulin analogs on pancreatic reserve one year after type 1 diabetes diagnosis

M. Ferrer-Camps, M. Perez-Maraver, J. Caballero-Corchuelo, S. Martin-Grillo, A. Boltaña-Lorenzo, R. Insa-Soria, E. Montanya-Mias, J. Soler Ramon; Endocrinology, HU Bellvitge, Hospitalet Llobregat, Barcelona, Spain.

Background and Aims: At the diagnosis of type 1 diabetes there is a remanent pancreatic reserve with beneficial metabolic effects that tends to decline progressively. Insulin analogs have been used for ten years and they have pharmacokinetic advantages with respect to human insulins. However

it is not known whether they have a beneficial effect on the evolution of pancreatic reserve at the beginning of type 1 diabetes. The aim was to compare the evolution of pancreatic reserve during the first year from type 1 diabetes diagnosis between patients treated with insulin analogs and those with a human insulin regimen.

Materials and Methods: Our study was a retrospective analysis. Every patient discharged from our Endocrinology Unit with a diagnosis of new-onset type 1a diabetes mellitus in the period 2002–2005 were included (n=78). Those diagnosed in 2002–2003 (n=41) were treated with an intensive human insulin protocol (regular and NPH, group 1). Patients diagnosed in 2004–2005 (n=37) were treated with an intensive insulin analogs therapy (aspart and glargine, group 2). At the beginning the following variables were analysed: age, gender, BMI, biochemical and clinical situation, HbA_{1c}, insulin dose at discharge as well as basal and stimulated C-peptide (glucagon test). During the follow-up (at six and twelve months) evolution of weight, insuline dose, HbA_{1c} and C-peptide were also evaluated. Both groups were compared with parametric tests. Statistical significance was defined as $p<0,05$.

Results: At the initial point both groups were comparable in terms of clinical and biochemical parameters. Initial basal and stimulated C-peptide in both groups were also comparable (basal: $0,23\pm0,18$ vs. $0,18\pm0,17$ nmol/l; stimulated $0,38\pm0,26$ vs. $0,32\pm0,28$ nmol/l, groups 1 and 2 respectively). Nine and six patients were lost of follow-up (group 1 and 2 respectively). At the end of the study groups were comparable in terms of BMI, HbA_{1c} ($5,6\% \pm 1,2$ vs. $6,1\% \pm 2,4$, groups 1 and 2 respectively) and insuline dose ($0,40\pm0,18$ UI/kg versus $0,42\pm0,15$ UI/kg, groups 1 and 2 respectively). Basal and stimulated C-peptide was statistically different between groups, with a better evolution in group 2 (basal: $0,18\pm0,15$ vs. $0,31\pm0,27$ nmol/l; stimulated $0,32\pm0,28$ vs. $0,51\pm0,44$ nmol/l; groups 1 and 2 respectively, $p<0,05$).

Conclusion: our results suggest that, in type 1 diabetes, treatment with insulin analogs from the diagnosis could be beneficial for the evolution of pancreatic reserve compared with traditional human insulin therapy.

PS 94 Novel insulins

Effectiveness of oral insulin delivery by means of solid lipid nanoparticles

B. Sarmento, S. Martins, A. Silva, D. Santos, E. Souto, D. Ferreira;
Department of Pharmaceutical Technology, Faculty of Pharmacy,
University of Porto, Portugal.

Background and Aims: The aim of this work was to produce and characterise cetyl palmitate-based solid lipid nanoparticles (SLN) containing insulin, and to evaluate the potential of these colloidal carriers for oral insulin administration. The new carrier is composed of a lipid core aimed to protect and to control the release of insulin.

Materials and Methods: SLN were prepared by a modified solvent emulsification-evaporation method based on a w/o/w double emulsion. The particle size, zeta potential and association efficiency of unloaded and insulin-loaded SLN were determined by photon correlation spectroscopy, laser doppler anemometry and HPLC, respectively. Insulin pharmacological activity was determined in diabetic rats in accordance with the FELASA and the European Union (Council Directive 86/609/EEC). Plasma glucose levels were plotted against time to evaluate the cumulative hypoglycemic effect over time after insulin administration.

Results: The attempts to develop an insulin-loaded SLN formulation for oral administration produced nanoparticles with spherical shape showed and homogenous size distribution of 361 ± 30 nm and slight negative zeta potential values. The microscopic appearance and the structural characterization of cetyl palmitate based SLN showed that these particles exhibited a spherical shape and a dense lipid matrix. The association efficiency of insulin in was around 45%, and is noteworthy that being a hydrophilic molecule a much lower association efficiency of insulin within the lipid matrix of SLN was expected. Nonetheless, the modified w/o/w double emulsion method was shown to be a suitable production procedure to achieve relatively high loading for insulin. Insulin-loaded SLN decreased glycemia by comparison with rats treated with oral insulin solution and empty nanoparticles. This hypoglycaemic effect was observed to occur in a biphasic way, with an initial peak between 4 and 8 h with a decrease of 25% of the initial glucose level and later after 12 h of assay prolonged for up to 24 h. This may be related with the typical biphasic drug release pattern with an initial burst and prolonged release from SLN, characterised by a microcrystal matrix structure. Such biphasic pattern can originate an immediate release of insulin but also retain a significant fraction of the drug entrapped into the lipid matrix during prolonged time. The solid matrix of SLN was able to partially protect insulin against chemical degradation in the gastrointestinal tract and to promote the intestinal absorption of insulin.

Conclusion: In conclusion, SLN were found to be suitable carrier systems for the administration of insulin through the oral route. This study may contribute for the development of an optimized oral insulin formulation.

Sustained weight reduction and improved glycemic control with inhaled Technosphere®/insulin

N. Tu, D. Kramer, R. Baughman;
MannKind Corporation, Danbury, United States.

Background and Aims: Improved glycemic control with insulin treatment is generally associated with weight gain. Two open-label randomised trials were conducted to compare the effect of inhaled Technosphere®/Insulin (T/I) with that of subcutaneous insulin aspart on glycemic control and weight.

Materials and Methods: Diabetic patients receiving glargine as basal insulin were randomised to receive T/I or aspart, with glargine as basal insulin in two separate trials: a 12-week study of 110 patients with type 1 diabetes and a 24-week study with a 22-week follow-up period of 309 patients with type 2 diabetes.

Results: Type 1 diabetic patients receiving T/I experienced a mean weight loss of 0.45 kg over 12 weeks versus a mean gain of 0.80 kg in the aspart group ($P=0.017$). In the 24-week treatment period, type 2 diabetic patients receiving T/I experienced a weight loss of 0.78 kg ($P=0.016$) compared with

a mean gain of 0.23 kg in the aspart group. When type 1 and type 2 patients were combined for analysis, the T/I patients experienced a mean loss of 0.69 kg ($P=0.001$) at Week 12. Type 2 diabetic patients who participated in the 22-week follow-up resumed conventional therapy. Patients initially randomised to receive aspart had a mean weight gain of 0.81 kg during follow-up. Patients originally in the T/I group similarly gained a mean 0.74 kg following resumption of conventional therapy ($P=0.8125$). In addition to treatment, baseline BMI, categorised into three groups (<27 , $27-29$, >29), was found to be a significant factor in weight change at 24 weeks (weight gain, no weight gain) based on multivariate logistics regression model for subjects with type 2 diabetes. Subjects with BMI $27-29$ are 3.09 (95% CI: 1.285–7.420) times more likely to have weight loss or no weight gain than those with BMI <27 .

Conclusion: T/I and aspart produced similar improvement in glycemic control as prandial insulin together with a basal insulin. There was a weight increase in the group receiving aspart, while there was no increase in weight during T/I treatment; when returning to conventional therapy, these patients gained weight. We conclude that in contrast to aspart, T/I offers the advantage of similar glycemic control without associated weight gain.

Pharmacokinetic/glucodynamic effects and safety of AIR® inhaled insulin in asthmatic subjects

M. Wolzt¹, A. de la Peña², F. Tibaldi³, P. Berclaz², D. Muchmore²;
¹Dept of Clinical Pharmacology, Medical University of Vienna, Austria,
²Eli Lilly and Co., Indianapolis, United States,
³Eli Lilly and Co., Mont-Saint-Guibert, Belgium,

Background and Aims: Pharmacokinetic (PK) and glucodynamic (GD) response to AIR® inhaled insulin (Lilly/Alkermes inhaled insulin system), relative to subcutaneous insulin lispro, has not yet been evaluated in asthmatic patients.

Materials and Methods: Non-smoking, non-diabetic healthy (n=13), mild persistent asthmatic (n=13), and moderate asthmatic (n=13) subjects (age 19–58 yrs) participated in this phase I, open-label, cross-over study. Subjects received either 12U-equivalent of AIR Insulin (replicate treatments), or 12U of SC insulin lispro, or salbutamol pretreatment + 12U-equivalent of AIR Insulin (moderate asthma group only), prior to undergoing up to 4 euglycemic glucose clamps.

Results:

	Healthy		Mild Asthma		Moderate Asthma		
	AIR®	SC lispro	AIR®	SC lispro	AIR®	SC lispro	AIR® + Salbutamol
Pharmacokinetic

* Data presented in the table above represent the geometric means (CV%), except for t_{max} and t_{Rmax}, which present median and range of values.

AIR Insulin was rapidly absorbed in all subject groups, comparable with SC insulin lispro. Overall mean AIR Insulin exposure in mild and moderate asthmatic subjects was reduced by approximately 30% and 40% respectively ($p<0.01$) compared to healthy subjects. Overall mean GD response (G_{tot}) in mild asthmatic subjects approximated that of healthy subjects ($p=0.16$), despite lower insulin exposure. In moderate asthmatic subjects, overall GD response was approximately 72% lower ($p<0.01$). In the moderate asthma group, pretreatment with salbutamol resulted in an approximate 50% increase in overall insulin exposure ($p<0.02$) and metabolic response ($p=0.03$), compared to AIR Insulin treatment alone. During the course of the study, there were no deaths, serious adverse events, or clinically significant alterations in laboratory values. No significant treatment-group effects were

noted from either bedside spirometry tests, or from laboratory pulmonary function tests. Adverse reactions related to AIR Insulin were mild to moderate (cough, headache, and dizziness) and have been reported in previous studies or are typical of insulin studies involving glucose clamp procedures. No subject discontinued the study because of an adverse event.

Conclusions: Data from this study suggests that pulmonary disease severity influences the metabolic effect of AIR Insulin in non-diabetic individuals with asthma, but does not affect the profile of AIR Insulin safety and tolerability. Furthermore, these data suggest that patients with diabetes and comorbid moderate asthma may require an increase AIR Insulin dosage, while patients with mild asthma would not likely require dosage adjustment. Pre-treatment with salbutamol increased both the overall exposure to and metabolic response of AIR Insulin.

Sustained long-term efficacy and safety of inhaled human insulin (Exubera[®]) following at least 8 years of continuous therapy

M. R. Burge¹, J. M. Reis², A. S. Krasner², P. F. Schwartz², J. G. Teeter²;
¹Department of Internal Medicine, University of New Mexico School of Medicine, Albuquerque, ²Pfizer Inc, Groton, United States.

Background and Aims: The efficacy and safety of inhaled human insulin (EXU; Exubera[®] (insulin human [rDNA origin]) Inhalation Powder) has been demonstrated previously in controlled clinical trials of up to 2 years duration. The aim of this study was to examine the trends in diabetes control and lung function in a trial of 8 years duration.

Materials and Methods: Continued open-label EXU therapy was offered to patients with diabetes who had completed any of three 3-month randomised controlled Phase 2 clinical trials. A total of 173 adult patients with type 1 (N = 61) or type 2 (N = 112) diabetes were treated with EXU as their exclusive prandial insulin. Concomitant diabetic therapies were not otherwise specified in this study. Fifty-two patients have received at least 8 years of EXU treatment (n = 23, type 1; n = 29, type 2). HbA_{1c} and forced expiratory volume in 1 second (FEV₁) were measured every 3 months.

Results: Mean (± SD) HbA_{1c} was 7.9 ± 1.2% after 8 years compared with 8.5 ± 1.4% at the start of EXU treatment. Overall rates of hypoglycemia decreased from 2.9 episodes/subject-month after 4 weeks of EXU treatment to 1.7 episodes/subject month after 8 years as measured over the final 6 months. Annualised change in forced expiratory volume in 1 second (FEV₁) after 4 years was -0.054 ± 0.004 L/y (N = 88) and -0.049 ± 0.004 L/y, (N = 54) after 8 years of continuous EXU treatment. This annualised change in lung function is similar to that observed in subjects with diabetes who have received comparator therapies as part of controlled clinical trials elsewhere in the EXU development program.

Conclusion: Long-term EXU use is effective in maintaining glycemic control for at least 8 years. Moreover, declines in FEV₁ are stable and predictable after 4 and 8 years of EXU therapy and are similar to those expected in an adult diabetic population.

Effects of inhaled human insulin (Exubera[®]) on postprandial glucose profiles compare favorably to those of glargine in patients with type 2 diabetes

M. Hompesch¹, C. Bowden¹, T. Strack², M. Mitnick², W. Canovatchel², S. Davies², P. Maheux²;

¹Profil Institute for Clinical Research, San Diego, United States,

²Pfizer Inc, New York, United States.

Background and Aims: Interventions aimed at reducing glucose excursions in patients with diabetes are potentially important as failure to do so may increase risk of vascular complications. This exploratory study is the first trial comparing inhaled human insulin (EXU; Exubera[®] [rDNA origin] Inhalation Powder) with glargine as the first insulin added to oral agents (OAs) in patients with inadequately controlled type 2 diabetes.

Materials and Methods: The single-site, 2-arm cross-over, open-label study of 40 patients on 2 OAs (baseline A1c, 7.9%) compared the effects of prandial

EXU to morning basal glargine on 24-hr CGMS. Patients were randomised to receive either treatment for 8 consecutive in-patient days separated by a wash-out phase of 7 to 10 days. The 24-hr CGMS means were calculated for the final 72 hrs of each treatment period.

Results: The 72-hr mean glucose, area under the curve (AUC) for 72-hr glucose, and glucose AUCs (0–4 hrs) around individual meals were significantly lower for EXU than for glargine ($P < 0.0001$ to 0.0318). Standard deviation, mean amplitude of glycemic excursions, and mean of daily differences in glucose concentration over 72 hrs were lower for EXU but did not reach statistical significance. Glucose AUC from midnight to 6 AM was similar between EXU and glargine (Figure). Hypoglycemia was the most frequent adverse event (EXU, 28; glargine, 13), but no events were rated severe.

Conclusions: In addition to lowering postprandial glucose, EXU achieved midnight-to-6-AM glucose concentrations similar to glargine. In managing both postprandial and overnight glucose, prandial EXU may be an attractive alternative to basal insulin for patients with type 2 diabetes inadequately controlled on OAs.

Discontinuation and readministration of inhaled human insulin (Exubera[®]) in adults with type 1 diabetes: 3-year pulmonary safety data

J. Skyler¹, P. Hollander², L. Jovanovic³, S. Klioze⁴, A. Krasner⁴, R. Riese⁴, J. Reis⁴, P. Schwartz⁴;

¹Division of Endocrinology, Diabetes & Metabolism, University of Miami Miller School of Medicine, Miami,

²Baylor Endocrine Center, Baylor University Medical Center, Dallas,

³Division of Diabetes, Sansum Diabetes Research Institute, Santa Barbara,

⁴Pfizer Inc, New London, CT, United States.

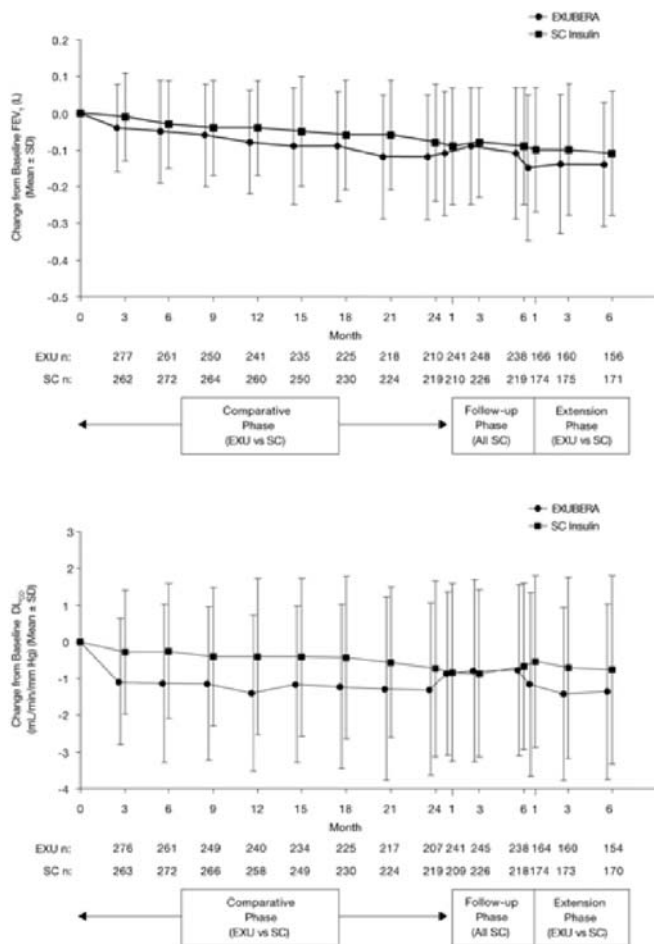

Background and Aims: Clinical trials in patients with type 1 diabetes have demonstrated that Exubera[®] (insulin human [rDNA origin]) Inhalation Powder (EXU) is as effective as subcutaneous (SC) regular insulin and well tolerated when administered for up to 2 years. This interim analysis assessed pulmonary safety following discontinuation and readministration of EXU therapy in adults with type 1 diabetes.

Materials and Methods: Adults with type 1 diabetes (18–65 years) received SC insulin for 4 weeks and were then randomised and received either premeal EXU (n = 290) or a short-acting SC insulin (n = 290), plus NPH insulin or Ultralente[®] once or twice daily, or insulin glargine once daily (comparative phase) for 2 years, followed by 6 months when all patients received SC insulin (follow-up phase) and a 6-month extension phase during which all patients received their original randomised therapy. Comprehensive lung function tests were performed.

Results: Small, nonprogressive treatment group differences favouring SC insulin in change from baseline forced expiratory volume in 1 second (FEV₁) (1% of baseline) and carbon monoxide diffusing capacity (DL_{CO}) (1.5% of baseline) (Figure 1) occurred early during the comparative phase, and were not driven by outliers. These differences completely resolved upon discontinuation of EXU, and recurred by the same magnitude during the

extension phase. Both treatment groups maintained glycaemic control, and hypoglycaemic event rates were similar. Increased median insulin antibody levels were detected in the EXU group within a few weeks of commencing therapy, peaking at 12 months before decreasing somewhat during the remainder of the initial comparative phase. During the follow-up phase when EXU was discontinued, median insulin antibody levels declined to near baseline levels. When EXU therapy was resumed during the extension phase, median insulin antibody levels again increased to levels similar to those observed in the original comparative phase. In patients receiving SC insulin, insulin antibody levels remained stable.

Conclusions: FEV₁ and DL_{CO} changes observed during discontinuation and readministration of EXU therapy are consistent with a reversible, non-progressive and non-pathologic effect on lung function in adults with type 1 diabetes. EXU readministration is not associated with an augmented insulin antibody response.

Insulin antibody responses to 2 years of inhaled human insulin (Exubera®) followed by discontinuation and readministration after 6 months

S. E. Fineberg^{1,2}, D. Finco-Kent³, T. T. Kawabata³, P. F. Schwartz², J. G. Teeter³, A. S. Krasner³;

¹Medicine, Indiana University School of Medicine, Indianapolis,

²School of Medicine, University of Alabama Birmingham,

³Pfizer, Groton, United States.

Background and Aims: Inhaled human insulin therapy (EXU; Exubera® (insulin human [rDNA origin]) Inhalation Powder) has been shown to be more immunogenic than subcutaneous (SC) comparator insulins in patients with type 1 diabetes and in insulin-using patients with type 2 diabetes. Previous studies have raised concerns that discontinuation and reinstatement of SC insulin therapy after EXU treatment might lead to enhanced immunologic responses with undesirable clinical effects.

Materials and Methods: In open-label trials lasting up to 24 months, patients with type 1 diabetes (aged 18–65 years) received EXU (n = 290) or SC human insulin (n = 290), and patients with type 2 diabetes received EXU (n = 316) or SC (n = 311). Following 24 months of therapy, EXU was discontinued (and replaced with SC) for 6 months, then the original therapy was resumed for an additional 6 months. Throughout, insulin antibody (IAb) responses were assessed using a quantitative assay (reported in µU/mL); pulmonary function was assessed by standardised measures of forced expiratory volume in 1 second (FEV₁ [L]) and carbon monoxide diffusing capacity (DL_{CO} [mL/min/mmHg]); and clinical outcomes, including hypoglycemic events, insulin dose, glycemic control, and evidence for immunological sequelae, were monitored periodically.

Results: No significant correlations with IAb response could be shown with changes in pulmonary function, insulin dose, hypoglycemic events, or glycemic control. Antibody levels in the EXU group increased initially, decreased from 12 months, then decreased further by 6 months from discontinuation (Table). An exaggerated anamnestic response was not seen after EXU resumption. Antibody levels upon readministration did not correlate with changes in glycemic control. Samples with the highest IAb levels were found to consist predominantly of IgG for both EXU- and SC-insulin-treated patients. A small mean treatment group difference in change from baseline FEV₁ was apparent after the first 3 months of EXU treatment, remained stable throughout the remainder of the initial 24-month comparative phase, resolved upon discontinuation, and recurred to the same magnitude upon readministration of EXU.

Conclusions: Immunologic safety was demonstrated with long-term EXU therapy, discontinuation and readministration. There did not appear to be any impact on safety parameters as a result of IAbs. (Tab. 1)

Significant predictors of preference for inhaled versus injectable insulin in patients with type 2 diabetesR. P. Hayes¹, T. E. Stump¹, D. B. Muchmore¹, J. Schmitke²;¹Eli Lilly and Company, Indianapolis,²Product Dev., Alkermes, Inc., Cambridge, United States.

Background and Aims: As new insulin therapy options become available for the patient with type 1 diabetes (T1D), information from the patient perspective may assist clinicians and their patients in treatment decision-making. The aim of this study was to determine patient factors that contribute to preference for inhaled insulin in patients with T1D.

Materials and Methods: This randomised, open-label, crossover trial (12 weeks each sequence) compared glycaemic control (A1C) of mealtime human insulin inhalation powder (HIIP) with mealtime injectable (SC) in patients with T1D. At a screening visit prior to lead-in (week -6), crossover (week 12), and endpoint (week 24), patient reported outcomes (PROs) were assessed using the SF-36 Vitality Scale; Cognitive Distress, Fatigue, Hyperglycemia, and Hypoglycemia Subscales of the Diabetes Symptom Checklist-Revised; and the Insulin Delivery System Questionnaire. A1C was assessed at randomisation (week 0), crossover, and endpoint. Preference for mealtime insulin delivery system (inhaled or injectable) was assessed at endpoint. A logistic regression model was developed with preference as the dependent variable, and PROs and clinical variables after treatment with inhaled insulin that were significantly ($p < 0.05$) associated with preference as independent variables. Baseline variables that differed significantly ($p < 0.05$) between the two preference groups (inhaled or injectable) were entered first. Then PRO scores and A1C after treatment with HIIP were entered into the model.

Results: Of 137 patients, 119 (87%) completed the study; 46% were male; mean age was 41 yrs; mean baseline A1C was 8.1%. At the end of the study, 80% of patients preferred inhaled insulin for their mealtime insulin. Univariate testing indicated that the group that preferred injectable insulin reported significantly ($p < 0.01$) more troublesome cognitive distress and hyperglycemia symptoms at baseline than the group that preferred inhaled. After controlling for these two baseline variables in the logistic regression model, only lifestyle impact of inhaled insulin and cognitive distress symptoms were significant predictors of insulin delivery system preference. After treatment with HIIP, patients who rated HIIP more positively on aspects of lifestyle impact were approximately 2.5 times more likely to prefer HIIP ($p = 0.015$) than those who rated it less positively; patients with greater cognitive distress were approximately 89% less likely to prefer HIIP ($p = 0.003$) than those with less symptom burden.

Conclusion: Many patients with T1D who are not at treatment goal with their injectable insulin therapy may prefer an inhaled insulin to assist them in meeting glycaemic goals. However, similar patients with more severe symptom burden may feel more comfortable using their familiar insulin delivery system, but possibly could benefit from additional education about managing symptoms and, perhaps, a change in insulin regimen to reach treatment goals.

Albulin-G, a sustained-exposure basal insulin intended for once-daily administrationA. C. Bell¹, J. B. Bock¹, P. Palanisamy Kanakaraj¹, B. L. Osborn¹, L. Pukac¹, M. A. Reitman¹, V. Roschke¹, P. Strange², D. Woods¹;¹CoGenesys, Inc., Rockville, ²Clinical Development Strategy, Poul Strange Consulting, LLC, Princeton Junction, United States.

Background and Aims: Current systemic insulin therapy results in low portal concentrations of insulin compared to the normal state resulting in an inadequate suppression of hepatic glucose production and a skewed GH/IGF-1 axis. In addition to this problem, the advances of long acting insulins including the reduced variability of insulin detemir and longer duration of action with insulin glargine, while good, are still not adequate to meet the characteristics of an ideal basal insulin, primarily because the action beyond 16–20 hours wanes and the peripheral to hepatic exposure ratio is reversed relative to natural insulin. Albulin-G was developed to address these issues by providing low variability, a longer duration of action than insulin glargine

and detemir, and a potentially greater hepatic exposure than is typical of subcutaneous insulin.

Materials and Methods: Albulin-G is a fully recombinant fusion protein generated by creating a single open reading frame that encodes a single-chain mini human insulin fused at its C-terminus to the N-terminus of human serum albumin. This protein product is engineered so that it is secreted from yeast in fully-functional form at near gram/liter titers, following a simple purification using conventional and scalable means. It can be formulated for convenient, low volume, subcutaneous injection with a 31-gauge needle. In vitro potency was assessed by measuring glucose uptake in 3T3-L1 adipocytes and mitogenicity was assessed using multiple IGF-1-responsive cell lines. The pharmacokinetic and pharmacodynamic properties of Albulin-G have been assessed in mice, rats, monkeys and Type 1 diabetic mini-pigs.

Results: The pharmacologic properties of Albulin-G are consistent with its composition as an insulin analog. Albulin-G increases glucose uptake in vitro and in vivo but is less mitogenic than other insulin preparations. In animals, Albulin-G had a longer and flatter time/action profile than insulin glargine and insulin detemir. The terminal half-life of Albulin-G in monkeys was 24 hrs and following repeated daily administration a steady-state with a daily peak-to-trough ratio of only ~1.2-fold was achieved. The pharmacokinetics and pharmacodynamic properties of Albulin-G predict once-daily dosing in man will provide continuous basal insulin coverage in man with low variation in daily insulin exposure and thus potential for consistent control of fasting blood glucose.

Conclusion: With the combined attributes of sustained exposure and low variability following daily administration and potential for greater liver exposure following subcutaneous delivery, Albulin-G has features potentially ideal for basal insulin treatment in Type 1 and Type 2 diabetics.

PS 95 Insulin analogues in type 2 diabetes

PREDICTIVE 303 Study: insulin detemir improves glycaemic control, weight and hypoglycaemia in patients previously treated with insulin glargine or NPH insulin

C. Koenen¹, L. Meneghini², W. Weng³, J.-L. Selam⁴;¹Novo Nordisk A/S, Bagsvaerd, Denmark, ²Diabetes Research Institute, University of Miami Miller School of Medicine, Miami, United States,³Novo Nordisk Inc., Princeton, United States,⁴Endocrinology, Diabetes Research Center, Tustin, United States.

Background and Aims: The PREDICTIVE 303 study (N=5604) evaluated the effectiveness of insulin detemir in patients with type 2 diabetes, using a simplified self-adjusted dosing algorithm (G1) compared to standard-of-care physician-driven adjustments (G2).

Materials and Methods: The study was conducted in predominantly primary care settings, over a period of 6 months. Study sites were randomised to either G1 or G2. Patients at G1 sites adjusted their detemir dose every 3 days based on mean fasting blood glucose (FBG) values using a simplified algorithm: mean FBG < 4.4 mmol/L, reduce dose by 3U; between 4.4 – 6.1 mmol/L, no change; > 6.1 mmol/L, increase by 3U. The detemir dose for patients from G2 was adjusted by physicians according to the standard of care. This subgroup analysis included patients who were on pre-study basal insulin only (glargine or NPH) or on basal + oral anti-diabetic medications (OADs).

Results: A total of 1663 patients on glargine ± OADs and 310 patients on NPH ± OADs were switched to detemir ± OADs following randomisation. In patients switched from glargine to detemir, HbA_{1c} decreased from 8.4% at baseline to 8.0% at 26 weeks for G1, and from 8.4 to 8.1% for G2 (p<0.0001, vs. baseline for both groups). In patients switched from NPH to detemir, HbA_{1c} decreased from 8.2 to 8.0 % for G1 and from 8.3 to 8.1% for G2 (p=0.046 vs. baseline for G1, p=0.112 for G2). The rates of hypoglycaemia (event/patient/year) were calculated based on episodes reported for the four weeks prior to each visit. In the glargine-switch group, the overall rate of hypoglycaemia decreased from 10.1 at baseline to 7.1 at 26 weeks for G1, and from 10.3 to 5.8 for G2. The group switched from NPH insulin showed a reduction in the rates of hypoglycaemia that did not reach statistical significance. Patients in both groups showed significant weight lost after switching to detemir insulin (see table).

Table. HbA_{1c}, Weight, and Rate of Hypoglycaemia at 26 Weeks (G1 and G2 combined)

	Baseline	26 weeks	Change from baseline	p value
Mean HbA_{1c} (%)				
Glargine to detemir (n=1663)	8.4	8.1	-0.3	<0.0001
NPH to detemir (n=310)	8.3	8.1	-0.2	0.0126
Mean Body Weight (kg)				
Glargine to detemir (n=1663)	98.9	98.2	-0.6	<0.0001
NPH to detemir (n=310)	97.2	95.7	-1.6	<0.0001
Hypoglycaemia (event/patient/year)				
Glargine to detemir (n=1663)	10.1	6.6	--	0.0001
NPH to detemir (n=310)	12.1	7.0	--	0.2754

Conclusion: Patients switched from glargine or NPH ± OADs to detemir ± OADs in this primary care setting showed improvements in glycaemic control, associated with both modest weight loss and a reduced risk of hypoglycaemia.

0977

Insulin detemir improves glycaemic control and reduces hypoglycaemia without weight gain, in type 2 diabetes: comparison of 26-week data from two PREDICTIVE™ studies

A. Robinson¹, J. B. Hansen², C. Koenen², F. Hernandez³, L. Meneghini⁴;¹Department of Diabetes and Endocrinology, The Royal Bolton Hospital, Bolton, United Kingdom, ²Novo Nordisk A/S, Bagsvaerd, Denmark,³Diabetes and Endocrinology, Endocare, Hialeah, United States,⁴Kosow Diabetes Treatment Center, University of Miami School of Medicine, Miami, United States.

Background and Aims: The efficacy and safety of insulin detemir has been examined in several randomised controlled trials and observational studies. These include PREDICTIVE – a multinational, prospective, observational study – and PREDICTIVE 303, a randomised, controlled trial conducted in the US. While the primary endpoint of PREDICTIVE was to assess safety, PREDICTIVE 303 investigated the efficacy two titration approaches. The PREDICTIVE 303 sites were randomised to either standard of care or a patient self-titration arm. Here we examine 26-week data from the two studies to assess similarities and variation between them.

Materials and Methods: The inclusion criteria for the PREDICTIVE 303 trial were: type 2 diabetes, HbA_{1c} ≤ 12%, BMI ≤ 45kg/m² and age ≥ 18 years. In order to accurately compare the two studies, these inclusion criteria were applied to the data collected from 6 European countries in the PREDICTIVE observational study ('EU'). One thousand nine hundred and ninety (52% male; mean age 59.9 years; BMI 31.0 ± 5.2 kg/m²; diabetes duration 11.9 years) EU patients were compared with 5,604 (51.6% male; mean age 58.6 years; BMI 33.8 ± 6.3 kg/m²; diabetes duration 11.4 years) patients in the PREDICTIVE 303 trial ('US'). All patients were treated with insulin detemir as an add-on to other glucose-lowering regimens and/or as a replacement for previous basal insulin.

Results: Total hypoglycaemia was significantly reduced from 13.0 to 6.6 episodes per patient-year for EU and 8.9 to 6.0 episodes per patient-year for US (P < 0.0005 for both groups). Major hypoglycaemia was also significantly reduced from 0.9 to 0.1 and 0.9 to 0.2 episodes per patient-year for EU and US respectively (P < 0.0005 for EU and P < 0.0005 for US). Nocturnal hypoglycaemia was reduced from 3.5 to 0.9 and 2.4 to 2.0 episodes per patient-year in the EU and US respectively (P < 0.0005 in the EU and P = 0.222 in the US). In the EU study, 59% of patients maintained or reduced their body weight while in the US study this value was 53%. Glycaemic control was significantly improved in both studies (Table).

Parameter	Baseline	26-weeks	Change from baseline at week 26	P-value
Total hypoglycaemia, episodes/patient-year				
EU	13.0	6.6	-6.4	< 0.0005
US	8.9	6.0	-2.9	< 0.0005
Major hypoglycaemia, episodes/patient-year				
EU	0.9	0.1	-0.8	< 0.0005
US	0.9	0.2	-0.7	< 0.0005
Nocturnal hypoglycaemia, episodes/patient-year				
EU	3.5	0.9	-2.6	< 0.0005
US	2.4	2.0	-0.4	0.222
Mean HbA_{1c}, % ± SD				
EU	8.4 ± 1.5	7.7 ± 1.6	-0.7 ± 1.5	< 0.0005
US	8.5 ± 1.6	7.9 ± 1.5	-0.5 ± 1.4	< 0.0005
Mean fasting glucose, mmol/L ± SD				
EU	10.1 ± 2.9	8.2 ± 2.4	-1.9 ± 2.9	< 0.0005
US	9.7 ± 4.0	8.1 ± 3.5	-1.5 ± 4.5	< 0.0005
Mean body weight, kg ± SD				
EU	88.8 ± 16.7	88.4 ± 16.9	-0.4 ± 6.1	0.024
US	97.6 ± 20.7	97.4 ± 20.7	0.0 ± 5.7	0.370

Conclusion: Despite the different settings (observational study vs randomised, controlled trial), the 26-week data for EU and US are similar and support the previously reported 12-week data for PREDICTIVE. The data show that insulin detemir improves glycaemic control and reduces hypoglycaemia, while maintaining a stable body weight in patients with type 2 diabetes.

Less weight gain and hypoglycaemia with once-daily insulin detemir than with NPH insulin in basal-bolus therapy of overweight type 2 diabetes patients: The PREDICTIVE-BMI trial

C. Fajardo Montanana¹, C. Hernandez Herrero², M. Rivas Fernandez³;

¹Diabetes Unit, Hospital de la Ribera, Alzira,

²Endocrinology, Hospital Virgen de Macarena, Sevilla,

³Endocrinology, Hospital Infanta Luisa, Sevilla, Spain.

Background and Aims: The majority of people with type 2 diabetes are overweight, yet, to maintain glycaemic control, many require intensified insulin therapy, which is well known to cause weight gain. The prospect of gaining further weight can act as a barrier to patients' acceptance of insulin intensification, potentially affecting prognosis. Insulin detemir (IDet), a long acting basal insulin analogue, has been shown to cause less weight gain than NPH insulin (NPH) and insulin glargine when added to OADs in type 2 diabetes. This weight-sparing effect increases with baseline BMI. The PREDICTIVE-BMI trial was conducted at 41 centres in Spain and aimed to assess weight change caused by IDet or NPH used as part of a basal-bolus regimen in already overweight type 2 diabetes patients.

Materials and Methods: This 26-week, parallel-group, randomised, controlled trial included men or women aged ≥ 18 years with type 2 diabetes who had been receiving 2 daily doses of insulin (at least one of them a premix) for ≥ 3 months. $7.5\% \leq \text{HbA}_{1c} \leq 11.0\%$, $25 \text{ kg/m}^2 \leq \text{BMI} \leq 40 \text{ kg/m}^2$. These subjects were randomised to receive either once-daily (evening) IDet (n=125 exposed) or NPH (n=146 exposed). All subjects also received insulin aspart at main meals. Concomitant treatment with metformin was also allowed. The basal insulin dose was continually and individually titrated, aiming for a pre-breakfast plasma glucose level of $\leq 6.1 \text{ mmol/L}$ without levels of hypoglycaemia considered unacceptable to the patient. Insulin aspart was also individually titrated aiming for postprandial glucose levels of $\leq 10.0 \text{ mmol/L}$ without unacceptable levels of hypoglycaemia. Endpoints included weight and BMI change, glycaemic control and frequency of hypoglycaemia.

Results: The two groups were well matched for demographic characteristics. Metformin was used by $\sim 50\%$ and $\sim 58\%$ of patients on IDet and NPH, respectively, but despite this non-significant slight excess in the NPH group, weight gain at 26 weeks was significantly lower with IDet (0.4 kg) than with NPH (1.9 kg), between-treatment difference: 1.5 kg, $p < 0.0001$ (mean baseline values were 79.5 and 82.2 kg, respectively). Similarly, BMI increased significantly less with IDet (0.17 kg/m^2) than with NPH (0.77 kg/m^2), between-treatment difference: 0.60 kg/m^2 , $p < 0.0001$ (mean baseline values were 31.6 and 32.2 kg/m^2 , respectively). HbA_{1c} changed from 8.9% to 7.8% in the IDet group and from 8.8% to 7.8% in the NPH group (ns for between-treatment difference in change or final value). Incidences of all hypoglycaemic events and nocturnal events were lower in the IDet group (relative risks 0.62 and 0.43, respectively, $p < 0.0001$ for both). Major hypoglycaemic episodes (requiring third party assistance) occurred too infrequently for statistical analysis (no episodes with IDet, three with NPH).

Conclusion: When used as the basal component of basal-bolus therapy for overweight or obese patients with type 2 diabetes, IDet reduces weight gain in comparison with NPH despite equivalent improvement in glycaemic control. At equivalent HbA_{1c} , patients using IDet have a lower incidence of hypoglycaemia. We therefore conclude that IDet is a better choice than NPH for overweight type 2 diabetes patients requiring intensive insulin therapy.

Use of insulin detemir once-daily results in less weight gain compared with the use of NPH insulin, particularly in obese subjects with type 2 diabetes

A. Philis-Tsimikas¹, C. Koenen², C. B. Pedersen², B. Thorsteinsson³;

¹Diabetes Department, The Whittier Institute for Diabetes-Scripps Health,

La Jolla, United States, ²Novo Nordisk A/S, Bagsvaerd, Denmark,

³Diabetes Department, Hillerod Hospital, Denmark.

Background and Aims: Obese patients with type 2 diabetes mellitus (T2DM) have a higher risk of cardiovascular complications than normal-weight patients. Therefore, potential weight gain is of particular concern once insulin therapy is initiated. Many trials suggest that insulin detemir (detemir) is associated with less weight gain than NPH insulin (NPH). The aim was

to investigate if there are any differences in weight development when using detemir or NPH, according to subjects' BMI.

Materials and Methods: This exploratory analysis was based on data from insulin-naïve subjects with T2DM ≥ 1 year poorly controlled on $1 \geq \text{OAD}(s)$ who were randomised to receive detemir (n=168) or NPH (n=163) once-daily in the evening as part of a 20-week multinational, open-label, randomised parallel group trial. Baseline characteristics for detemir- and NPH-treated subjects, respectively, were: mean age 58.7 vs. 58.4 yrs, HbA_{1c} 8.9 vs. 9.2%, weight 83.5 vs. 85.3 kg and BMI 29.7 vs. 30.4 kg/m^2 at baseline. Insulin treatment, initiated at 10 units/day as an add-on to OADs, was titrated individually based on fasting plasma glucose (FPG) with pre-breakfast and pre-dinner PG targets of 6.0 mmol/L. The trial demonstrated similar glycaemic control as measured by HbA_{1c} and FPG and less weight gain (0.7 vs. 1.6 kg, $p=0.005$) with detemir than with NPH when administered once-daily in the evening at equal doses (0.4 units/kg). To further explore any difference in weight development, weight changes were compared between detemir and NPH by baseline BMI, using linear regression (lr) with BMI at baseline as a covariate.

Results: The linear regression confirmed the overall weight benefit of detemir. Furthermore, it demonstrated less weight gain with increasing baseline BMI when detemir was used, whereas more weight gain with increasing baseline BMI was seen when using NPH, as illustrated in the figure. This difference between detemir and NPH in weight change by BMI was statistically significant ($p=0.004$). For detemir and NPH respectively, there was a mean weight increase of 2.2 kg and 1.2 kg for lean patients (BMI $\leq 25 \text{ kg/m}^2$), 1.2 kg and 1.8 kg for overweight patients (BMI 25–30 kg/m^2), 0.6 kg and 2.2 kg for obese patients (BMI 30–35 kg/m^2) and 0.2 kg and 1.8 kg for very obese patients (BMI $> 35 \text{ kg/m}^2$).

Conclusion: Once-daily detemir when added to OADs in T2DM improves glycaemic control with less weight gain compared with NPH, particularly in overweight or obese subjects initiating insulin therapy.

Basal insulin and oral antidiabetic therapy (BOT) plus a single dose of insulin glulisine (BOT+) reduces HbA_{1c} and blood glucose values in patients with type 2 diabetes

M. Lankisch¹, K. Ferlinz², W. A. Scherbaum³; for the OPAL study group,

¹Medizinische Klinik III, Kardiologie, Herzzentrum Wuppertal,

²sano-aventis Deutschland GmbH, Berlin, ³German Diabetes Clinic,

Heinrich-Heine-University Düsseldorf, Germany.

Background and Aims: Oral antidiabetic drugs (OADs) may initially be used to control hyperglycaemia in patients with type 2 diabetes (T2DM). However, most patients with T2DM will ultimately require insulin therapy to maintain tight glycaemic control. Basal insulin and oral antidiabetic drug therapy (BOT), a single daily injection of basal insulin and OAD therapy, has been shown to be highly effective when using long-acting insulin glargine as the basal insulin. However, a more intensive insulin regimen may be required if HbA_{1c} targets are not reached. We show the results of a single daily prandial dose of insulin glulisine plus BOT (BOT+).

Materials and Methods: A 26-week, randomised, multicentre study assessed the efficacy of BOT+ in patients with T2DM (n=316 per protocol set), poorly controlled ($\text{HbA}_{1c} > 6.5\% - \leq 9.0\%$) on previous BOT. Patients (fasting blood

glucose [FBG] ≤ 6.7 mmol/L [≤ 120 mg/dL]) were stratified by the main meal (breakfast, lunch or dinner), determined by the highest postprandial blood glucose (BG) level, and randomised to BOT+ (insulin glargine as basal insulin) with insulin glulisine given at breakfast ($n=162$) or to BOT+ with insulin glulisine taken at the main meal ($n=154$). We aimed to show equivalence in baseline to endpoint HbA_{1c} change between both arms.

Results: Baseline demographics were similar in both groups. The regimens were equivalent (equivalence margin=0.4%; Table), with overall HbA_{1c} reduced at endpoint (6.99 ± 0.83 vs. $7.32\pm 0.70\%$ at baseline, $p<0.0001$). Most BG values improved significantly within each group (Table). Overall, 84.2% of patients reached titration target (2h postprandial BG ≤ 7.5 mmol/L [≤ 135 mg/dL]) on ≥ 1 visit and 30.7% of patients achieved HbA_{1c} $\leq 6.5\%$ at endpoint (27.8% breakfast group and 33.8% main meal group, $p=0.21$). Mean insulin glargine dose was unchanged whereas insulin glulisine dose increased (starting dose of 5 U/day). The rate of on-treatment hypoglycaemia (BG ≤ 3.3 mmol/L [≤ 60 mg/dL]) was 3.21 per patient year ($n=393$ safety set).

Conclusions: This is the first prospective study to assess the benefits of adding a single dose of rapid-acting insulin to BOT. We show that insulin glulisine given at breakfast is equivalent to insulin glulisine given at the main meal in lowering HbA_{1c}. However, taking insulin glulisine at the main meal shows a slightly better responder rate.

Parameter	Breakfast	Main meal
HbA _{1c} (%)	7.35/7.03*	7.29/6.94*
Adjusted mean difference in HbA _{1c} (% change between groups (95% CI)	0.048 (-0.115; 0.211)

A comparison of insulin dosing algorithms in a study of prandial premixed therapy vs. basal bolus therapy in type 2 diabetes patients inadequately controlled by glargine plus OAMs

S. A. Martin¹, H. Jiang¹, M. Palaisa¹, S. Jacober¹,

¹Eli Lilly and Company, Indianapolis/United States.

Background and Aims: Little information has been published comparing the effectiveness of dosing algorithms in insulin regimens. In a study comparing prandial premixed therapy (PPT) to basal bolus therapy (BBT) in type 2 diabetes (T2D) patients, 2 algorithms differing in the aggressiveness of dose escalation were also evaluated. This analysis aims to compare the efficiency of 2 dosing algorithms (See Algorithms Table: ALGO1, ALGO2) as measured by the weeks to reach the maximum dose (with no subsequent dose modification of more than 5%).

Materials and Methods: This 24-week, randomised, open-label, active-controlled trial was conducted at 58 centers in the US and Puerto Rico. Patients with T2D and inadequate glycemic control (defined by A1C level $\geq 7.5\%$ and $\leq 12\%$) were randomised to PPT (lispro mix 50; 50% insulin lispro, 50% insulin lispro protamine suspension; $n=187$) tid with meals or BBT (glargine at bedtime + mealtime lispro; $n=187$). Within each therapy patients were then randomized to one of 2 recommended dosing algorithms. Strict adherence to dosing requirements of the algorithms was not mandatory or specifically documented by sites.

Results: Baseline characteristics were similar (mean \pm SD): age (53.8 ± 9.1 vs. 55.6 ± 9.9 years, $P=0.076$), weight (99.0 ± 20.0 vs. 99.9 ± 21.1 kg, $P=0.666$),

A1C (8.9 ± 1.0 vs. $8.8\pm 1.1\%$, $P=0.336$), and duration of diabetes (10.9 ± 6.1 vs. 11.3 ± 6.3 years, $P=0.525$) for ALGO1 and ALGO2, respectively. There was no difference in time to reach maximum dose (ALGO1 18.8 ± 6.0 weeks vs. ALGO2 18.0 ± 7.0 weeks, $P=0.278$). ALGO1 was associated with a higher endpoint insulin dose (1.3 ± 0.8 u/kg vs. 1.2 ± 0.6 u/kg, $P=0.015$) and more weight gain (4.8 ± 9 kg vs. 3.7 ± 3.6 kg, $P=0.015$). ALGO1 resulted in greater reduction from baseline of A1C ($-2.1\pm 1.0\%$ vs. $-1.85\pm 1.2\%$, $P=0.028$), lower fasting plasma glucose (PG), (7.9 ± 2.2 mmol/L vs. 8.2 ± 2.1 mmol/L, $P=0.037$), and lower mean 2-hour postprandial PG (8.6 ± 2.3 mmol/L vs. 9.4 ± 2.6 mmol/L, $P=0.005$). Percent of patients reaching glycemic targets were similar: A1C $\leq 6.5\%$ (47.0% vs. 38.1%, $P=0.129$) and A1C $< 7.0\%$ (64.2% vs. 57.8%, $P=0.286$) for ALGO1 and ALGO2, respectively. Both algorithms were generally well tolerated with a low incidence of severe hypoglycemia (3.2% vs. 2.2%, $P=0.52$) and similar rates of overall hypoglycemia (54.8 ± 50.7 vs. 45.0 ± 47.3 events/pt/yr, $P=0.055$) for ALGO1 and ALGO2, respectively.

Conclusion: Both algorithms were equally efficacious in time to reach maximum dose. Randomization to the more aggressive dosing algorithm (ALGO1) yielded a slightly greater reduction of A1C levels, a larger endpoint insulin dose, more weight gain, and a slight but not significant increase in rates of overall hypoglycemia.

Dosing Algorithms

Preprandial Blood Glucose (mg/dl [mM])	ALGO1 (TDI < 100) (Units Dose Increased)	ALGO1 (TDI ≥ 100) (Units Dose Increased)

Efficacy and safety of insulin glargine added to ongoing therapy with multiple oral antidiabetic drugs (OADs) in patients with type 2 diabetes mellitus (T2DM)

P. Raskin¹, R. J. Tanenberg², A. Vljajnic³, P. Hollander⁴;

¹Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, ²Division of Endocrinology, Brody School of Medicine, Greenville, ³sanofi-aventis U.S., Bridgewater, ⁴Endocrinology Center, Baylor University Medical Center, Dallas, United States.

Background and Aims: Intensive glycemic control can reduce the microvascular and macrovascular complications associated with diabetes. Owing to the progressive nature of the disease, patients often progress from treatment with OADs to basal insulin therapy and ultimately, prandial insulin therapy. The objective of the current analysis is to assess the efficacy, as measured by A1C and fasting plasma glucose (FPG), and safety of basal insulin added to OADs.

Material and Methods: We conducted an open-label, parallel, 3-arm study in adult patients with T2DM who had basal insulin glargine added to existing OADs, and were 1:1:1 randomised to 1, 2, or 3 injections of prandial insulin glulisine. Efficacy and safety were analyzed during the 14-week run-in phase of this study ($N=643$). Inclusion criteria were an A1C $\geq 8.0\%$ while on a combination of ≥ 2 OADs for ≥ 3 months. Oral therapy subgroups consisted of patients treated with combinations of metformin (MET), sulfonylureas (SUs), and/or thiazolidinediones (TZDs). Data pertaining to medication dose were obtained from self-report diaries.

Results: Values for demographic characteristics (50.5% male, 65.3% white, mean \pm SD age 52.3 ± 10.2 y; body mass index (BMI) 35.8 ± 14.2 kg/m²; T2DM duration 8.5 ± 6.2 y; mean A1C 9.8 ± 1.4 ; mean FPG 231.8 mg/dL ± 71.4) were relatively similar among 3 of the OAD subgroups. Subjects initially received

10U of glargine while continuing their oral regimens; dose adjustments were made based on mean morning FPG to a target of <96mg/dL. After 14 weeks of insulin glargine treatment, but prior to randomisation to prandial insulin, adjusted mean A1C decreased among all subgroups by 2.47%; the adjusted mean FBG decreased by 104.8mg/dL; and 40.6% of patients achieved an A1C<7.0%. (Tab. 1)

Conclusion: The subjects in the MET+TZD+GLAR subgroup experienced the greatest adjusted mean reduction in A1C ($P=0.003$ vs MET+SU+GLAR) and the highest adjusted percentage of subjects reaching A1C<7.0% ($P=0.0001$ vs MET+SU+GLAR). This group also reported the lowest event rate of hypoglycemia. These results demonstrate that addition of insulin glargine to ongoing OAD combinations yields excellent glycemic results.

Advancing insulin therapy in T2DM: emerging dynamics among parameters affecting tight glycaemic control

M. Johnson¹, M. A. Powers¹, P. Hollander², A. Vlajnic³, R. Bergenstal¹; ¹International Diabetes Center, Park Nicollet Institute, Minneapolis, ²Endocrinology Center, Baylor University Medical Center, Dallas, ³sanofi-aventis U.S., Bridgewater, United States.

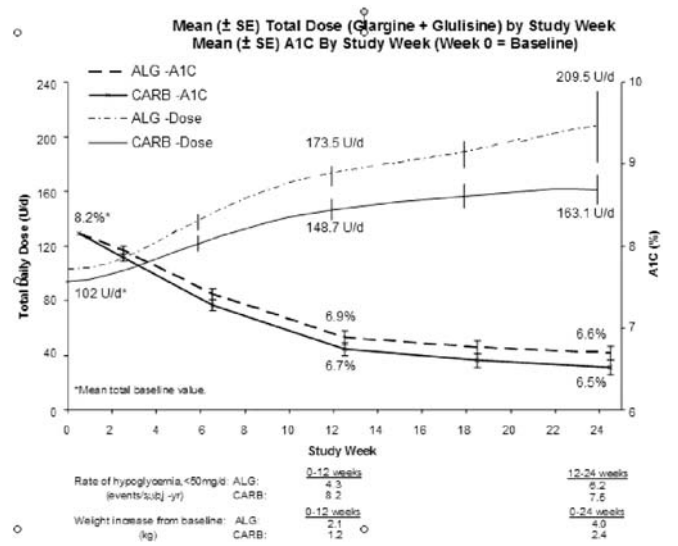

Background and Aims: An insulin-to-carbohydrate ratio allows flexibility in food choices and accuracy in dosing of mealtime insulin. However, insulin-to-carbohydrate ratio is complex and often difficult for patients to implement. Thus, there is a need for a simple, effective method that can be more easily executed. The purpose of this study was to compare glycemic control, as measured by A1C, in subjects receiving a basal-bolus insulin regimen, wherein prandial insulin was dosed based on either carbohydrate (CARB) counting or using a fixed algorithm. This subanalysis focused on the relationship among Body mass index (BMI), and A1C, the method of insulin titration, and evaluated the implications for weight gain and hypoglycemia.

Material and Methods: This was an open-label, controlled, parallel-group, randomised study. Subjects with uncontrolled type 2 diabetes mellitus (T2DM) on ≥ 2 insulin injections were switched to basal-bolus therapy with insulin glargine and insulin glulisine \pm metformin. Glargine was adjusted for 24 weeks based on fasting plasma glucose and glulisine by using a simple algorithm (ALG) based on preprandial glucose patterns (ALG; n=136) or by carbohydrate (CARB) counting (CARB; n=137).

Results: Total insulin doses increased from baseline (102U) to 12 weeks in both groups; the largest increase was in the ALG (174 U) versus CARB (149 U) group. By 12 weeks, the mean A1C decreased to <7.0% (ALG 6.9%, CARB 6.7%). From 12 to 24 weeks, A1C improved incrementally (ALG 6.6%, CARB 6.5%; $P=0.15$) but required 21% more total insulin in the ALG group (210 U) versus 9% in the CARB group (163 U) (Figure). There was a similar pattern of weight gain in the 0- to12-week period (ALG gained 2.1 kg, CARB gained 1.2 kg) compared with the 12- to 24-week period. Rates of moderate hypoglycemia were not significantly different between the 0- to

12- and 12- to 24-week periods. We also noted that longer T2DM duration increased the risk of hypoglycemia ($P=0.025$) and higher BMI showed a trend toward lower risk of hypoglycemia ($P=0.055$). Following a weekly titration regimen with basal-bolus (glargine-glulisine) insulin therapy, the greatest A1C reduction was in the first 12 weeks of titration; subsequent A1C lowering was associated with continued weight gain, with no increase in hypoglycemia.

Conclusion: This is one of the few clinical trials where obese (baseline BMI 36.7 kg/m²) patients with T2DM reached near-optimal glycemic control. In obese patients with T2DM, clinicians need to be aware of interactions among insulin dose, weight, and hypoglycemia over time to achieve optimal glycemic control (A1C 6.5%–6.6%).

Relationship between HbA_{1c} and hypoglycaemia in type 2 diabetes patients treated with prandial+basal insulin mixture or basal insulin regimens

J. Chan¹, B. M. Frier², M. Leyk¹, C. A. Jones¹, M. H. Tan¹;

¹Eli Lilly and Company, Indianapolis, United States,

²Dept of Diabetes, Royal Infirmary of Edinburgh, United Kingdom.

Background and Aims: Achieving glycaemic targets with minimal hypoglycaemia is a challenge for insulin-requiring patients with type 2 diabetes (T2D). Understanding the different effects insulin formulations have on glycaemic targets and hypoglycaemia risk helps to optimise treatment.

Materials and Methods: Data comparing a prandial+basal insulin lispro mixture +metformin (25% lispro/75% insulin lispro protamine suspension (IPLS) bid [2 studies] or 50% lispro/50% IPLS tid [1 study]; LM+Met) with basal insulin glargine bedtime (G+Met) were pooled. Data were analyzed using ANCOVA model for responses with data from the last visit having an HbA_{1c}; treatment and study were model covariates. Baseline values were included in HbA_{1c}, BG, and insulin dose models. Hypoglycaemic episodes were defined as BG <3.5 mM (63 mg/dL), calculated as episodes/pt/yr, and analyzed (a) at endpoint and (b) over the study period.

Results: At baseline, both groups (LM+Met, n=253; G+Met, n=241) had similar mean HbA_{1c} (8.3%), age, sex, BMI, T2D duration, and fasting and postprandial BG (FBG, PBG). At endpoint, there was an inverse relationship between hypoglycaemia and HbA_{1c} in the combined treatment cohort. For a 1% reduction in HbA_{1c}, the increase (slope) was 1.4 episodes (p=0.04) for all hypoglycaemia, 1.1 episodes (p=0.04) for daytime hypoglycaemia, and not significant for nocturnal hypoglycaemia. At endpoint, the LM+Met group had lower HbA_{1c} than the G+Met group (7.2±0.1 vs. 7.7±0.1%, p<0.0001) and all-meals combined PBG (8.9±0.1 vs. 10.2±0.1 mM, p<0.0001), but higher FBG (8.1±0.1 vs. 6.8±0.1 mM, p<0.0001) and insulin dose (0.7±0.01 vs. 0.6±0.01 U/kg, p<0.0001). For hypoglycaemia at endpoint, the LM+Met group had a higher rate for all (8.1 vs. 4.4 episodes, p=0.01) and daytime (6.2 vs. 1.4 episodes, p<0.0001) hypoglycaemia. Nocturnal hypoglycaemia was similar between groups (1.9 vs. 3.0 episodes). Over the study period, no difference was observed between groups for all hypoglycaemia (12.4 vs. 9.5 episodes), the LM+Met group had a higher daytime rate (10.3 vs. 3.5 episodes, p<0.0001), and the G+Met group had a higher nocturnal rate (3.4 vs. 6.6 episodes, p=0.003). In both groups, severe hypoglycaemia was rare. About 78% of all patients had no hypoglycaemia at endpoint and 55% had none over the study period.

Conclusions: As HbA_{1c} decreased, all and daytime hypoglycaemia episodes increased. The lispro mixture+Met group had lower HbA_{1c} and PBG and higher FBG and insulin dose. Daytime hypoglycaemia was higher in the lispro mixture+Met group, both at endpoint and over the study period. Nocturnal hypoglycaemia was similar between groups at endpoint and higher in glargine+Met over the study period. Providing prandial+basal insulins in 2-3 injections daily vs. basal insulin (both +Met) resulted in different glycaemic control and hypoglycaemia profiles.

Paulescu Institute, Bucharest, Romania, ⁹Institution of Diabetology, Russian Academy of Medical science, Moscow, Russian Federation, ¹⁰Internal Medicine Department, Taiba Hospital, Kuwait, ¹¹Med, Novo Nordisk, Beijing, China.

Background and Aims: The efficacy and safety of biphasic insulin aspart 30 (BIAsp 30) in clinical practice in T2DM of different duration were investigated in a multi-national, observational study (PRESENT study).

Materials and Methods: Patients (mean BMI 27 kg/m²) were categorised by diabetes duration (years/hrs): < 5 (n = 4779); 5–10 (n = 6332); 10–20 (n = 6776); ≥ 20 (n = 1999). Mean age increased with duration from 50.1 yrs (< 5 yrs group) to 63.4 yrs (≥ 20 yrs group). Prior treatment with only OAD was more common in patients with shorter duration (< 5 yrs) (41.6%), compared with those with longer duration (≥ 20 yrs) (27.5%), conversely for insulin-only prior treatment: < 5 yrs group (21.9%), ≥ 20 yrs group (39.1%); and OAD + insulin prior treatment: < 5 yrs group (15.3%), ≥ 20 yrs group (28.1%). Treatment followed physician discretion. Most initiated treatment at breakfast and dinner (75.6–81.6%). Hypoglycaemia incidence at baseline was based on patient recollection over 3 months prior to the first visit, and from the last visit for 3 and 6 month data points.

Results: Mean HbA_{1c}, FPG and PPPG decreased significantly in all groups (Table). The greatest reductions were observed in < 5 yrs group, which also reported the lowest insulin dose (Figure). At 6 months, the proportion of

* p < 0.001 (paired t-test)

patients in all groups having $HbA_{1c} < 7\%$ increased significantly from baseline ($p < 0.001$), with the highest in < 5 yrs group. 21% in this group used the once-daily regimen, compared with 15.7% (5–10 yrs); 13.2% (10–20 yrs); 12.1% (≥ 20 yrs). Overall hypoglycaemia (events/patient-yr) was low at 6 months: 2.1 (< 5 yrs); 2.0 (5–10 yrs); 2.3 (10–20 yrs); 2.8 (≥ 20 yrs).

Conclusions: BIAsp 30 treatment initiation in patients with poorly controlled early T2DM improved glucose control to a greater extent, with fewer injections and lower doses, compared with patients having longer diabetes duration. (Fig. 1, Tab. 1)

Biphasic insulin aspart is associated with a reduced risk of hypoglycaemia compared with biphasic human insulin

J. Davidson¹, A. Liebl², J. S. Christiansen³, G. Fulcher⁴, R. J. Ligthelm⁵, A. Tofft⁶, T. Gylvin⁶, H. Frimer-Larsen⁷, R. Kawamori⁸;

¹Diabetes Dpt, Endocrine & Diabetes Associates of Texas, Dallas, United States, ²Diabetes Dpt, Center for Diabetes and Metabolism, Bad Heilbrunn, Germany, ³Endocrinology, Aarhus University Hospital, Denmark, ⁴Endocrinology, Royal North Shore Hospital, Sydney, Australia, ⁵Diabetes Dpt, EHM, Hoofddorp, The Netherlands, ⁶Novo Nordisk, Bagsvaerd, Denmark, ⁷Statistics, Larix Aps, Værløse, Denmark, ⁸School of Medicine, Juntendo University, Tokyo, Japan.

Background and Aims: To compare the risk of hypoglycaemia (all, major, minor, nocturnal, daytime) associated with once- or twice-daily use of the premixed insulin aspart (BIAsp 30) and premixed human insulin (BHI 30) using a meta-analysis including all Novo Nordisk-sponsored studies comparing these insulins. A total of nine randomised, parallel or crossover, trials (duration 12 weeks to 4 years) were included involving 151 type 1 (BIAsp 30, n=79; BHI 30, n=72) and 1674 type 2 (BIAsp 30, n=1142; BHI 30, n=849) diabetes patients.

Materials and Methods: At baseline, subjects (58% male) had a mean (SD) age of 59.4 (12.0) years, mean BMI of 26.5 (4.6) kg/m², and average HbA_{1c} was 8.2 (1.4)%. Hypoglycaemia was classified as major (requiring third party assistance) or minor (symptoms of hypoglycaemia confirmed by BG < 2.8 mmol/L [PG < 3.1 mmol/L]). In one Japanese trial, minor hypoglycaemia was not defined by BG values. Analysis of minor hypoglycaemia was therefore performed with and without data from this trial. All hypoglycaemic endpoints were analysed using a generalised linear regression model assuming a negative binomial distribution and accounting for exposure time.

Results: Over the 24-hour period, the relative risk (RR) for all major hypoglycaemia was lower with BIAsp 30 than with BHI 30 (RR, 0.41 [0.22; 0.75], $p < 0.01$) across trials. The RRs for major daytime and nocturnal hypoglycaemia were also lower for BIAsp 30. The estimated RR for minor hypoglycaemia, excluding data from Japanese trial was 1.11 (95% CI, 0.85; 1.45; NS). Results of the result of the analysis were unchanged when including this trial. The RR for nocturnal hypoglycaemia was statistically significantly lower with BIAsp 30 than BHI 30 across trials (RR, 0.65 [0.47; 0.88], $p = 0.005$) and was statistically significantly lower in subjects on BIAsp 30 with type 2 (RR, 0.64 [0.45; 0.90], $p < 0.01$) but not type 1 (RR, 0.73 [0.34; 1.56], NS) diabetes. The estimated risk of daytime hypoglycaemia was significantly higher in BIAsp 30- than in BHI 30-treated subjects (RR, 1.23 [1.03; 1.46] $p < 0.05$). In each trial, results for nocturnal hypoglycaemia were consistent with these findings but heterogeneity was observed between trials for daytime hypoglycaemia.

Conclusion: Use of BIAsp 30 was associated with a reduced risk of major and nocturnal hypoglycaemia but increased risk of daytime minor hypoglycaemia compared with BHI 30. The higher estimated risk for daytime hypoglycaemia with BIAsp 30 may be a consequence of the dose regimens employed in these trials that gave 70% of the total daily dose in the morning as opposed to currently recommended, more physiological, dose regimens for BIAsp 30 that provide 50% of the daily insulin dose in the morning due to its improved pharmacokinetics relative to BHI 30.

Efficacy and safety of dietary counseling coupled with initiation of biphasic insulin aspart 30 in type 2 diabetes patients – The INITIATE plus Study

D. S. Oyer¹, M. D. Shepherd², F. C. Coulter³, A. Bhargava⁴, J. Brett⁵, P.-L. Chu⁵, B. S. Trippé⁶;

¹Endocrinology, Associates in Internal Medicine, LTD., Chicago, ²Diabetes Treatment Center, North Mississippi Health Services, Tupelo, ³Endocrinology, Coulter Clinic, Orangeburg, ⁴Endocrinology, Iowa Diabetes and Endocrinology Center, Des Moines, ⁵Novo Nordisk Inc., Princeton, ⁶Endocrinology, Endocrinology Associates of Montgomery, Montgomery, United States.

Background and Aims: The impact of nutritional counseling on glycaemic control and the risk of hypoglycaemia were studied in a 24-week, open-label, Phase IV trial, conducted predominantly in the primary care setting (934 sites in the United States) in 4820 insulin-naive patients with poorly controlled T2DM.

Material and Methods: Patients initiated BID biphasic insulin aspart 30 (30% soluble and 70% protaminated insulin aspart; BIAsp 30) with 6U pre-breakfast and 6U pre-supper. Doses were titrated according to self-measured blood glucose (SMBG) values by the following algorithm: -3U if BG < 4.4 mmol/L; no change if BG = 4.4 to 6.1; +3U if BG = 6.2 to 7.7; +6U if BG = 7.8 to 10.0; and +9U if BG > 10.0 mmol/L. The breakfast dose was titrated to pre-supper SMBG; evening dose was titrated to pre-breakfast SMBG. Patients were randomised (1:1:1) to 1 of 3 dietary counseling groups provided by a registered dietician: no dietary counseling (NC), 1 counseling session (1C), or 3 counseling sessions (3C).

Results: The mean baseline HbA_{1c} was 9.9%, BMI was 34 kg/m², and age was 53.6 years. At the end of the study, mean HbA_{1c} values decreased approximately 2.5% in each group to 7.49% \pm 1.48, 7.48% \pm 1.50, and 7.44% \pm 1.46 in the NC, 1C, and 3C groups, respectively. Within these respective groups, an end-of-study HbA_{1c} value $< 7\%$ was achieved by 40.2, 41.6 and 41.8% of patients; and a value $\leq 6.5\%$ was achieved by 28.6, 27.8, and 28.3% of patients (between group differences not significant). Hypoglycaemia (major and minor) was experienced by a similar percentage of patients in each group (10.2% to 11.4%). In general, the rates of minor and major hypoglycaemia were low but decreased as dietary counseling increased (minor hypoglycaemia: 0.56 vs. 0.50 vs. 0.45 episodes per pt-yr; major hypoglycaemia, 0.09 vs. 0.06 vs. 0.04 episodes per pt-yr, for the NC vs. 1C vs. 3C groups, respectively). The rates of major and minor hypoglycaemia in the 3C group were significantly less than those in the NC group. At the end of the study, all counseling groups had a weight increase (3.13, 3.40, and 2.88 kg for the NC, 1C, and 3C groups, respectively).

Conclusion: In the primary care setting, biphasic insulin aspart 30 was safe and effective in achieving recommended HbA_{1c} targets even with minimal dietary counseling.

Comparison of the efficacy and safety of three different premixed combinations of biphasic insulin aspart – a randomised controlled clinical trial in subjects with type 2 diabetes

D. Cucinotta¹, A. Liebl², J. Sandahl Christiansen³, K. Kanc Hanzel⁴, C. Le Dèvehat⁵;

¹Policlinico Universitario, Dipartimento Malattie Metaboliche, Messina, Italy, ²Fachklinik Heilbrunn, Diabeteszentrum, Bad Heilbrunn, Germany, ³Department of Endocrinology, Aarhus University Hospital, Denmark, ⁴NovoNordisk A/S, Bagsvaerd, Denmark, ⁵URCHB, Hopital Pierre Beregovoy, France.

Background and Aims: Biphasic insulin aspart (BIAsp) is a premixed insulin analogue, containing soluble, rapid-acting insulin aspart (IAsp) and intermediate-acting protamine-bound IAsp. We compared the efficacy and safety of three different BIAsp formulations: BIAsp 30, BIAsp 50 and BIAsp 70, the numbers denoting the percentage of the rapid-acting fraction, in a 36-week three-arm, open-label treat-to-target study, with algorithm controlled insulin titration.

Materials and Methods: A total of 599 subjects currently treated with insulin and metformin with or without other oral antidiabetic drugs (OADs) were

randomised 1:1:1 to treatment with BIAsp 30 twice daily (BID), BIAsp 50 three times daily (TID) or BIAsp 70 TID, all in combination with metformin. Insulin was injected immediately before the meals. All OADs except metformin were discontinued at randomisation. After 12 weeks of treatment subjects in the TID regimens with fasting plasma glucose (FPG) > 7.0 mmol/L were switched to BIAsp 30 at dinner. This was needed for ~50% of the TID treated subjects. The changed regimen was maintained for the rest of the treatment (24 weeks). Primary endpoint was HbA_{1c} after 36 weeks.

Results: HbA_{1c} decreased between 1.5 and 1.8%-points in the three arms. The study was designed to test for non-inferiority of the TID regimens versus BIAsp 30 BID and to test for superiority if non-inferiority was shown. Both TID regimens were non-inferior and the BIAsp 50 regimen was superior to BIAsp 30 BID (difference BIAsp 50 BIAsp30: -0.3%, 95% CI [-0.47;-0.14] p=0.004; difference BIAsp 70 BIAsp 30: -0.07%, CI [-0.25;0.10], p=0.404). Mean PG decreased with all regimens and significantly more with the two TID regimens than with BIAsp 30 BID (difference BIAsp 50 BiAsp 30: -0.55 mmol/L, p=0.0001; difference BIAsp 70 BIAsp 30: -0.32 mmol/L, p=0.03). Also prandial PG increase was lower with both TID regimens (difference BIAsp 50 BIAsp 30: -0.60mmol/L, p=0.0002; difference BIAsp 70 BIAsp 30: -0.69, p<0.0001). Insulin dose increased significantly more with the TID regimens than with BIAsp 30. In general, the profile of adverse events was similar with all three regimens; most events were of mild or moderate severity and most were considered not related to treatment. The frequency of hypoglycaemic episodes was 15.8, 21.6, and 13.7 episodes/patient-year for BIAsp 50, BIAsp 70, and BIAsp 30 respectively (BIAsp 50 vs. 30 relative risk was 1.2, p=0.16; BIAsp 70 vs. 30 relative risk was 1.58, p=0.0002).

Conclusion: A TID regimen with BIAsp 50 provided a superior glycaemic control than BIAsp 30 BID without increasing the risk of hypoglycaemia; BIAsp 70 was non-inferior with respect to HbA_{1c} but the rate of hypoglycaemic episodes was higher.

Efficacy and safety of BIAsp 30 (Biphasic insulin aspart 30) TID in combination with oral hypoglycaemic agents in non-obese patients with type 2 diabetes

S. S. Lund¹, L. Tarnow¹, B. B. Nielsen¹, H.-H. Parving², O. Pedersen¹, A. A. Vaag¹;

¹Steno Diabetes Center, Gentofte,

²Dept of Medical Endocrinology, Rigshospitalet, Copenhagen, Denmark.

Background and Aims: To investigate the efficacy and safety of BIAsp 30 injected three times daily (TID), we performed a post-hoc analysis on the subset of patients that received BIAsp 30 TID at end of study of the 12-month REFORM study.

Materials and Methods: Patients inadequately controlled on OAD combination therapy were enrolled in REFORM (n=101). At baseline patients were randomised to repaglinide 6 mg/day or metformin 2 g/day (double-masked) both in combination with BIAsp 30. BIAsp 30 was initiated with 6U once-daily pre-dinner. Patients self-adjusted insulin dose according to an algorithm aiming for fasting plasma-glucose (FPG) of 4.0–6.0 mmol/l and HbA_{1c} <6.5%. Patients intensified to 2 or 3 daily injections after 3, 6 or 9 months if target glycaemic goals were not reached, or earlier if hypoglycaemia prevented an increase in insulin dose. At end of trial, 42 patients (42%) were receiving BIAsp 30 TID in combination with OAD.

Results: Baseline data for patients on BIAsp 30 TID at end of study were mean (SD) BMI 24.5 (2.5) kg/m², mean age 64.6 (7.4) years, and mean duration of disease 12.0 (6.4) years. The patients were 54.8% male, and 45.2% were insulin-naïve. Mean HbA_{1c} was 8.7 (1.5) % at baseline and 7.0 (0.7) % at the 12-month end-of-trial visit (difference from baseline, -1.7%: p<0.0001). In comparison, mean HbA_{1c} for all patients who finished the REFORM study receiving BIAsp 30 dropped from 8.1 (1.4) % at baseline to 6.8 (0.7) % at end-of-trial visit. Among patients on BIAsp 30 TID at end of study, 11 (26.2%) had met the glycaemic target of HbA_{1c} <6.5% at end-of-trial visit. FPG and postprandial plasma glucose (PPG) levels after each meal were reduced. In the majority of patients, intensification from BID to TID occurred at the 6 or 9 month visit (7% and 45% of subjects used TID at 6 and 9 months, respectively). From 6 months to 12 months, mean HbA_{1c} improved by 0.4%, from 7.4% to 7.0%, and patients achieving HbA_{1c} <6.5% increased from 7% to 26%. The mean total daily insulin dose was 0.40 (0.24) U/kg after 3 months and 0.59 (0.30) U/kg at study end. The dose distribution was 0.20

(0.12) U/kg, 0.10 (0.07) U/kg, 0.29 (0.17) U/kg, at breakfast, lunch and dinner, respectively. Six patients reported a total of 9 major hypoglycaemic episodes over 12 months, a rate of 0.2 major episodes/subject/year. Minor episodes were reported by 38 patients (561 episodes, 12.8 episodes/subject/year). Mean weight increased by 4.8 kg during the first 9 months of the study, but stabilised during the final 3 months.

Conclusions: For non-obese patients with T2DM and poor glycaemic control, initiation of BIAsp 30 in combination with OADs, and adherence to a strict dose-escalation algorithm over 12 months significantly reduces HbA_{1c}. Results suggest that adding a third injection of BIAsp 30 to a BID regimen was important in improving glycaemic control. At study end, more than a quarter of the cohort met the aggressive target for HbA_{1c} of <6.5%, and the overall frequency of major hypoglycaemia was low, indicating that BIAsp 30 TID is both efficacious and well tolerated in this non-obese population.

⁶Dept.Endocrinology, Shanghai Changzheng Hospital, ⁷Dept.Endocrinology,

Metabolic Disease Hospital, Tianjin, ⁸Dept.Endocrinology, Sun Yixian

Commemorative Hospital, Guangzhou, China.

Background and Aims: Twice-daily (BID) treatment with biphasic insulin aspart (BIAsp 30) immediately before breakfast and dinner is a commonly used regimen to initiate insulin therapy in insulin naïve patients with type 2 diabetes inadequately controlled with oral antidiabetic drugs (OADs). Knowing the short duration of action of IAsp we hypothesised that adding a third injection (a TID regimen) could be more effective and as safe as a BID regimen. This trial was designed to evaluate the efficacy and safety of BIAsp 30 TID or BID in patients with type 2 diabetes.

Materials and Methods: In this 24-week randomised, open-labelled, parallel-group, treat-to-target trial (pre-meal BG target: 4.4–6.1mmol/L), a total of 321 Chinese subjects with type 2 diabetes (FBG≥7.8mmol/L; HbA_{1c}≥7.5%) were randomised 1:1 to receive BIAsp 30 BID or TID and with algorithm-controlled insulin titration throughout the trial. Previous OAD treatments were discontinued at randomisation. Initially, daily dose distribution was 50–50% in the BID group and 25–25–50% in the TID group. Change in HbA_{1c}, pre-meal blood glucose, hypoglycaemic episodes, insulin dose and weight were assessed.

Results: Demographic characteristics were comparable between the two groups and approximately half of the subjects in both groups were treated with more than two OADs at trial entry. Baseline HbA_{1c} was 9.5%. BIAsp 30 TID reduced HbA_{1c} significantly more after 24 weeks (primary endpoint) compared to BIAsp 30 BID (2.8% versus 2.5%, difference: -0.33%, 95%CI [-0.527;-0.127], p<0.01). A significantly better effect of the TID regimen was registered already after the first 12 weeks (p<0.01) and this was maintained until the end of treatment. Decrease in pre-breakfast self-measured BG was significantly lower with the TID regimen (-3.59mmol/L) than the BID regimen (-3.24mmol/L) (difference:-0.35mmol/L,95%CI[-0.604;-0.098],p<0.01). Pre-dinner self-measured BG decreased more in the TID group (-4.75mmol/L) than in BID group (-3.84mmol/L, difference: -0.91 mmol/L, 95%CI[-1.262;-0.560],p<0.01). No difference was observed for pre-lunch BG between the two groups. Most hypoglycaemic episodes were reported in the first 12-week treatment period. No significant difference in rates of major & minor (relative risk=0.75, p=0.32) and nocturnal (relative risk=0.81, p=0.51) hypoglycaemic episodes per patient year between the treatment groups was reported. No significant difference in adverse events, weight gain and mean daily insulin doses between two groups were observed.

Conclusion: In subjects with type 2 diabetes, both twice-daily and thrice-daily BIAsp30 were efficacious and safe after 24 weeks of treatment. BIAsp 30 TID offered a better long-term glycaemic control than BIAsp 30 BID, without an increased rate of hypoglycaemia.

Advancing insulin therapy in type 2 diabetes previously treated with glargine plus oral agents: prandial premixed (Lispro/ILPS) vs basal/bolus (Glargine/Lispro) therapy

A. J. Ahmann¹, J. Rosenstock², G. Colon³, J. Scism-Bacon⁴, H. H. Jiang⁴, S. Martin⁴;

¹Diabetes and Clinical Nutrition, OHSU, Portland, ²Dallas Diabetes and Endocrine Center, Dallas, ³The San Juan Health Centre, San Juan, Puerto Rico, ⁴Eli Lilly and Company, Indianapolis, United States.

Background and Aims: Initiation of insulin therapy with a single bedtime injection of intermediate-acting insulin, or a bedtime or morning injection of long-acting insulin is a common approach to insulin initiation. Further treatment advancement is recommended via the addition of mealtime insulin injections, such that basal/bolus therapy is eventually achieved. Premixed insulin is a convenient alternative if the proportion of rapid and basal insulin used is similar to fixed proportions available. However, there is a lack of clinical trial data providing head-to-head comparisons of prandial premixed therapy (PPT) to analog basal bolus therapy (BBT), thus limiting the ability to clearly recommend one insulin regimen over the other. Therefore, we conducted a head-to-head comparison of two insulin therapies (PPT vs. BBT) in T2D patients previously treated with insulin glargine (≥ 30 U/d) + oral agents, with the aim of demonstrating non-inferiority of PPT to BBT.

Materials and Methods: Patients with A1C ≥ 7.5 and $\leq 12\%$ were randomised to PPT (lispro mix 50; 50% lispro, 50% ILPS: insulin lispro protamine suspension; n=187) tid with meals or BBT (glargine at bedtime + mealtime lispro; n=187) in a 24-wk, multicenter, open-label, non-inferiority trial using structured insulin titration to achieve preprandial plasma glucose (PG) values < 110 mg/dL (< 6.1 mM). Patients on PPT not reaching fasting PG target could switch to lispro mix 25 (25% lispro, 75% ILPS) at the evening meal.

Results: Baseline characteristics were similar (mean): age 55yrs, diabetes duration 11yrs, BMI 34 kg/m² and A1C (Table). At wk 24, A1C was lower with BBT than PPT, but A1C was reduced significantly from baseline for both therapies ($P < 0.0001$), resulting in final A1C $< 7.0\%$ for both insulin regimens. The difference in A1C change from baseline to endpoint (BBT minus PPT) was -0.22% with a 90% CI from -0.38% to -0.07% . Non-inferiority was not demonstrated based on the pre-specified margin of 0.3%. The % of patients achieving target A1C values $< 7.0\%$ and $\leq 6.5\%$ was greater for BBT than PPT (Table), but did not differ for target $\leq 6.0\%$ (14.3% vs. 14.6%, $P=1.0$) or for target $< 7.5\%$ (83% vs. 81%, $P=0.76$). Treatment with BBT was associated with higher insulin dose, however both groups had similar weight gain (PPT: 3.98 kg vs. BBT: 4.55 kg, $P=0.22$). Rates of overall, nocturnal, severe, or hypoglycemia confirmed by PG values were also similar.

Conclusion: In conclusion, as non-inferiority of PPT to BBT was not demonstrated, findings on A1C reduction, % achieving specific A1C targets, hypoglycemia, insulin dosing complexity, and number of injections need to be considered in the individual decision-making process of selecting PPT vs BBT in T2D necessitating advancement of insulin therapy.

Efficacy of combining insulin glulisine with basal insulin glargine in patients with type 1 and type 2 diabetes previously on premix insulin therapy

S. Schreiber¹, K. Ferlinz², B. Donaubauer³;

¹Diabetes Zentrum Schreiber, Quickborn, ²sanofi-aventis Deutschland GmbH, Berlin, ³Schwerpunktpraxis Diabetes, Oschatz, Germany.

Background and Aims: A 12-week, observational, cohort study – LADI (Lantus and ApiDra in an Intensified insulin [INS] regimen) – assessed the efficacy of introducing INS glargine (GLAR) as basal INS and INS glulisine (GLU) as the prandial INS therapy in patients (pts) with type 1 diabetes (T1DM; n=2325) and type 2 diabetes (T2DM, n=9001), poorly controlled on their previous INS therapy. A sub-analysis of pts previously on premix INS was conducted.

Materials and Methods: Both T1DM (n=123) and T2DM (n=1674) pts previously on premixed INS were included in this sub-analysis. The majority of pts received regular INS premixes (90.5%) and a minority were on premixed analogues (9.5%). A small percentage of pts on premix INS were

Data are mean \pm SD

also taking basal (3.5%) or bolus (6.8%) INS. At study start, all pts changed from their previous premix therapy and placed onto a basal-bolus regimen with 1–3 daily injections of GLU as the prandial INS and once-daily INS glargine (GLAR) as the basal INS. All treatment decisions were made by the physician. At study start >97% of pts were on GLAR.

Results: Data are T1DM and T2DM, respectively. Demographics at study start (mean±SD) were: age=47.5±14.5 and 63.8±10.0 years; body mass index=26.1±3.9 and 30.7±5.3 kg/m²; diabetes duration=15.0±12.8 and 10.8±7.1 years. HbA_{1c} improved significantly (study start vs. 12 weeks) in the T1DM (8.7±1.4 vs. 7.2±0.8, n=116; p<0.0001 Wilcoxon signed rank test) and T2DM (8.6±1.2 vs. 7.3±0.9, n=1470; p<0.0001). Other blood glucose parameters improved after 12 weeks for both groups (Table). At previous therapy, the total daily dose of INS (including premix, basal and bolus INS) was similar for T1DM (46.8 U) and T2DM (48.5 U) pts. There were small increases in GLAR and GLU dose after 12 weeks in both groups (Table). At study end, the majority of pts took GLU three times daily in the T1DM (82%, n=101) and T2DM (88%, n=1466) groups. Body weight was stable during the study for T1DM (−0.5±3.1 kg) and T2DM (−0.8±4.8 kg) pts. Treatment satisfaction (TS) was assessed by the Diabetes Treatment Satisfaction Questionnaire (maximum 36=most satisfied). The TS scores were improved (study start vs. last available questionnaire) in T1DM (17.2±9.2 vs. 30.9±4.2, p<0.0001; Wilcoxon signed rank test) and T2DM (17.6±7.2 vs. 29.3±5.3, p<0.0001) pts. There was no specific question for recording hypoglycaemia on the documentation forms (only adverse events [AEs] were noted) and thus hypoglycaemia was under-reported (a total of 27 pts reported 43 AEs; of which 10 were hypoglycaemia).

Conclusions: Switching from a premix INS therapy to an intensive basal-bolus INS regimen, with GLU as the prandial INS and GLAR as the main basal INS, is accompanied by improvements in HbA_{1c} and blood glucose control in T1DM and T2DM pts in everyday clinical practice. (Tab. 1)

A comparison of analogue and human short acting insulin for the treatment of type 1 and type 2 diabetes in UK general practice

A. J. Tynan¹, C. J. Currie², A. Simpson¹, C. D. Poole³;

¹Eli Lilly and Company Limited, Windlesham, United Kingdom,

²Department of Medicine, Cardiff University, United Kingdom,

³Healthcare Research, 360° Research, Penarth, United Kingdom.

Background: There exists two general classes of short acting insulins (SAI) for the treatment of people with types 1 and 2 diabetes (T1DM and T2DM, respectively), these are the analogue insulins (AI) and the soluble regular human insulins (RHI). The purpose of this study was to compare outcome using these diabetes regimens using routinely available data from general practice.

Methods: Data were extracted from the GPRD, that describes the primary care of around 7% of the UK population from 1990 to 2007. Subjects were selected if treated with an SAI. GPRD records detail a number of experiences including: diagnoses, treatments, biochemistry/other tests, blood pressure, height and weight, and mortality. Comparisons were made using a variety of appropriate statistical tests to compare these classes of treatment for typical diabetes-related outcomes over the first year (by quarterly period) following switching to SAI. Patients who had switched between alternative SAI regimens were excluded for homogeneity.

Results: In total 4400 cases with T1DM and 2582 cases with T2DM met the selection criteria. The patient characteristics in each group with T1DM were as follows for AI and RHI, respectively: age, 35.0 years vs. 39.1 (p<0.001); percent female, 45.1% vs. 44.8% (p=0.844); mean HbA_{1c} in the Quarter prior to switching, 9.0% vs. 8.7% (p=0.015); mean time from first observation to SAI switch, 7.1 years vs. 6.8 (p=0.088); and percent with a history of macrovascular disease, 5.1% vs. 8.9 (RR 1.73, p<0.001). For T2DM and for AI and RHI, respectively: age, 55.3 years vs. 58.4 (p<0.001); percent female, 43.7% vs. 49.4% (p=0.008); mean HbA_{1c} in the Quarter prior to switching, 9.3% vs. 9.2% (p=0.40); mean time from first observation to SAI switch, 8.8 years vs. 8.0 (p<0.001); and percent with a history of macrovascular disease, 23.3% vs. 34.1% (RR 1.48, p<0.001). Both alternative regimens showed improvement in HbA_{1c} in the year post switching (table) and in T1DM subjects, after standardising for age, prior HbA_{1c}, and macrovascular disease history, subjects treated with AI showed consistently greater reduction in HbA_{1c} from baseline than those treated with RHI (Q1, −0.18% [p=0.005]; Q2, −0.15% [p=0.059]; Q3, −0.17% [p=0.072]; Q4, −0.12% [p=0.274]). Increases in weight were similar between people treated with either AI or RHI (table). The risk ratio (RR) for glycaemic coma was notably higher in cases using RHIs compared to AI (T1DM, RR=1.64, p=0.007; T2DM, RR=2.12; p=0.06). **Conclusion:** SAI regimens were effective in improving control. In T1DM, AI resulted in consistently better improvement in glycaemic control than did RHI over the year following switching, with similar weight gain. These data suggest that the incidence of glycaemic coma was reduced using AI regimens.

Near normoglycaemic control under supplementary insulin therapy in type 2 diabetes with insulin aspart and insulin detemir – is a fixed dose regimen as effective as a flexible therapy regimen?

K. Milek¹, E. Wizemann², S. Martin³, K. Böhme⁴, T. Rendschmidt⁴;

¹Diabetologist practice, Hohenmölsen, ²Diabetologist practice, Herrenberg, ³Krankenhaus Gerresheim, Duesseldorf, ⁴Novo Nordisk Pharma GmbH, Mainz, Germany.

Background and Aims: Prandial insulin therapy with short acting insulin is known to have a high potential of effective HbA_{1c} reduction in type 2 diabetes. This study compares two clinical concepts of insulin supplementation both common in Germany: A type 1 derived flexible therapy regimen with extended patient education, daily blood glucose profiles, carbohydrate count and patient driven insulin dose adjustment (FLEX) vs. a simple fixed dose regimen with rare blood glucose monitoring up to two profiles per week (FIX). Main endpoints are efficacy in terms of blood glucose control, safety and quality of life.

Materials and Methods: In this 52 weeks open labelled, randomised multicentre (61 diabetologists across Germany) parallel group trial 373 patients with insufficiently controlled type 2 diabetes previously treated with OAD, long acting or premixed insulin or a combination of those were randomised to either FIX or FLEX with insulin aspart at mealtimes. Patient characteristics (FIX vs. FLEX): 54% vs. 57% males, age 63.4±9.2 vs. 61.8±8.7 years, BMI 31.6±4.5 vs. 31.4±4.6 kg/m², diabetes duration both 10.1±7.0 years; HbA_{1c} 8.20±0.81 vs. 8.24±0.95 % (all ns). In both regimen insulin detemir and metformin could be added. Efficacy parameters were assessed at baseline and after 12, 26, 39 and 52 weeks, quality of life by DTSQ and WHO-5 at baseline and after 26 and 52 weeks. Safety assessment was performed continuously.

Results: Primary objective HbA_{1c} showed a significant difference of 0.25% in ITT group (FIX 6.97±0.066; FLEX 6.72±0.066; p=0.0074) and 0.21% in PP group (FIX 6.81±0.063; FLEX 6.60±0.061; p=0.0191). However, only ANCOVA of the PP group showed a non-inferiority of FIX vs. FLEX (mean difference 0.207%, 95%CI [0.034, 0.379]) based on the assumption of 0.4% HbA_{1c} difference as clinically relevant. 61.1% of the FIX and 69.2% (ns) of the FLEX group reached HbA_{1c}≤7.0%. Postprandial blood glucose control did not differ on a near normoglycaemic level. Education was longer in FLEX (11.40±6.29 vs. FIX 6.70±4.14 hours; p<0.0001). Mean total insulin aspart dose was FIX 48.6±27.9 vs. FLEX 45.2±34.4 units (ns). Insulin detemir once daily at dinner or bedtime was added in FIX 78% vs. FLEX 75% (ns) of the patients. Mean total insulin detemir dose was FIX 27.1±16.4 vs. FLEX 25.4±17.2 units (ns). No difference in the incidence of total hypoglycaemic events (FIX 0.08 vs. FLEX 0.106 events per subject week; p=0.3073) could be observed. Only one case of severe hypoglycaemia occurred in each treatment group. No significant difference or change in quality of life could be detected.

Conclusion: Supplementary insulin therapy reaches safely HbA_{1c} targets ≤7.0% in previously uncontrolled type 2 diabetics under conditions close to daily practice. A flexible regimen is associated with more resources in terms of education, therapy monitoring and patient compliance. However, it offers a significant advantage in HbA_{1c} reduction over a fixed dose regimen. Preprandial administration of insulin aspart ensures an effective control of postprandial glucose regulation in both study arms.

More subjects achieve an HbA_{1c} ≤7% without hypoglycaemia or weight gain when treated with insulin detemir in comparison with NPH insulin

K. Hermansen¹, J. Larsen², S. C. Tamer², C. Mathieu³;

¹Endocrinology and Metabolism, Aarhus University Hospital, Denmark,

²Novo Nordisk A/S, Bagsvaerd, Denmark,

³Medical Department, Katholieke Universiteit, Leuven, Belgium.

Background and Aims: To avoid macro- and micro-vascular complications, type 2 diabetes patients are continuously encouraged to aim for as normal a HbA_{1c} level as possible. As the disease progresses, most patients need insulin treatment to achieve good glycaemic control. However, the most important barriers to the initiation of insulin therapy are hypoglycaemia and weight gain, which may also discourage compliance once insulin treatment has been started. It is therefore most important to identify insulin regimens that can limit such harmful effects, whilst ensuring good glycaemic control. The

aim of this study was to investigate whether the HbA_{1c} improvement with detemir could be obtained without the compromise of having a high risk of hypoglycaemia and weight gain.

Materials and Methods: This explorative analysis was based on a multicentre, open-labelled, parallel-group, randomised trial involving 475 insulin-naive subjects with type 2 diabetes treated with detemir (237) or NPH (238) for 24 weeks. Detemir or NPH was added to oral antidiabetic drugs and administered twice daily using a treat-to-target regimen. Baseline HbA_{1c} was 8.6% and 8.5% with detemir and NPH, respectively. Baseline weight was 82.7 and 82.5 kg. Responders were defined as subjects treated ≥12 weeks who achieved an HbA_{1c} ≤7%, without any confirmed hypoglycaemia within the last 3 months of treatment (PG <3.1 mmol/L ± symptoms or symptomatic episode with PG <4.0 mmol/L) and a weight gain of no more than 2% of baseline value. A comparison of the treatments using Fishers exact test was made with respect to responders.

Results: Excellent glycaemic control, with an HbA_{1c} of around 6.6%, was achieved in both groups at end of the trial. The risk of hypoglycaemia was 47% lower with detemir than with NPH and body weight gain was less with detemir in comparison with NPH (1.2 versus 2.8 kg, p<0.001). However, a significantly larger proportion of subjects treated with detemir (23%) than with NPH (15%) achieved an HbA_{1c} ≤7% without confirmed hypoglycaemia, and with less than 2% gain in weight, (p=0.024).

Conclusion: This explorative analysis showed that more subjects achieved good glycaemic control without unwanted side-effects by adding insulin detemir rather than NPH insulin to oral agents. It remains to be investigated what characterises these subjects are and what it takes to increase the proportion of responders.

Non-glycaemic effects of insulin-therapy: a comparison between insulin aspart and normal insulin during two consecutive meals in patients with type 2 diabetes

A. DeCampo¹, I. Schmoelzer¹, E. Kettler-Schmut¹, H. Sourij¹, T. Forst², T. C. Wascher¹;

¹Metabolism and Vascular Biology Research Group, Medical University, Graz, Austria,

²Institute for Clinical Research and Development, Mainz, Germany.

Background and Aims: To control postprandial hyperglycemia in insulin-treated type 2 diabetic patients prandial therapy with normal insulin or short acting insulin-analogues is used. Postprandial hyperglycemia is reduced more effectively with insulin analogues, but there are no data concerning the effect on lipolysis or pancreatic insulin- and proinsulin-secretion of normal insulin in comparison to insulin analogues. The aim of our study was, thus, to compare prandial insulin therapy with normal insulin or insulin aspart regarding the effectiveness on postprandial lipolysis and secretion of insulin and proinsulin in a “near-physiological” situation of two consecutive meals (breakfast and lunch) in type 2 diabetic patients.

Materials and Methods: 14 patients with type 2 diabetes mellitus (7 men; age 62.2±2.7 years) with pre-existing insulin therapy were included in this prospective, open, randomised study. Examinations were performed after a fasting period of at least 12 hours on two different occasions. Each participant was treated either with normal insulin or insulin aspart in the setting of a standardised breakfast (634 kcal; 100 g KH, 35 g fat, 13.6 g protein) with 1.8 IE/12g KH and 4 hours later a standardised lunch (608 kcal; 84g KH, 21g fat, 21.5g protein) with 1.5 IE/12g KH. The second test meal was performed 3 days later. Blood samples for determination of free fatty acids (FFA), c-peptide (cP) and specific proinsulin (PI) were drawn fasting and every 30 minutes until 4 hours after the second test meal. Statistical analysis was done with ANOVA for repeated measurements and paired student's t-test.

Results: Both therapies reduced the total amount of FFA after the consecutive meals but mean reduction of FFA was significantly higher with insulin aspart in comparison to normal insulin (0.47/0.04 vs. 0.35/0.04 μmol/l, p<0.001). This effect was seen after breakfast (p=0.004) and after lunch (p=0.001). Increase of cP, as a marker of insulin-secretion, was significantly lower after insulin aspart (1.34/0.17 vs. 2.3/0.25 ng/ml, p<0.001) than after normal insulin. The mean increase of PI was significantly lower after insulin aspart than normal insulin (12.3/1.4 vs. 16.7/2.3 pmol/l, p=0.002). This effect was more pronounced after lunch (p<0.001) than after breakfast (ns, p=0.152).

Conclusion: In the setting of two consecutive meals insulin aspart on the one hand reduces lipolysis more effective than normal insulin, on the other hand pancreatic secretion of insulin is reduced and therefore also the secretion of potentially proatherogenic proinsulin. These effects of insulin aspart should be further investigated concerning their importance for insulin resistance and atherogenesis in type 2 diabetics.

Factors predicting long partial remission of new onset type 1 diabetes

S. Pilacinski, D. Zozulinska, P. Uruski, A. Sporna, A. Uruska, P. Niedzwiecki, M. Kasprzak, B. Wierusz-Wysocka; Department of Internal Medicine and Diabetology, Poznan University of Medical Sciences, Poland.

Background and Aims: Factors predicting prolonged clinical remission of type 1 diabetes are not definitely identified. Studies have demonstrated that low initial insulin requirement is a predictor of entering remission, but its usefulness in predicting long remission is not established. Therefore, the aim of this study was to assess the value of insulin dose in the beginning of diabetes in predicting length of partial remission of the disease.

Materials and Methods: In this cohort study we followed prospectively 104 patients (47 women and 57 men, aged 16–34, mean age 23±4), admitted to the Department with newly diagnosed type 1 diabetes and then attending the outpatient clinic. Mean hospitalisation time was 7±2 days. 16 patients presented with diabetic ketoacidosis (DKA), mean glycaemia at diagnosis was 24.1±8.9 mmol/l, HbA1c 11.5±2.5 % and BMI 21.3±3.2 kg/m². In all patients intensive functional insulin therapy in multiple injections was introduced. Partial remission was defined as an insulin dose ≤0.3 U/kg/24h and an HbA1c value <7% with baseline serum C-peptide concentration over 0.5 µg/l. Length of remission was counted from the onset of disease. Statistical analysis was performed using Statistica 5.1 software. Mann-Whitney U test, Fisher's exact test and multivariate logistic regression were used.

Results: Fifty-four patients remained in partial remission after one year of observation, in 28 patients partial remission ended before 12 months of disease and 22 patients did not enter remission. Group with long remission did not differ from the remaining patients (with no or short remission) in age, gender, presence of DKA at diagnosis, initial: glycaemia, HbA1c, serum TC, LDL-C and HDL-C and serum C-reactive protein (hsCRP) concentration. Daily insulin dose (U/kg/24h) at the end of initial hospitalization was significantly lower in patients with remission exceeding 1 year (0.22±0.14 vs. 0.32±0.13 U/kg/24h, p<0.0001). Significantly lower mean fasting and postprandial glycaemia in the last 3 days of initial hospitalisation (7.7 ± 1.9 vs. 8.5 ± 1.8 mmol/l, p<0.05 and 11.2±3.9 vs. 12.5±2.9 mmol/l, p<0.05, respectively) and lower serum triglyceride concentration at diagnosis (1.11±0.57 vs. 2.03±2.05 mmol/l, p<0.05) were also noted in this group. In the multivariate logistic regression model, insulin requirement at the end of initial hospitalisation was the predictor of long partial remission of diabetes, independent from age, BMI, and presence of DKA at diagnosis (RR: 18.5; 95%CI: 2.1–162.7, p<0.01)

Conclusion: Low insulin requirement in the early days after diagnosis may be considered as predictor of long partial remission of type 1 diabetes.

0998

Insulin glargine provides good glycaemic control in those diabetic patients on gastrostomy feeding

N. B. Tutuncu, S. Ayturk, A. D. Unal, A. N. Demirer, A. Gursoy, N. G. Demirag; Endocrinology and Metabolism, Baskent University Faculty of Medicine, Ankara, Turkey.

Background and Aims: Percutaneous endoscopic gastrostomy (PEG) tube feeding is a critically important mode of nutritional support for diabetic patients with cerebrovascular events which end up with impairment of swallowing reflex. Achievement of the optimal glycaemic control in the long term is a big problem for these cases due to the frequent bedside capillary glucose monitoring and continuous insulin infusion or frequent subcutaneous insulin regimens for each gastrostomy feeding session. Our aim was to evaluate

the effectiveness of once daily injection of subcutaneous insulin glargine for the control of glycemia in these patients.

Materials and Methods: We enrolled 13 adult patients receiving PEG tube feeding due to cerebrovascular sequela. All these patients staying in the intensive care unit were receiving five times daily 200–420cc of commercially prepared enteral nutritional products specific for the diabetic patients. Their glycaemic control was done by continuous insulin infusion or frequent subcutaneous short acting insulin regimen before each feeding session. After achievement of the optimal glycaemic regulation for each patient, 75% of the total daily insulin requirements were given as once daily insulin glargine. Glycaemic monitoring was done each week and the HbA1c was determined after 3 months of insulin glargine regimen.

Results: Mean age of the patients was 70.2±6.9 years (4 female, 9 male). Mean insulin requirement and mean daily blood glucose levels during insulin infusion were 3.0±1.3 Units/hour, 170.7±30.4 mg/dl, respectively. Total daily insulin requirement during the frequent subcutaneous insulin regimen was 57.1±27.4 Units/day, and the mean daily blood glucose was 177.8±39.7 mg/dl. Mean HbA1c level at the beginning of the gastrostomy feeding was 7.2±1.5%. At the end of the 3 months of insulin glargine regimen mean daily insulin requirements and capillary glucose levels, as well as the HbA1c decreased significantly (43.9±21.8 Units/day, 138.4±25.3 mg/dl and 6.7±0.8%, respectively).

Conclusion: Insulin glargine is a good alternative to frequent subcutaneous insulin regimens in those with gastrostomy feeding. While achieving the optimal glycaemic goal it has the advantage of ease of administration for once a day.

Transference from intravenous to subcutaneous insulin in critically ill patients with artificial nutrition

S. Torrejon¹, L. Zapata², J. M. Cubero¹, B. Biagetti¹, P. Vera², A. J. Betbesé², A. Pérez¹;
¹Endocrinology, ²Intensive Care Unit, Hospital Sant Pau, Barcelona, Spain.

Background and Aims: To evaluate a strategy for the transference from intravenous insulin infusion to subcutaneous long acting insulin analogue (glargine) in critical care patients receiving artificial nutrition.

Materials and Methods: Between June to December 2006, 120 consecutive patients hospitalised in Intensive Care Unit (ICU) were included in an intensive glycaemic control with intravenous insulin infusion protocol (IIT). We studied a subgroup of 74 patients (mean age 65.3±14.6, 74.3% men, Apache II score 19.7±11.5, 69% without diabetes) receiving parenteral and/or enteral nutrition. Transference to subcutaneous insulin was started after patient's clinical status improve (off pressor agents or corticoids) and the blood glucose was stable and in target range. The 24-hour long lasting insulin glargine dose was estimated as a 50% of average amount of insulin infused during previous 12 hours. Blood glucose was checked ≥ 4 times daily and insulin dose was adjusted each evening. Correction doses of rapid acting insulin analogue for hyperglycemia were administered every 4–6 hours.

Results: Basal subcutaneous insulin was started at 6±5 days after admission in ICU and mean duration of treatment in ICU was 10±9 days. Initial insulin dose was 27±15 UI and increased to 33±21 at 10th day. The mean blood glucose during the period of treatment was 138±34 mg/dL, the percentage of glycemia in the target range (80–120 mg/dl) was 54.7% and only 6.7% were > 200 mg/dL. Only 3 hypoglycemic episodes were observed (4.1 episodes/1000 days of treatment). As compared to the subgroup of patients with total enteral nutrition (TEN) (n=27), patients with total parenteral nutrition (TPN) (n=14) had higher mean plasma glucose (147±37 vs. 136±35 mg/dL) and a 40% dose increase was necessary to achieve the target blood glucose levels.

Conclusion: Long acting insulin glargine is an effective and safety alternative in the transference from intravenous to subcutaneous insulin on patients with artificial nutrition. Estimation of total subcutaneous dose as 50% of average insulin infused during the last 12 hours is suitable for patients with TEN but insufficient for patients with TPN.

Intensive intravenous insulin treatment in patients admitted to an intensive care unit

J. M. Cubero¹, L. Zapata², B. Biagetti¹, S. Torrejón¹, I. Vinagre¹, P. Vera², A. Betbesé², A. Pérez²;

¹Endocrinology and Nutrition,

²Intensive Care Unit, Hospital Santa Creu i Sant Pau, Barcelona, Spain.

Aims: To evaluate the efficacy and safety of an intensive insulin treatment protocol (IIT) in patients with hyperglycaemia admitted to an Intensive Care Unit (ICU).

Materials and Methods: We compared a prospective cohort in whom an IIT was used to maintain the blood glucose at a level between 80 and 120 mg/dl with a retrospective cohort (control group). We studied 272 patients (158 as IIT group, and 114 as control group). The IIT consisted in 6 algorithms with a decision table for the adjustment of continuous intravenous insulin infusion according to glycaemia measurements. Once patients were stabilised without needing inotropic or vasopressor drugs or corticoids, and receiving any type of nutrition, we started subcutaneous insulin treatment (bolus-basal with lispro and glargine insulin). Total initial dose was estimated at 50% of the intravenous insulin requirements in the previous 12 hours. Glycaemias < 40 mg/dl were considered as severe hypoglycaemias. In the control group no predefined protocol was used in the management of hyperglycaemia.

Results: No differences were found in the mean age (62.9+/-16 vs. 62.2+/-16 years) and APACHE II score (20.1+/-8 vs. 18.5+/-8) between control and IIT groups. We collected 2600 capillary glucose measurements in the control group and 12036 in the IIT group. The mean glucose level during the stay in ICU was 143.1+/-32 mg/dl in the control group vs. 118 +/-16 mg/dl in the IIT group (p<0.001). In the IIT group, the percentage of glycaemias at a level between 80–120 mg/dl was higher (59.3+/-15% vs. 36.3+/-25 %; p<0.001) while the percentage of glycaemias > 200 mg/dl was lower (4.7+/-8 % vs. 12.6+/-19 %; p<0.001). Severe hypoglycaemias were similar in both groups (6 vs. 9 episodes). Mortality in ICU was 30.1% in the control group vs. 21.1% in the IIT group (p=0.08) and in-hospital death 37.2% in the control group vs. 26.8% in the IIT group (p=0.06). No significant differences were observed in morbidity except for hyperbilirubinemia (39% in the control group vs. 24.4% in the IIT group; p<0.01).

Conclusion: The IIT protocol established allows us to maintain a target blood glucose range of 80–120 mg/dl without increasing severe hypoglycaemic episodes.

(AG) were assessed daily and expressed as changes from baseline, HBA_{1c} (changes from baseline) and safety criteria on days 1, 28, 56, and 84. The Wilcoxon-Mann-Whitney test was used for statistical analysis. Results are presented as effect sizes of the univariate Mann-Whitney test (MW).

Results: 105 patients were included in stage II (53 test/52 control). A total of 55 patients (33 test/22 control) participated until day 84, most frequent reasons for premature discontinuation were “regained swallowing” and “referral to other institution”. After 84 days, median changes of TI with data as available were -8.0 vs. +2.0 U (test vs. control, MW=0.8326, P<0.0001) and of FG -39.0 vs. -12.1 mg/dl (test vs. control, MW=0.8030, P<0.0001); the effect sizes denote a large superiority of the test group for both variables as well as for the combined efficacy criteria (days 56/84, MW=0.7899, P<0.0001, P value to be reached in stage II: P<0.0309). For HBA_{1c}, relevant and for AG large superiority of the test group could be demonstrated on day 84/days 56 and 84, respectively. Feeding tolerance was comparable in both groups. The number of relevant hypoglycaemic episodes (FG < 60 mg/dl) was 1 (test) vs. 5 (control), suggesting a slight superiority of the test group.

Conclusion: Statistically significant beneficial effects on total insulin dosages and fasting blood glucose with disease specific compared to standard formula could be shown for the formal combination of the two stages. Long-term treatment with a disease specific enteral formula improves and stabilises glycaemic control. The formula is safe and well tolerated in tube-fed type 2 diabetes patients with neurological disorders.

Glycaemic control in type 2 diabetic patients during long-term tube feeding with a disease specific enteral formula: final results of a randomised, controlled multicentre trial

P. Mayr¹, M. Mertl-Roetzer², F. Lauster², M. Pohl³, B. Hipper⁴, D. Steube⁵, J. Eriksen⁶, V. W. Rahlfs⁷;

¹Health Care Centre, Stockach, Germany, ²Schoen-Clinic, Bad Aibling,

Germany, ³Clinic Bavaria, Kreischa, Germany, ⁴Median Clinic, Magdeburg,

Germany, ⁵Clinic, Bad Neustadt/Saale, Germany, ⁶County Hospital,

Herning, Denmark, ⁷Data Analysis and Planning, idv, Gauting, Germany.

Background and Aims: Achieving optimal glycaemic control in tube-fed diabetic patients is complicated by metabolic stress, immobility and feeding difficulties. Results of stage I of a pre-planned two-stage procedure in type 2 diabetics after brain injury have provided good evidence for improved glycaemic control with a disease specific enteral formula low in carbohydrates, high in monounsaturated fatty acids, fish oil, chromium and antioxidants (Diben, Fresenius Kabi) as compared to a standard formula. Since the confirmatory P value of stage I (summarising Wei-Lachin procedure) was lying between the pre-planned benchmarks, the study was continued to confirm beneficial effects with a reduced set of primary variables and adjusted sample size.

Material and Methods: Randomised, double-blind, controlled multicentre trial. Insulin treated type 2 diabetic patients [HBA_{1c} ≥ 7.0 % and/or fasting blood glucose (FG) > 120 mg/dl] with neurological disorders and indication for long-term enteral tube feeding were randomised to receive either 27 kcal/kg BW/d (max. 2025 kcal/d) of the disease specific formula (test, n=53) or an isoenergetic, isonitrogenous enteral standard formula (control, n=52) for up to 84 days. Total insulin requirements (TI), FG and afternoon blood glucose

Pilot study of the effects of gastric electrical stimulation (Tantalus®) on glycaemic control in obese patients with type 2 diabetes (T2DM)

C. Rosak¹, B. Ludvik², R. Jung¹, M. Schramm³, A. Bohdjalian⁴, G. Prager⁴, R. Weiner³;

¹Dept of Diabetology, Sachsenhausen Hospital, Frankfurt a. Main, Germany,

²Dept of Internal Medicine III, Medical University of Vienna, Austria,

³Dept of Surgery, Sachsenhausen Hospital, Frankfurt a. Main, Germany,

⁴Dept of Surgery, Medical University of Vienna, Austria.

Background: The TANTALUS System (MetaCure Ltd.) is a minimally invasive, implantable device that automatically detects food intake and delivers non-excitatory electrical stimulation to the gastric wall during meals. Previous studies showed that this modality can induce weight loss in morbidly obese subjects.

Aim: To investigate the potential effect of the TANTALUS System on glycemic control and weight in obese subjects with T2DM.

Patients and Methods: In this European multi-center, open label study, 24 T2DM obese (9 m, 15 f, BMI: 41.7±0.9 kg/m²) subjects treated either with insulin (7) or oral anti-diabetic medications (17) were implanted laparoscopically with the TANTALUS System. The system includes a pulse generator, three bipolar leads and delivers a non-excitatory signal initiated upon automatic detection of food intake.

Results: Sixteen subjects initially on oral anti-diabetic medications that have completed one year follow up show a significant ($p<0.05$) decrease in weight of 5.5±2kg. A subset of eight patients initially not well controlled ($A1c>7\%$) on stable oral medications decreased HbA1c from 8.34±0.3% to 7.44±0.4%, FBG dropped from 206±12mg/dl to 158±15mg/dl ($p<0.05$). Self glucose monitoring data in this subset available at 9 months showed a significant ($p<0.05$) decrease in 2-hour post-prandial glucose (176±12mg/dl to 141±13mg/dl). The other eight patients on oral meds either changed drug regime during treatment or were initially well controlled ($A1c\leq 7\%$). The four insulin subjects that have completed one year showed no significant changes in HbA1c and weight.

Conclusion: Interim results with the TANTALUS System suggest that non-excitatory stimulation applied during food intake can potentially improve glucose levels and induce weight loss in obese T2DM subjects on oral anti-diabetic therapy. Further evaluation is required to determine underlying mechanisms of glucose lowering and weight loss.

1003

The relationship between self-monitoring of blood glucose results and glycosylated haemoglobin in type 2 diabetes: the Fremantle Diabetes Study

T. M. E. Davis, K. Van-Minnen, D. G. Bruce, W. A. Davis;

School of Medicine and Pharmacology, University of Western Australia, Fremantle, Australia.

Background and Aims: Self-monitoring of blood glucose (SMBG) and its frequency did not predict glycosylated haemoglobin (HbA_{1c}) in patients with type 2 diabetes participating in the observational community-based Fremantle Diabetes Study (FDS), regardless of treatment modality. This could reflect problems with one or more steps in the complex process of obtaining and applying SMBG data. The aim of the present FDS sub-study was to assess whether the SMBG results documented by the patients correlated with HbA_{1c} and thus could, if properly applied, be used to guide therapeutic change.

Materials and Methods: 900 out of the 1294 type 2 FDS patients performed SMBG, and 554 of these (61.6%) provided documented SMBG results from which were abstracted the highest and lowest results before and after meals during the week before assessment. We assessed the associations between the averages of these levels and HbA_{1c}.

Results: There was a highly significant correlation between both pre- and post-prandial average SMBG results and HbA_{1c} ($P<0.0001$ in each case). The 95% confidence intervals for HbA_{1c} (normal reference range <6.0%) at three SMBG levels are shown in the Table.

Conclusion: These data suggest that, despite wide confidence intervals, pre-prandial SMBG data could be used to justify intensification of therapy,

especially at levels above 10 mmol/L. Post-prandial levels had a flat relationship with HbA_{1c} and are thus of limited value in optimising management.

Glycosylated haemoglobin 95% c.i. for three pre- and post-prandial average SMBG results

	SMBG 6 mmol/L	SMBG 10 mmol/L	SMBG 14 mmol/L
Pre-prandial average	4.2 to 9.9	5.6 to 11.3	7.0 to 12.7
Post-prandial average	2.4 to 7.9	2.5 to 8.1	2.6 to 8.2

Reliability of self-recorded blood glucose data in patient logbooks compared with SMBG data saved in device memory and printed out with Accu-Chek Smart Printer

J. K. Tshiang Tshiananga¹, D. Franke², M. Luebker³, C. Weber¹, K. Neeser¹;

¹IMIB: Institute for Medical Informatics and Biostatistics, Basel, Switzerland,

²Medical clinic, VS-Villingen, Germany,

³Roche Diagnostics, Mannheim, Germany.

Objectives: This study aimed to examine the reliability of self-recorded blood glucose (BG) values in a handwritten diary compared with memory data of SMBG devices printed out with Accu-Chek Smart Printer, to investigate possible sources of errors and to deduce predictive factors in order to avoid recording errors in the future.

Methods: Patients in this study were followed during 28 days by a diabetologist for their disease management in south of Germany. The discrepancies in the BG-values were determined as difference between diary correct documented values and the averages resulting from corresponding device memory values (one or four) of measurements performed in the morning, at midday, in the evening and at bedtime. ANOVA models were built to determine the influences of variables on discrepancies at the different measuring points.

Results: 94 of 176 patients (44% females) aged between 16–90 years were performing SMBG daily. The mean age was 66.38±13.92 and the mean duration of diabetes 11.37±8.99 (range:1–44) years. Device BG-values were likely to be higher than self-recorded diary-values for the corresponding measurements ($p<0.001$). Only 8% of patients could properly transfer BG-values in their handwritten logbooks ($p<0.001$). This proportion was most elevated in the morning and was fading at the following measuring points ($p<0.001$). Diary-values were higher than values in device memory during the bedtime measurement. Five recording errors were detected: 1)fully different values in both diary and device memory for the same measurement period, 2)inversed numbers, 3)same value but different recording times, 4)missing values in diary but available in memory or vice versa and 5)missing values as well as missing dates. ANOVA models have shown influences of various sociodemographic and metabolic characteristics, number of SMBG measurements and frequency of errors on BG-discrepancies at different measurement periods.

Conclusion: This study has shown a higher reliability of patients to record correctly the measured SMBG-values in their logbooks during the morning time than at the other measuring points. The discrepancies are related to Sociodemographic features as well as to reasons varying from cognitive capacity, visual impairment and compliance to their physician. Our findings have shown a trend maybe also existing beyond our particular study population and would have serious implications in disease management (patient guidance and adjustment of therapy). Therefore we would recommend not to rely on only handwritten logbooks but to favorize recorded BG-values and analysed with electronic systems like the Smart Printer or similar devices.

Evaluating the effect of miscoding on a large number of glucose meter results collected over 4-years

J. M. Ellison¹, A. Cariski¹, C. Davis¹, K. Delaney², F. Urquhart²;
¹LifeScan, Inc., Milpitas, United States, ²LifeScan Scotland, Inverness, United Kingdom.

Background and Aims: Results from 4 published studies suggest that the incidence of patient meter miscoding ranges from 3–16%. As with other sources of procedural error such as blood collection and application, miscoding can result in glucose measurement errors. The magnitude of the error depends on the degree of miscoding (how many codes the meter setting differs from the correct value) and the glucose meter system. The objective of this study was to evaluate the impact of miscoding the OneTouch® Ultra® (Ultra) Meter on measured blood glucose readings taken from a very large data set.

Materials and Methods: The data set comprises blood glucose results from ongoing clinical evaluations conducted at three clinical sites in the UK. During each evaluation, capillary blood samples were collected from donors with diabetes and tested on an Ultra meter. Additional capillary blood was then collected and a reference value determined from duplicate tests performed on the YSI 2300 Glucose Analyzer. A random sample of 45,343 glucose results collected over a 4-year period (October 2000 to December 2004) from 552 lots of Ultra Test Strips was obtained and the Ultra glucose values were recalculated by applying each of the 49 calibration codes to each of these results.

Results: Of the original 45,343 samples measured with the correct calibration code, 98.6% of values were in zone A, 1.4% were in zone B, and 3 results were in zone C of the Consensus Error Grid (Table). The calculations produced over 2.2 million glucose values, of which only 65 fell outside zones A and B; only these 65 zone C results were likely to affect clinical outcome. No values were sufficiently inaccurate to cause a treatment decision with significant medical risk (zone D) or dangerous consequences (zone E).

Conclusion: Our study confirms that correct meter coding optimises system accuracy and reinforces the need to code in accordance with label instructions. However, if the code on the meter does not match the code on the test strip vial, there is a low risk of adverse health outcomes in the Ultra meter system.

Summary of Consensus Error Grid Analysis

Error Grid Zone	Meter results coded correctly	Meter results all codes applied
A	98.6%	78.8%
B	1.4%	21.2%
C	0.0% (3 results)	0.0% (65 results)
D	0.0% (0 results)	0.0% (0 results)
E	0.0% (0 results)	0.0% (0 results)

1006

Differences in dose accuracy of insulin pens

A. Pfützner, A. Weise, W. Sun, H. Hänel, T. Forst;
 IKFE Institute for Clinical Research and Development, Mainz, Germany.

Background and Aims: Modern insulin injection pens provide a convenient and accurate way for diabetes patients to inject insulin. Their use is widespread among children and adults with type 1 diabetes as well as those with type 2 diabetes in Europe. A previous study in Japan brought the accuracy of an insulin pen system in question. This investigation was performed to establish whether this could be reproduced on insulin pens available in Europe. This study compared the dosing accuracy of two commonly available insulin pens, the OptiClik pen from sanofi-aventis which is available with insulin glulisine and insulin glargine, and the FlexPen pen from Novo Nordisk which is available with insulin aspart, biphasic insulin aspart and insulin detemir.

Materials and Methods: Insulin and pens were obtained from the stock of a local pharmacy in Düsseldorf, Germany and the dosing accuracy was tested for both pens with 24 x 10 U and 9 x 30 U injection volumes to investigate, whether both pens comply within the acceptable limits of 10% (+/- 1 U) for 10 U and 5% (+/- 1.5 U) for 30 U. These limits are based on the limits set forth by ISO. The needles used were chosen following the recommendations

of both manufacturers of the insulin pens (NovoFine 31 gauge (G) 6mm needles for the FlexPen and BD Micro-Fine 31 G 5mm needles for the OptiClik). A new needle was used for every dose, which was delivered according strictly according to the instructions for use for both devices. A sensitive pharmaceutical balance was used for the assessment of the applied volumes, and the results were corrected for the specific density of the insulin formulations. Four insulin pens from 2 different lots were used for the two volumes, respectively, resulting in a total of 192 dosings per pen with 10 U and 72 doses per pen with 30 U.

Results: FlexPen was more accurate than the OptiClik insulin pen at both doses as shown in the table. Each OptiClik pen underdosed at least on one occasion, while all doses from the FlexPen were within the specified accuracy range.

Conclusion: A direct head-to-head comparison of both insulin pens with a standardised protocol resulted in a more stable accuracy of the FlexPen in comparison to the OptiClik pen. Even though all insulin delivery systems undergo rigorous testing before being approved for sale, it seems there may be reason to be attentive to the performance of the devices in practical use. As an increasing amount of delivery systems are introduced by all the major insulin producers (i.e. NovoPen 4, Novo Nordisk; SoloSTAR, sanofi-aventis; HumaPen Luxura, Lilly) in response to an ever increasing amount of patients treated with insulin, emphasis must be put on device manufacturers to ensure an important but evident task; delivering the correct amount of insulin to the patients in an easy and convenient way.

Table: % of doses outside accuracy range

Selected dose	OptiClik	FlexPen
10U (+/- 1U max)	8.33%	0 %
30U (+/- 1.5U max)	16.66%	0 %

Supported by Novo Nordisk

A silicon beta cell: towards an intelligent closed loop insulin delivery system

N. S. Oliver, P. Georgiou, C. Toumazou;
 Institute of Biomedical Engineering, Imperial College, London, United Kingdom.

We have developed a bioinspired electronic version of the beta cell which replicates the normal bursting behaviour of the beta cell. Beta cells show electrical excitability which is coupled to insulin secretion by exocytosis. The membrane potential oscillates in slow wave bursts with action potentials superimposed on the active phase. These bursts do not appear unless blood glucose concentrations rise above 7mM and, as glucose concentration rises, the pulse width of the bursts increases up to a concentration of 20mM at which the mechanism is saturated and a continuous train of action potentials remains. Implementation of the beta cell in silicon requires accurate modelling of the dynamics of the ionic currents. The silicon beta cell uses an ion-sensitive field effect transistor (ISFET) coupled with glucose oxidase as the glucose sensor. Glucose is metabolised by glucose oxidase to produce hydrogen ions which are detected by the ISFET sensor. Glucose may be sensed up to 25mmol/L. Mathematical modelling of the ionic behaviour of the beta cell has been replicated using low power MOS transistors and the circuit has been fabricated in silicon. Simulation results confirm that the membrane dynamics of the silicon beta cell are comparable to those seen in actual beta cell data. The resting potential is -68mV and appropriate bursting behaviour is observed at varying glucose concentrations.

Results mimic the pancreatic beta cell and, as bursting behaviour is associated with insulin release by exocytosis, physiological insulin delivery may be driven by the output from the silicon cell. This circuit is an important step towards creating an artificial bionic pancreas utilising an insulin pump for blood glucose regulation in type 1 diabetes. The silicon beta cell shows bursting behaviour similar to that observed in beta cells *in vitro* as well as demonstrating low power consumption making it ideal as an implantable or wearable device.

Outpatient assessment of KADIS®-based decision support

P. Augstein, L. Vogt, K.-D. Kohnert, E.-J. Freyse, P. Heinke, E. Salzsieder; Institute of Diabetes, Karlsburg, Germany.

Objective: To assess the benefit of the Karlsburg Diabetes Management System (KADIS®) in conjunction with continuous glucose monitoring (CGMS™) in an outpatient setting.

Research Design and Methods: A multicentric trial was performed in insulin-treated outpatients (n=49), aged 21–70 years with a mean diabetes duration of 14.2 years. Subjects were recruited from 5 outpatient centers and randomised for CGMS™- or CGMS™/KADIS®-based decision support and followed up for 3 months. After two CGMS™ monitorings, the outcome parameters HbA_{1c} (%), mean sensor glucose of the CGMS™ profile (MSG, mmol/L) and duration of hyperglycemia (h/day) were evaluated.

Results: In contrast to the CGMS™ group (0.27±0.67 %), mean change in HbA_{1c} (Δ HbA_{1c}), decreased in the CGMS™/KADIS® group during the follow up (−0.34±0.49 %; p<0.01). MSG levels were not affected in the CGMS™ group (7.75±1.33 vs. 8.45±2.46 mmol/L), but declined in the CGMS™/KADIS® group (8.43±1.33 vs. 7.59±1.47 mmol/L; p<0.05). Net KADIS® effect [−0.60 (95% CI −0.96 – −0.25 %); p<0.01] was associated with reduced duration of hyperglycemia (4.6 vs. 1.0 h/day; p<0.01) without increasing hypoglycemia. Multiple regression revealed that the HbA_{1c} outcome was dependent on KADIS®-based decision support. Age, sex, physician's specialty, diabetes type and BMI had no measurable effect.

Conclusions: If physicians were supported by CGMS™/KADIS® in therapeutic decisions, they achieved a better glycaemic control for their patients compared to CGMS™ alone. KADIS® is a suitable decision support tool for physicians in outpatient diabetes care and has the potential to improve evidence-based management of diabetes.

Detection of hypoglycaemia in patients with T1DM using the FreeStyle Navigator® continuous monitoring system and traditional blood glucose monitoring

G. V. McGarraugh;

Abbott Diabetes Care, Alameda, United States.

Background and Aims: The FreeStyle Navigator Continuous Glucose Monitoring System (CGM), a 5-day, subcutaneously inserted electrochemical sensor, was compared to blood glucose monitoring (BG) at an average testing frequency of 8/day for the detection of hypoglycemia. A single measurement indicating hypoglycemia could occur immediately after the onset of an episode or many hours later. In order to understand hypoglycemia detection, the onset and duration of the hypoglycemic event must be defined – very frequent or continuous reference values are necessary. CGM was evaluated in a 5-day clinic study where YSI reference glucose tests were performed at 15-minute intervals. BG testing was studied in the home environment where testing regimens were integrated into normal daily activities. The reference in the home environment was CGM with results masked from the patients. CGM does not have the accuracy of a laboratory reference, but the performance of CGM was well characterised in the clinic study, and the home use study of BG can be interpreted with an understanding of the CGM reference method limitations.

Materials and Methods: The clinic study included 58 subjects with T1DM where reference readings were taken for 50 hours, and subject schedules were staggered to include the sensor's 120 hour lifetime. Hypoglycemia was defined as at least two successive YSI readings <70 mg/dL – a duration >15 minutes. The 20-day home use study included 91 adult subjects with T1DM. A hypoglycemic event was defined as successive CGM readings <70 mg/dL for >15 minutes, similar to the clinic study. A BG reading of ≤85 mg/dL was considered detection of hypoglycemia since this indicated necessary treatment to reverse or avoid hypoglycemia.

Results: Using the CGM threshold alarm set at 85 mg/dL, 90.6% (155/171) of hypoglycemic events were detected within ±30 minutes of onset. When a CGM alarm was activated, the YSI reference glucose was ≤85 mg/dL for 77.2% (217/281) of alarms, indicating treatment was necessary to reverse or avoid hypoglycemia. In actual use, a BG test would be performed to determine if treatment was necessary. Projected alarms give advanced indication of impending hypoglycemia, and more alarms occur when these are used. Detection was 93.5% (160/171) when high sensitivity projected alarms were employed and 72.2% (281/389) of the alarms occurred when YSI was >70 mg/dL. Projected alarms would be used in order to avoid rather than reverse hypoglycemia. Using CGM<70 mg/dL for >15 minutes to identify events in the clinic study, 52.0% of the YSI-defined events were also identified by CGM. When CGM indicated an event, YSI was ≤70 mg/dL 85% of the time and ≤85 mg/dL 97.5% of the time. CGM will not identify all events in the home use study – mild hypoglycemia of short duration is less likely to be identified. When an event is indicated, however, it is very likely to be true or impending hypoglycemia. With an average testing frequency of 7.9/day in the home use study, 27.5% (303/1103) of events were detected within ±30 minutes, and 12.7% (49/385) were detected during nocturnal hours. If an hour was allowed for detection the rate was 35.3% (389/1103) or 19.0% (73/385) during nocturnal hours. Since the actual number of events was underestimated by CGM, the true detection rates by BG are likely to be lower.

Conclusion: CGM provides superior detection of hypoglycemia and patients can customize projected and threshold alarm settings to allow a suitable balance of alarm frequency and treatment strategy.

Improved glycaemic control with real-time continuous glucose sensors in patients with type 1 diabetes

S. L. Ellis, M. Voelmlle, P. Gottlieb, R. Gutin, S. Garg;
Department of Clinical Pharmacy, School of Pharmacy, Barbara Davis
Center for Diabetes, Aurora, United States.

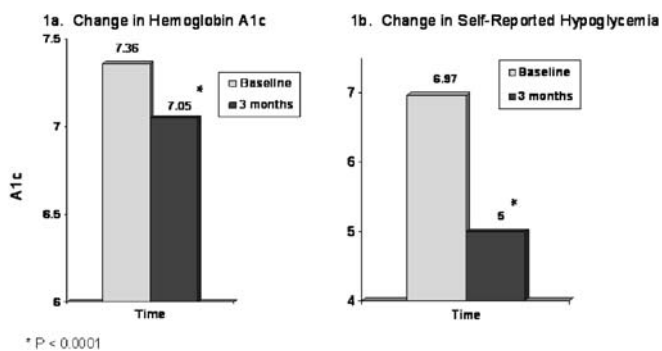

Background and Aims: Continuous glucose sensors have been shown to decrease glycemic excursions in short-term studies but data are lacking on their effects on long term glycemic control.

Materials and Methods: We performed a retrospective study of patients initiated on either the DexCom STS or Medtronic Paradigm RT glucose sensors for 3 months. The primary outcome of this study was change in A1C values. Data were also collected on hypoglycemic episodes, insulin use, and weight and mean home blood glucose during monitoring (SMBG) before, during and after sensor use.

Results: A total of 34 patients had both baseline and 3 month data available. Baseline characteristics included 25 (74%) females, duration of diabetes was 23.7±16.2 years and mean A1c was 7.36%±1.01%.

Average sensor use was 17±9 days/month (range 1–30 days). A1C values decreased significantly at 3 months (Figure 1a; $p < 0.0001$), despite no change in overall insulin dose (43.0U vs. 42.7U, $p=0.58$). Self-reported total hypoglycemic events decreased 23% (Figure 1b; $p < 0.0001$) whereas nocturnal hypoglycemia was reduced by 41% (1.16 vs. 0.69 $p=0.01$). Severe hypoglycemic events were 0.173 and 0.088 events/patient before and after sensor use, respectively ($p=0.15$). Mean SMBG was reduced from 164.3±74.5 to 153.2±69.9 ($p=0.053$) at 3 months. Frequent sensor usage (>15 days each month) was associated with a 30% increase in the number of patients achieving an ADA target A1c of < 7% compared to patients using the sensors less often.

Conclusion: The use of a real-time continuous glucose sensor significantly improved A1C values while reducing overall and nocturnal hypoglycemic events after 3 months.

1011

Evaluation of continuous use of real-time glucose monitoring, alone and after combined insulin pump therapy, as a mean to normalize glycaemic control in IDDM

C. S. Zoupas¹, N. Kefaloyannis², A. Pappas², O. Kepaptzoglou¹, E. Kyrilaki², I. Taraoune¹, F. Giannakopoulos¹, P. Garoutsou¹, H. Vasilopoulos³;

¹Diabetes Center, "Hygeia" General Hospital, Athens,

²Diabetes Center, "Venizelio-Panania", General Hospital, Heraklion,

³Diabetes Center, "Evangelismos" General Hospital, Athens, Greece.

Background and Aims: It is well known that insulin pumps improve glycemic control in adults and children. The Paradigm REAL- Time System (PRT, Medtronic Minimed) is an Insulin Infusion Pump combined with a Continuous Glucose Monitoring System (CGMS) and a subcutaneously self-inserted electroenzymatic glucose sensor with continuous telemetered display of real time glucose values. The aim of this pilot study was to evaluate the impact on glycemic control of PRT Pump in IDDM for a long period of time.

Materials and Methods: A total of 9 patients, mean age 32.9±11.2 years and diabetes duration 16.7±9.1 years ($X \pm SD$), wore the Sensor-Augmented Pump system continuously for 6 months. For educational purposes all subjects were

on real time CGM for the 1st month without the Pump function (remained on MDI). The Pump therapy was added in a second stage. HbA1c, average daily and monthly glucose and hypo/hyperglycemic excursions were evaluated at baseline, 4 and 6 months respectively.

Results: HbA1c(%) decreased from 8.79±1.49 at baseline, to 6.91±0.67 after 4 and 6.98±0.73 after 6 months ($X \pm SD$), ($p=0.009$). Glycemic control improved from the beginning and the average Daily and Monthly Glucose Values did not significantly differ after 1, 4 and 6 months (Table 1). The average Area Under the Curve (AUC) above 180 mg/dl*24h was 11.07±6.77mg/dl*24h after the 1st month use of real time CGM without Pump. Tend to be reduced after the introduction of pump and remained lower, 9.23±4.79 and 9.22±3.15 mg/dl*24h at 4 and 6 months respectively. Average monthly AUC below 70mg/dl remained constant throughout the study period (Table 1), and severe hypoglycemia occurred only once! No significant weight gain were noticed. There was a statistically significant decrease of Total Daily Insulin Dose from 56.1±16.1 to 48.7±19.0 and 45.4±16.8 units ($X \pm SD$) at 4 and 6 months respectively with increased number of bolus (Table 1). All patients remained on the combined therapy after the end of the study.

Conclusion: Our results indicate that continuous use of real time CGM provide a useful tool to optimize glycemic control in patients with IDDM, on both MDI (after 1 month) and pump therapy thereafter. The additional use of CSII leads to a decrease of Total Insulin Dose less hyperglycemic excursions due to increased number of bolus and coupled with the information from real time CGM, it significantly improves glycemic profiles without increasing the risk of hypoglycemia.

Use and acceptability of two minimally invasive continuous blood glucose monitors

D. Cooke¹, L. Steed¹, S. J. Hurel², A. Nunn³, J. Ahlquist⁴, J. Weaver⁵, D. Kerr⁶, M. Barnard⁷, S. Newman¹;

¹Centre for Behavioural & Social Sciences in Medicine, University College London, ²Dept of Diabetes & Endocrinology, UCLH, LONDON, ³Clinical Trials Unit, MRC, LONDON, ⁴Dept of Diabetes & Endocrinology, Southend Hospital, Southend, ⁵Dept of Diabetes & Endocrinology, Queen Elizabeth Hospital, Newcastle, ⁶Royal Bournemouth Hospital, BDEC, Bournemouth, ⁷Dept of Diabetes & Endocrinology, Whittington Hospital, LONDON, United Kingdom.

Background and Aims: Continuous glucose monitoring has been developed to overcome the limitations of traditional blood glucose monitoring methods that only provide a snapshot view of blood glucose levels over time. Widespread use of new technology in healthcare, such as these devices is predicated on their acceptability to patients. Although a number of devices have been introduced in diabetes care, relatively little work has been performed on their acceptability. The aim of this study was to examine the relative use and acceptability of two such devices.

Materials and Methods: As part of a randomised controlled trial, 102 people were randomised to the CGMS (Minimed) and 100 to the Biographer (Animas). All were insulin-requiring people with diabetes who had an HbA1c of at least 7.5%. The acceptability of the devices was assessed over 3-months, using a measure developed specifically for the trial. This examined the relative level of interference of the devices in participants' lives as well as the degree to which they were willing to accept this interference. Both the levels of interference and acceptability were compared between the groups using Mann-Whitney U Tests. Frequency of use was treated as a further indicator of acceptability and analysed using t-tests and ANOVAs.

Results: Four CGMS and 6 Biographer participants chose never to wear the devices. More Biographer than CGMS participants had stopped wearing the device by follow-up (48% v. 10%, $p < .001$). In the CGMS arm, reasons for stopping use included fear of using the monitor ($n=1$), psoriasis requiring treatment ($n=1$), and being too uncomfortable to sleep ($n=1$). Skin reactions ($n=21$) and difficulty using the device ($n=8$) were the main reasons for stopping use in the Biographer group. Mean usage over 3 months was 2.5 in the CGMS group (83% of that requested) and 10 times in the Biographer group (all less than requested). Skin problems were reported in 7% of the CGMS and 98% of the Biographer group. The Biographer group reported greater interference with work ($p=0.046$) and skin care routine ($p=0.001$) while the CGMS group rated more interference with mobility ($p=0.001$). No association between ratings of interference and acceptability was found. Participants in the high-use Biographer group had higher fear of hypoglycemia scores but this was not significant.

Conclusion: Overall, the CGMS was more acceptable to participants than the Biographer in terms of both discontinuation rates and interference with lifestyle. It is notable that many participants continued to use both of these devices despite reporting significant interference with daily living. The use of these devices in the face of significant interference suggests that this is balanced by patients' perception of the potential value or importance of the devices in their care. This study demonstrates that it is possible to assess the relative acceptability of devices in diabetes. This is a crucial aspect in determining whether a device can be routinely incorporated into diabetes management.

Postprandial instead of preprandial calibration allows better accuracy of real-time continuous glucose monitoring (CGM)

I. Capel¹, B. Pons¹, M. E. Hernando^{2,3}, G. García², E. Brugués¹, A. de Leiva^{1,3}, E. Gómez², A. Prados¹, L. Erdozain¹, M. Rigla^{1,3};

¹Endocrinology, Hospital de Sant Pau, Barcelona, ²GBT, Universidad Politécnica de Madrid, ³Isciii, CIBER BBN, Madrid, Spain.

Background and Aims: The last generation of CGM systems have the advantage of showing glucose data in real-time but their accuracy seem to be worse than the previous CGM systems with retrospective data download. The aim of our study was to find out calibration strategies for improving the agreement of both monitoring systems.

Materials and Methods: Eight patients with type 1 diabetes treated with insulin pumps were requested to use simultaneously the blind CGMS-Gold and the real time Guardian RT from Minimed-Medtronic (72 hours) in 3 different periods. Both needles were placed in the same abdominal side (distance < 3 cm) and monitor's time was synchronised with the pump and the glycometer. The CGMS-Gold was calibrated preprandially along the study while, for the Guardian RT, 3 strategies were tested: 3 pre-meal calibrations, calibration at 1 hour postprandial and, finally, pre- and 1 hour postprandial. The simultaneously measured glucose levels were analysed with Pearson correlation and their mean absolute differences with the Wilcoxon test.

Results: Correlation between capillary glucose (used and not used for calibration) and glucose values of the monitor was better for the CGMS-Gold than for the Guardian RT (0.937 vs. 0.784). Calibrations including glucose at 1 hour after meals achieved a stronger correlation between Guardian RT and capillary glycemia and also a significant decrease in the mean absolute difference (see table).

Conclusion: One-hour postprandial calibration of the Guardian RT achieves a better accuracy than preprandial time. No benefit was shown when adding pre- to postprandial values.

	Before meals calibration	1 hour after meals calibration	Before and 1 hour after meals calibration
Correlation GuardianRT-Capillary glucose	0.784	0.950	0.964
Mean absolute difference GuardianRT-CGMS Gold (mg/dl)	38.27	23.4 ($p < 0.05$)	27.6
Correlation GuardianRT-CGMS Gold	0.775	0.928	0.920

Performance of FreeStyle Navigator against standards for Continuous Glucose Monitoring Systems and ISO15197 system accuracy blood glucose meter guidelines

J. R. Bugler, H. Pryor, C. Harris;

Abbott Diabetes Care, Witney, United Kingdom.

Materials and Methods: The FreeStyle[®] Navigator Continuous Glucose Monitoring System is an investigational continuous glucose monitor (CGM) based on Wired Enzyme[™] glucose transduction technology. The FreeStyle Navigator system includes a disposable subcutaneous sensor that can be worn up to 5 days, measuring interstitial glucose concentrations. The accuracy and performance of the sensor were evaluated in a multi-center, prospective, single-arm study. Fifty-eight subjects aged 18 to 64 were enrolled, and each wore two sensors, one on the arm and one on the abdomen. Venous blood glucose measurements were taken using a standard laboratory reference (YSI[™] 2300) every 15 minutes for 50 hours distributed across the 5-day sensor wear, a total of 20,362 comparative measurements were made with the reference method. In the absence of specific ISO performance requirements for CGM's, performance, assessments are likely to be made against the ISO 15197 performance requirements for blood glucose meters. These requirements are designed for evaluation of the same sample on the test device and reference method and generally at times of stable glucose (as subjects attend a clinic appointment). It has not been possible to compare the same interstitial glucose sample for the FreeStyle[®] Navigator measurements to a reference method, hence a venous sample is drawn and glucose measurement made for comparison.

Results: The results demonstrate that at times of relative glucose stability (glucose changing at rates of $< \pm 30$ mg/dL/hr) 87.0% (8984/10331) of FreeStyle[®] Navigator CGM readings were within ± 0.83 mmol/L (± 15 mg/dL) and within $\pm 20\%$ of YSI venous reference values. By glucose range, system accuracy was 64.8% (263/406) within ± 15 mg/dL for glucose concentrations of less than 4.2mmol/L (75mg/dL) and 87.2% (8721/9925) within $\pm 20\%$ for glucose concentrations of at least 4.2mmol/L (75mg/dL). The data set is considerably larger (50-fold) than recommended by the ISO15197 guidelines.

To date, the most widely quoted proposals on CGM performance assessment criteria is the Continuous Error Grid Analysis (Kovatchev, Clarke et al, Diabetes Care Aug 2004). Considering readings at all glucose levels and rates of change ($n=19,627$), FreeStyle[®] Navigator provided accurate readings of 53.2% (≤ 70 mg/dL), 95.7% (70–180mg/dL) and 95.4% (> 180 mg/dL). If just stable glucose results (glucose changing at rates of $< \pm 30$ mg/dL/hr) are assessed accurate readings of 68.0% (≤ 70 mg/dL), 99.5% (70–180mg/dL) and 99.6% (> 180 mg/dL) are calculated ($n=9950$).

Conclusion: The study results support the accuracy and clinical performance of the FreeStyle Navigator Continuous Glucose Monitoring System and demonstrate it as approaching ISO15197 expectations. However a full judgment against the ISO15197 criteria needs to account for the comparison of different samples (blood vs. ISF) and physiologic rates of change when evaluating CGM's. Any future 'standards' developed on performance requirements for CGM's need to account for this issue

Continuous glucose monitoring system glycaemic variability in pediatric type 1 diabetes patients on basal insulin plus prandial insulin:**utility of Fourier analysis**M. Miller¹, N. H. White², H. Chase³;¹sanofi-aventis U.S., Bridgewater, United States, ²Pediatrics and Medicine, Washington University School of Medicine, St. Louis, United States,³Barbara Davis Center, University of Colorado, Aurora, United States.

Background/Aims: Glycemic variability may be an important contributor to the risk of diabetes-related complications and glycemic control, independent of A1C level. In a subset (n=90) of pediatric patients with type 1 diabetes (T1D) participating in a trial comparing insulin glargine (GLAR) (n=45) vs intermediate acting insulin (NPH/Lente) (n=45) as part of a basal-prandial regimen, Continuous Glucose Monitoring System (CGMS) was used to assess glycemic variability. Each patient had complete 24-hour CGMS records at baseline and the results have been reported previously (EASD 2006). Notably, the CGMS standard deviation was significantly reduced from its baseline value for the GLAR group (-13.4 ± 3.1 mg/dL, $P < 0.001$) but not for NPH/Lente (-2.4 ± 3.0 mg/dL, $P = \text{NS}$) at week 24 ($P = \text{NS}$, between groups). The current analysis applies Fourier methodology as a novel approach to assess whether components of glycemic variability at baseline are predictive for A1C.

Material/Methods: Each subject's 24-hour CGMS profile was approximated using the baseline 24-hour glucose mean plus a sum of trigonometric functions having integral frequencies of oscillation (starting from 1 cycle per 24 hours, then 2 cycles, then 3 cycles, etc). Amplitudes of each cycle can be considered components of the overall standard deviation. Patients' baseline data yielded sufficient precision for discerning cycles 1 through 5. The 24-hour glucose mean, A1C, and amplitudes of the first 5 harmonic cycles assessed at baseline for each subject were used in a multiple regression model predicting week 24 A1C.

Results: Baseline factors that were significant predictors of week 24 A1C were A1C and the amplitudes of cycles 2 and 3. Combination of cycle 2 and cycle 3 baseline sinusoidal functions yielded a harmonic amplitude that was the most predictive factor for week-24 A1C ($P < 0.0025$). This amplitude was associated with baseline A1C and baseline mean 24-hour glucose (both at $P < 0.01$). The higher this amplitude at baseline, the higher the week-24 A1C (even after adjusting for baseline A1C).

Conclusions: These data support that glucose variability may contribute to A1C outcome. The baseline amplitude of the second and third harmonic functions is not a component of the 24-hour mean glucose, but a component of variability about the mean, and thus likely most affected by patient meals (size and timing). Fourier analysis is a novel method for examining the relationships between glucose variability and clinical outcome. Further study will determine the ultimate utility of this approach.

Week 24 A1C* versus Baseline CGM Amplitude (2nd + 3rd Harmonic)

*Week 24 A1C estimates are least squares means adjusted for baseline A1C ($P = 0.03$), age ($P = 0.06$), study arm ($P = \text{NS}$). The P value for the second and third harmonic amplitude was $P = 0.003$.

PS 100 Health care delivery: national variations in practice

1016

Comparison of an American and a Swedish diabetes population: Better glucose but worse blood pressure control in the SwedesU. Lindblad¹, A. Melander², R. D. Langer³;¹Clinical Sciences, CRC, University Hospital, Malmö, Sweden, ²Nepi Foundation, CRC, University Hospital, Malmö, Sweden, ³Geisinger Center for Health Research, Geisinger Health System, Danville, United States.

Background and Aims: The hyperglycaemia of diabetes promotes both vascular and neuronal damage. Hypertension is common in diabetes patients and is a major contributor to the vascular complications. Hence, optimum control of both glucose and blood pressure levels is important, and it is of interest to assess and compare the extent of glucose and blood pressure control in populations in different countries. The populations served by the Geisinger Health System (GHS) in Pennsylvania, USA, and the Skaraborg Primary Health Care (SPH) in southwest Sweden differ geographically but have important demographic similarities. Both are primarily rural, have similar ethnic mix, health care infrastructure and physical environment, and minor immigration and emigration. Both have experienced a shift from physically demanding jobs to more sedentary occupations, and their prevalence of obesity is higher than their country average. Comprehensive longitudinal electronic health care records are available in both areas. Our aim was to compare glucose and blood pressure control in these two diabetes populations.

Materials and Methods: Diabetes patients seen within two preceding years were identified from the electronic records. Equivalent data on demographics, height, weight, HbA1c, systolic/diastolic blood pressure and medication were extracted. Uncontrolled glucose was defined as HbA1c $\geq 7.0\%$ and uncontrolled blood pressure as $\geq 140/90$ mm Hg. Logistic regression analyses were carried out with age, gender, body mass index (BMI), number of antihyperglycaemic drugs, insulin dependence, treatment with an ACE inhibitor (ACEI) or angiotensin II receptor blocker (ARB), and type of health insurance as covariates when appropriate, and differences calculated as Odds Ratios (OR).

Results: Diabetes was present in 26,443 GHS and 10,391 SPH patients. The US diabetes population had a higher proportion of women (51.5 vs. 47.3%; $p < 0.001$), was younger (mean 62.7 vs. 67.9 years; $p < 0.001$), more overweight (mean BMI 33.2 vs. 29.5 kg/m²; $p < 0.001$), treated with more antihyperglycaemic drugs ($n = 1.6$ vs. 0.9; $p < 0.001$), and had worse glucose control (proportion with HbA1c $\geq 7.0\%$ 59.9 vs. 25.4%; $p < 0.001$, and mean HbA1c 7.54 vs. 6.29%; $p < 0.001$). The difference in glucose control remained after adjustments for differences in gender distribution, age, BMI, insulin dependence, antihyperglycaemic drug treatment and access to care. In contrast to their worse glucose control, the US diabetes population had better blood pressure control. Mean blood pressure was lower (126/70 vs. 141/78 mm Hg; $p < 0.001$); more had antihypertensive medication (78 vs. 60%; $p < 0.001$), including an ACEI or ARB (48.8 vs. 37.4%; $p < 0.001$) and a diuretic (36.6 vs. 31.1%; $p < 0.001$), and more of those on antihypertensive drug treatment had blood pressure $< 140/90$ mm Hg (67 vs. 32%; $p < 0.001$). The difference in blood pressure control remained after adjustments for differences in gender distribution, age, BMI, and type of antihypertensive treatment.

Conclusion: In comparable American and Swedish diabetes populations, glucose control was better among the Swedes but blood pressure control better among the Americans. While differences in diet, alcohol, physical activity and gene-environment interactions may contribute, differences in screening, physician attitudes and treatment compliance are more likely.

1017

Does Quality and Outcomes Framework (QoF) reflect a good standard of care for individual patients with diabetes?J. Pachaippan¹, S. Koganti¹, R. Gadsby², J. Morrissey¹, V. Patel¹;¹Diabetes Centre, George Eliot Hospital, Nuneaton,²Red Roofs Surgery, Nuneaton, United Kingdom.

Background and Aims: The UK GMS (General Medical Services) contract is devised to improve services to patients in primary care. The QoF (Quality

and Outcomes framework) is the mechanism to assess GP (General Practice) performance. It enables payment for the quality of care given to patients not just the size of the list. Most practices achieved maximum points, reflecting good standards of care. The aim of this study is to find out whether QoF reflects a good standard of care for *individual* patients with diabetes.

Materials and Methods: 3 diabetes centres (one each from general practice, community and hospital) were selected. From GP, all patients with diabetes (who were included for QoF, n=537) were selected. From community and hospital centres 99 and 100 patients were randomly selected respectively. QoF points for diabetes (except Flu indicator) for each of these centres and *individualised QoF (i-QoF)* points for every patients in the study were calculated. Results were analysed.

Results: GP centre achieved 89 QoF points (maximum of 90 points excluding “Flu” indicator) compared to community 69.7 points and hospital 63.5 points reflecting different cohorts of patients looked after in each setting. *i-QoF* varied widely between the three settings, the average *i-QoF* being 79.9 for GP, 65.5 for community and 64.8 for hospital. Only 42% (n=270) of patients in GP, 8% in community and 3% in hospital achieved maximum *i-QoF*. The two poorly performed clinical indicators in the three (GP;community;hospital) settings were HbA_{1c} of 7.5 or less (75%;39%;35%) and BP of 145/85mmHg or less (78%;63%;71%).

Conclusion: Although QoF reflects improved standard of care for patients with diabetes, *i-QoF* showed the need for better standard of care for *individual* patients.

QoF vs i-QoF

Diabetes Centre	QoF points	average <i>i-QoF</i>	<i>i-QoF</i> points (inter-quartile range)
GP	89	79.9	73–90
Community	69.7	65.4	52–73
Hospital	63.5	64.8	54–75

1018

Quality and Outcomes Framework (QOF) and GMS Contract: are they really representative of quality of service delivered in primary care in the UK

L. Varadhan¹, S. Sankaranarayanan¹, P. O Hare¹, V. Patel²;

¹Diabetes Centre, University Hospital Coventry and Warwickshire, Coventry, ²Diabetes Centre, George Eliot Hospital NHS Trust, Nuneaton, United Kingdom.

Background: The General Medical Services contract in the UK is a novel method of investing in primary care to facilitate flexibility of care delivery and reward practices based on their clinical and organisational quality. Apart from providing essential services, the practices could choose what services to provide, and get scored and paid based on depth of quality and breadth of framework delivered, as measured by the QOF indicators. A maximum of 99 points could be scored in diabetes care as shown in the table below, calculated as 3 points if 90% of patients had HbA_{1c} checked and 16 points if 50% of them were <7.4%. However this system does not consider the proportion of patients beyond the threshold percentage needed to reach to score.

The aim of our study was to assess if the overall QOF score was actually representative of the individual diabetes care every patient was receiving, by calculating and correlating with an individualised QoF score (*i-QoF*).

Methods: Records of 404 patients with type 2 diabetes were collected from 6 different general practices from socially deprived area in Coventry, UK. The overall QOF score was calculated. However we calculated a maximum of 79 points only as data on smoking and feet examination were not available. Individual QOF scores were then calculated based on the same criteria and its average achieved.

Results: The overall QOF score achieved on this cohort of patients was 78.6/79.

Parameter	Target	GP/Max	% to target
DM1 – Record keeping for patients	100%	6/6	100%
DM11 – BP measured	25–90%	3/3	97.5%
DM12 – BP≤145/85	25–55%	17/17	67.3%
DM16 – Total cholesterol (TC) measured	25–90%	3/3	98.5%
DM17 – TC ≤5mmol/L	25–60%	6/6	81.7%
DM13 – Microalbuminuria	25–90%	2.6/3	80.9%
DM14 – Record of creatinine	25–90%	3/3	98.5%
DM5 – HbA _{1c} record	25–90%	3/3	98.3%
DM6 – HbA _{1c} ≤7.4%	25–50%	16/16	59.2%
DM7 – HbA _{1c} ≤10%	25–85%	11/11	91.1%
DM8 – Eye screening record	25–90%	5/5	100%
DM15 – MA on ACE/ARB	25–70%	3/3	76.2%
Total QOF		78.6/79	62.95

Apart from record of retinopathy, 100% was not achieved in any of the above targets recommended. 2.5% of the patients did not have a proper record of blood pressure and 33% failed to reach the target range recommended. 1.5% had not had their cholesterol or HbA_{1c} checked in the previous 15 months. 40.8% had an HbA_{1c} above 7.4% and 8.9% had above 10%. The average of *i-QoF* calculated was 62.95/79, ranging from 11 to 79, with 9% of the patients scoring less than 40 and only 39.1% reaching more than 70. Considering HbA_{1c}≤7.4%, BP≤145/85 and TC ≤5mmol/L as essential indicators of good diabetes management, 3.2% of the patients had all 3 parameters out of range, 17.3% had at least 2 out of range and 41.8% were not treated to target in at least one of them.

Conclusion: The QOF scoring method may be overestimating the quality of care provided to patients with diabetes in the community. A significant number of patients may still not be treated to targets and require better service, which could be overlooked by the QOF scoring method. Individualised strategies are required to optimise diabetes service delivery in the community to achieve comprehensive results in terms of prevention of complications.

1019

Influence of the national programme “Diabetes in the Community” on the diabetes patients’ cost in Israel between the years 2003 – 2004

M. Goldfracht^{1,2}, R. Adler³, N. Lieberman⁴, A. Porath⁴;

¹Quality Improvement Department, Medicine Section, Community Division, Clalit Health Services, Tel-Aviv, ²Department of Family Health Care, Bruce Rappaport Faculty of Medicine, The Technion, Haifa, ³Economics Revision Department, Community Division, Clalit Health Services, Tel-Aviv, ⁴Medicine Section, Community Division, Clalit Health Services, Tel-Aviv, Israel.

Background and Aims: The ‘Diabetes in the Community’ program has been in operation for over 10 years, the aims of which are to improve control and management of diabetes patients in Clalit, Israel. This study reviewed the relationship between quality of care and cost of diabetes in patients under the management of the Clalit Health Maintenance Organization (HMO), Israel during the years 2003 and 2004. Clalit is Israel’s largest HMO and insures 70% of diabetes patients in Israel, according to the National Indicators Program.

Materials and Methods: The study analysed the cost impact of improved control of diabetes in approximately 200,000 diabetes patients in Clalit from 2003–2004, taking factors such as age, gender, ethnicity, socio-economic status, type of treatment, additional diagnoses, serious illnesses and oncology, into account.

Results: During the study period, the prevalence of diabetes in Israel was 3.6% of the population, and 5.0% for Clalit. This population has multiple illnesses (20% having diabetes alone) and were older, 80% over 55 years of age. The low socio-economic status of this population was mirrored by the 39% of the diabetes population who relied on social security benefits, the costs for whom were, on average, 34% more than for those not receiving social security. Interestingly, the incidence of diabetes was 10% more in the non-Jewish sectors compared with the Jewish population. The financial burden of serious illness or oncology was such that these patients (11%)

were not included in the calculations. It is accepted that the costs for diabetes patients are likely to increase over time due to complications of the disease; however, despite the projected increase in weighted per-capita costs for diabetes patients between 2003 and 2004, the report found a 3.3% decline in costs, with a saving of approximately corrected for purchasing power parity, PPP, US\$3.46 million per year. The decline in costs, observed in all age groups and districts, was primarily attributed to a reduction of 6.4% in the number of hospitalization days. Fewer hospitalization days and more ambulatory services were required for patients with well-controlled diabetes ($HbA_{1c} \leq 7$), who used 21.2% fewer resources than those whose diabetes was poorly controlled ($HbA_{1c} > 9$). This study showed that the average diabetes patient incurred costs 1.54 times more than the average HMO patient. Between 2003 and 2004, the weighted per capita cost of diabetes patients declined by 3.3%, in contrast with stable costs for all policyholders. The annual savings totaled PPP US\$ 3.45 million, primarily due to the decline in hospitalization costs, as a result of better control of the disease. An inverse correlation was established between diabetes patient costs and level of diabetes control, in that the well-controlled group used 21.2% fewer resources in comparison with the poorly controlled group.

Conclusion: The 'Diabetes in the Community' program has resulted in better control of diabetes in Clalit and, as well as improving the quality of life, morbidity and mortality of diabetes patients, has reduced associated costs by PPP US\$2.56–3.45 million per year.

Improvements in the quality of clinical diabetes care in Norwegian general practice 1995 – 2005

J. G. Cooper¹, T. Claudi², A. K. Jennum³, M. F. Hausken⁴, W. Ingskog³;

¹Department of Medicine, Stavanger University Hospital,

²General practice, Rønvik Medical Centre, Bodø, Norway, ³Diabetes Research Centre, Aker University Hospital, University of Oslo, Norway,

⁴Stavanger Health Research, Stavanger University Hospital, Norway.

Background and Aims: Norway has had national guidelines for the care of diabetes in general practice since 1988. The guidelines have been revised in 1995, 2000 and 2005. The aim of this study is to assess changes in quality of care for patients with type 2 diabetes between 1995 and 2005.

Materials and Methods: 33 general practices in two geographical areas of Norway (Rogaland and Salten) participated in the study. Medical record data were collected from 1470 patients with type 2 diabetes in 1995 and 2792 patients in 2005. All known patients with diabetes in the practices were included in the study. Most of the practices were rural serving defined geographical populations. The same 33 practices participated in 1995 and 2005. Quality of care was assessed against predefined review criteria based on key recommendations in the national guidelines. Data collection from computerised records was manually validated by a research nurse/doctor in 1995 and by a research nurse in 2005.

Results: Between 1995 and 2005 mean age decreased from 69.1 to 67.4 years, mean weight increased from 81.1 to 86.5 kg, mean diabetes duration increased from 6.6 to 7.0 years. The quality of care improved markedly from 1995 to 2005. Important changes occurred in several variables potentially related to improved health outcomes. These included significantly improved glycaemic control ($HbA_{1c} \leq 7.5\%$) from 52.1% to 69.0%, control of systolic blood pressure (≤ 140 mmHg) from 40.6% to 59.4% and control of serum cholesterol (≤ 5.0 mmol/l) from 18.1% to 54.0%. Mean values improved significantly HbA_{1c} 7.74% to 7.15%, systolic blood pressure 150.0 to 140.4 mmHg and serum cholesterol 6.28 to 5.0 mmol/l. There was an improvement in the percentage of patients with a recorded HbA_{1c} 88.5% to 92.5%, recorded blood pressure 86.5% to 89.2% and recorded serum cholesterol 50.0% to 87.8%. Significant improvements also occurred in referral to ophthalmological examination 52.6% to 76.1%, documentation of smoking habits 21.4% to 60.0%, recording of height 14.6% to 42.0% and weight 41.6% to 57.4%. The percentage of patients treated with diet alone 30.4% vs. 28.3%, oral agents alone 43.0% vs. 46.1% and insulin (with or without oral agents) 26.6% vs. 25% was similar in 1995 and 2005. Drug treatment of associated conditions was intensified in the same period, hypertension 33.1% vs. 59.8%, dyslipidemia 4.8% vs. 45.7% and 19.7% vs. 33.9% received ASA. The number of patients with diabetes in the practices increased by 90% from 1995 to 2005. Even after taking into account new diagnostic criteria in 1998 (with a lower cutoff for fasting plasma

glucose) and increased efforts to diagnose diabetes early, our study suggest that there has been a striking increase in the prevalence of diabetes between 1995 and 2005.

Conclusion: Substantial improvements were seen in the quality of diabetes care in Norwegian general practice between 1995 and 2005.

Current diabetes care status in China: an observational survey study (DIABCARE 2006)

C. Pan¹, W. Yang², W. Jia³, J. Weng⁴, H. Tian¹;

¹Dept. Endocrinology, Chinese PLA General Hospital, Beijing,

²Dept. Endocrinology, China-Japan Friendship Hospital, Beijing,

³Dept. Endocrinology, Shang Hai No. 6 People's Hospital, Shanghai,

⁴Dept. Endocrinology, The First Affiliated Hospital, Sun Yet San University, Guangzhou, China.

Background and Aims: China is one of the countries with largest diabetes population. Surveillance of diabetes is an urgent and necessary step for the diabetes prevention and control. DIABCARE studies were designed to describe the current status of diabetes care in China and explore the relationships among diabetes control, diabetes management and late diabetic complications status, which may affect the quality of diabetes management. Four studies were initiated in the year of 1998, 2001, 2003 and 2006, providing an opportunity to demonstrate the change in diabetes management in China.

Materials and Methods: In 2006, a total of 2779 subjects with diabetes (mean age: 61.5 years; BMI: 24.6 kg/m²), who registered for management of diabetes for more than 12 months at 60 hospitals in 18 cities, were participated in this surveillance. The subjects were enrolled in an order of visit. No more than 10 consecutive subjects would be screened every day. Data were collected on a retrospective manner by reviewing patient medical records, interview and laboratory assessments. HbA_{1c} was measured at central laboratory. All data were tabulated and the descriptive statistical analysis was used.

Results: Mean age at the time when diabetes being diagnosed, diabetes duration, sex distribution and type of diabetes were comparable with previous DIABCARE studies. Of all, 97.8% of subjects were diagnosed as type 2 diabetic patients in DIABCARE 2006 project. The mean age at the time when diabetes being diagnosed was 52.8 years, and the mean diabetic duration was 8.6 years. Furthermore, BMI was increased from 23.7 kg/m² in 1998 to 24.6 kg/m² in 2006. The mean HbA_{1c} was decreased from 8.8% in 1998 to 7.6% in 2006. Geographical difference in HbA_{1c} levels was observed in cities. The biggest gap of HbA_{1c} levels among cities was more than 1%. In 2006, only one fourth of subjects achieved the target of $HbA_{1c} \leq 6.5\%$. 40% of subjects met the HbA_{1c} target $< 7\%$. An increase in the frequency of self blood glucose monitoring was observed: 9 times per month in 2006 compared to 4 times per month in 1998. 96.9% and 87.5% of subjects had at least one time of FPG and PPG monitoring in the past 12 months respectively. In subjects treated with OADs, most of subjects had combination therapy (55.9%). More subjects were treated with insulin either in combination with OAD or insulin alone in 2006. This increase was associated with diabetic duration. In 2006, 22.8% of subjects were treated with insulin. Eighty-eight percent of insulin treated patients achieved the treatment with human insulin, which was the most popular insulin therapy. More than half of insulin treated patients used with premixed human insulin (58.2%).

Conclusion: The glycaemic control was improved in the majority of patients with diabetes during 1998–2006. However, glycaemic control was still unsatisfactory mainly due to lacking of more comprehensive and effective therapy. The gap between therapeutic guideline and daily clinical practice strongly indicates that there is an urgent requirement for dramatic improvements in diabetes management in China.

A nationwide quality improvement project in Belgium: evolution over 5 years

N. Debacker¹, F. Nobels², P. Van Crombrugge², A. Scheen³, C. Mathieu⁴, V. Van Casteren⁵;

¹Epidemiology, Scientific Institute Public Health, Brussels,

²Endocrinology, OLV Ziekenhuis, Aalst, ³Endocrinology, CHU Sart Tilman, Liege, ⁴Endocrinology, UZ Gasthuisberg, Leuven, Belgium.

Background and Aims: Describe the organisation of the Initiative for Quality Improvement and Epidemiology for Diabetes (IQED), a quality assurance system that was set up in 2001 in Belgian hospital-based multidisciplinary diabetes centres, and its effects on the quality of care in the 5 following years.

Material and Methods: Up to now four cross-sectional data collections (2001, 2002, 2004 and 2006) were organised. Approximately 120 diabetes centres provided data on a random sample of 10% of their adult diabetes patients on ≥ 2 daily insulin injections. By using the DiabCare[®] basic information sheet at start and the new IQED-software from 2006 on, data on patient characteristics, glycemic control, cardiovascular risk profile, diabetes complications, blood glucose self-monitoring, follow-up procedures and treatment were obtained. Local quality evaluation and promotion were encouraged by returning an elaborate feedback (benchmarks) regarding process and outcomes, by a generation of a global report and by organising information meetings.

Results: The pooled sample consists of 9,194 (32%) type 1 and 19,828 (68%) type 2 diabetes patients, with a mean age of respectively 46 and 66 years and a mean diabetes duration of respectively 17 and 14 years. Especially the type 2 diabetes population presents a high prevalence of complications as expected in hospital-based centres. At start quality of care was much better in terms of risk factor testing rates, than in terms of patients meeting goals for risk factor management (table 1). Indeed except for the determination of LDL cholesterol, the other processes of care were carried out in at least 80% of the patients. After 5 years significant improvements were seen in almost all risk factor testing rates. Improvements in intermediate outcomes were less obvious, except for a clear reduction in LDL-cholesterol (from a mean of 121 mg/dl in 2001 to 99 mg/dl in 2006). An enquiry revealed that at least 80% of the centres value the tools offered by this study. Moreover at least 50% of the centres initiated local quality promoting initiatives using the feedback data.

Conclusions: The obligatory participation to the quality assurance system has led to a large sample of representative data on intensively treated diabetes patients in Belgium. The results show that it is feasible to implement a continuous quality improvement project on a nation-wide scale, with clear improvements in process indicators and to a lesser extent in intermediate outcome indicators.

Table 1: Risk factor control at start and in 2006

		Type 1 diabetes		Type 2 diabetes	
		2001	2006	2001	2006
HbA1c (%)	% tested	96.4	99.6*	95.4	99.3*
	% < 7%	28.5	21.3*	32.5	29.7*
LDL-cholesterol (mg/dl)	% tested	42.2	48.2*	48.6	53.2*
	% < 130 mg/dl	68.1	84.7*	64.0	82.7*

Quality indicators of diabetes care: the Italian experience

M. C. Rossi¹, F. Pellegrini¹, A. Cimino², C. Giorda³, I. Meloncelli⁴, G. Vespasiani⁴, G. De Bigontina⁵, U. Valentini², A. Nicolucci¹;

¹Clinical Pharmacology and Epidemiology, Consorzio Mario Negri Sud,

S. Maria Imbaro (CH), ²Diabetes Unit, A.O. Spedali Civili, Brescia,

³Diabetes and Metabolism Unit, Local Health Unit and Maggiore Hospital, Chieri (TO), ⁴Diabetes Unit, Madonna del Soccorso Hospital,

S. Benedetto del Tronto (AP), ⁵UOS di Diabetologia, Ospedale del Cadore, Dolomiti – Belluno, Italy.

Background and Aims: In the context of a national quality improvement program developed by the Associazione Medici Diabetologi (AMD), a comprehensive yet parsimonious set of process and outcomes indicators (www.aemmedi.it) identified to describe the performance of Diabetes Outpatient Clinics (DOCs) – AMD members – in Italy.

Materials and Methods: Information on quality indicators was derived from computerised medical records using a software specifically developed, allowing the creation of a standardised dataset to be analysed on an annual basis (AMD Data File). The first analysis was performed on all the patients who had had at least one encounter with the DOC during 2004. Process measures included frequency of testing of HbA1c, lipids, blood pressure, microalbuminuria, and serum creatinine, and foot examination. Outcome measures included HbA1c, blood pressure, and lipid levels. The percentage of patients achieving specific therapeutic goals were also evaluated. Centres performance was compared to a gold standard, that was based on the 75[°] percentile of the values distribution of each process or favourable outcome indicator (or 25[°] percentile for unfavourable outcomes) obtained in those centres with adequate completeness of their AMD Data File.

Results: Overall, 77 centres were included in the analysis. The gold standard was calculated on 30 centres. The final database contained 123,863 patients (median=1,286 per centre; range=149 – 6,076); of these, 6,999 (5.7%) had T1DM, 114,249 (92.2%) had T2DM, and the remaining had other conditions. Among patients with diabetes, 53% were males and 56% were aged >65 years. Over 16,000 patients had been referred to a DOC for the first time during the examination year. Results show an acceptable metabolic control in both T1DM and T2DM (over 90% of patients had HbA1c measured every year and mean HbA1c values were 8.0 \pm 1.5 and 7.4 \pm 1.5, respectively), but process indicators document an unsatisfactory low rate of renal function monitoring (59% in T1DM and 48% in T2DM) and foot examination (23% in T1DM and 22% in T2DM). Outcomes indicators highlight a significant rate of patients with uncontrolled hypertension (>130/85 mmHg; 56% in T1DM and 70% in T2DM) and dyslipidemia (LDL cholesterol >100 mg/dl: 68% in T1DM and 70% in T2DM). A wide geographic variation was also documented, and the performance of individual centres showed marked differences in comparison with the gold standard for most of the quality indicators utilised.

Conclusion: Patterns of diabetes care will be re-analysed on annual basis and published in AMD Annals. Each centre will be able to compare its own performance against the gold standard and longitudinally across years, as a benchmarking activity. The use of “real” reference targets as a gold standard as opposed to theoretical guidelines could greatly help in improving the quality of diabetes care, by setting realistic objectives.

PS 101 Health care delivery: keeping up with the guidelines

1024

Primary care physicians identify and act on glycaemic abnormalities found in episodic, intensive blood glucose monitoring data from non-insulin treated type 2 diabetics

W. H. Polonsky¹, R. S. Wagner²;

¹Psychiatry, University of California, San Diego, Del Mar, United States,

²Roche Diagnostics, Indianapolis, IN, United States.

Background and Aims: Primary care physicians (PCPs) often make therapy adjustments for non-insulin treated (NIT) type 2 diabetes (T2D) on the basis of A1c alone without considering self-monitoring blood glucose (SMBG) data. The purpose of this study was to determine if PCPs could accurately identify glycaemic abnormalities in episodic (short term), intensive SMBG data from NIT T2D and if their therapeutic decisions would be changed by evaluation of SMBG data.

Materials and Methods: Twenty-five case studies demonstrating a range of glycaemic states were prepared from data from subjects with T2D who participated in a prior study on episodic, intensive SMBG. Case studies included patients' history, current medications, current A1c values, and 3–7 days of SMBG data. Five diabetes care experts evaluated the case studies, identified glycaemic abnormalities, and determined if and how the patients' therapy should be changed. Subsequently, board certified Family Practitioners (n = 36) and Internists (n = 25) evaluated the case studies first without SMBG data and then with SMBG data. Their interpretations of the SMBG data were compared to the interpretations of the experts. The PCPs' therapeutic recommendations for case studies without SMBG data were compared to those the PCPs made for case studies with SMBG data to determine if the availability of SMBG data in addition to A1c values changed the PCPs' therapeutic recommendations. At the end of the study, a survey questionnaire evaluating the value of episodic SMBG data in addition to A1c results was administered.

Results: Two case studies representing normoglycemia were discarded after review due to poor design. For the 23 remaining case studies with SMBG data, 78% of the PCPs correctly identified normoglycemia, hypoglycemia, hyperglycemia, elevated fasting values and elevated postprandial values. When the PCPs assessed case studies with SMBG data, 77% of them changed the therapeutic decisions they had made previously when evaluating the case studies without SMBG data. When hypoglycemia was identified, PCPs decided to change the time the current medication was given, reduce the dose of the current medication, discontinue the medication altogether, or change to a new medication. When frequently elevated fasting levels or elevated postprandial SMBG levels were apparent, PCPs elected to change the time the current medication was given, increase the dose of the current medication, switch to a new medication, or add a new medication to the current treatment regime. PCPs were asked to assess the added value of SMBG data when presented with A1c data. The PCPs (86%) found the BG information to be of equal or greater value than the A1c while less than 14 % found it to be of lesser or no value.

Conclusion: These data show that PCPs can correctly identify glycaemic abnormalities in episodic, intensive SMBG data. Indeed, PCPs' assessment of the SMBG data prompted most of them to change the therapeutic choices made initially when the case studies did not include the SMBG data. In addition, the vast majority of participating PCPs found the SMBG data to be valuable when evaluating the case studies. These findings suggest that PCPs can effectively utilize SMBG data in addition to A1c when managing NIT T2D. Additional studies may be worthwhile to determine the impact of episodic, intensive SMBG monitoring on glycaemic control in actual clinical practice.

1025

Effect of nurse-led intensified management of hypertension in patients with and without advanced diabetic nephropathy

S. Anandarajah, R. Squires, K. Kular, T. Khong, D. Harry, K. Zitouni, K. A. Earle;

Cellular and Molecular Medicine, Thomas Addison Diabetes Centre, London, United Kingdom.

Background and Aims: Lowering blood pressure is the key strategy for preserving renal function in patients with diabetes. Recent reports suggest that a nurse-led approach is more effective than conventional care in achieving this aim. It is unknown to what extent this strategy is applicable or advantageous in patients with advanced nephropathy in secondary care

Materials and Methods: Consecutive patients with diabetes and a systolic (SBP) and/or diastolic blood (DBP) pressure > 130 and/or > 80 mmHg with either advanced nephropathy (ADN) from a nephrology clinic, or with preserved renal function (PRF) from a diabetes clinic were eligible to enter a 6 month programme of nurse-led, intensified care for hypertension.

Patients received a baseline assessment and standardised non-pharmacological advice. Sitting BP was measured after 5 minutes rest using a digital oscillometric device. Venous blood was sampled to measure total cholesterol (TC) by enzymatic method, glycated haemoglobin (HbA1c) by HPLC and creatinine by a Jaffe rate-reaction. Patients were reviewed monthly by a nurse not specialised in diabetes care who adjusted treatment according to an algorithm and addressed issues of concordance.

Results: One hundred patients (57% male) were studied. There were no differences in mean [SD] age and baseline SBP, DBP and TC between the PRF (n=39) and ADN (n=61) groups (61.6 [13.1] vs. 64.8[12.6] yrs; p=0.23, 143.2[18.0] vs. 146.3[20.7] mmHg; p=0.42, 78.8[12.7] vs. 76.1[12.4] mmHg; p=0.30 and 4.5[1.3] vs 4.7[1.0] mmol/l;p=0.58) respectively. Plasma creatinine (89.4[38.8] vs. 123.1[59.5] umol/l; p=0.002) and HbA1c (7.1[1.3] vs. 8.2[1.7];p=0.001) were significantly lower in PRF compared with the ADN group. At the end of the programme there were significant decrements in the PRF and ADN groups for mean [95% confidence interval] SBP (- 9.9 [-2.1 to -17.7]; p=0.02 and -9.6 [-3.3 to -16.0]; p=0.003) and DBP (-5.5[-0.2 to -10.9];p=0.04 and 5.2[-1.4 to - 9.1];p=0.009) and a tendency for HbA1c to be lower (-0.5 [0.0 to -1.0]; p=0.05 and - 0.42 [0.03 to -0.87];p=0.07 respectively). There was a significant fall in total cholesterol in the ADN group (-0.60[-0.3 to -0.9]; p=0.001)

Conclusion: Patients with advanced diabetic renal disease benefit from a nurse-led approach in the management of uncontrolled hypertension similarly to less complex patients. This intervention also positively impacts on cardiovascular disease risk and diabetes control. A regimen of monthly review by nurses is a useful adjunct to secondary care.

1026

Variation in efficiency of diabetes care across 28 medical groups: potential for improved care and reduced costs

P. J. O'Connor, T. J. Flottesmesch, R. R. Paskach, G. J. Kitching;

Research, HealthPartners Research Foundation, Minneapolis, United States.

Background and Aims: The objectives of this analysis are: 1) to explore methods of measuring the efficiency of diabetes mellitus (DM) care across medical groups (MGs), 2) to quantitate variation in the provision of diabetes care provided by MGs, and 3) to estimate potential resource savings and quality improvements.

Materials and Methods: Study subjects were 2,511 adults with DM, insured by a single payer during 2003–2004, and receiving care at one of 33 Minnesota medical groups. Chart abstractions assessed A1c <8%, BP<130/85, and LDL<130 mg/dl. Standard methods were used to calculate resource utilisation by converting all billing into resource value units (RVUs) scaled by a single cost factor. Quality of care was quantified as the proportion of patients achieving two or more clinical goals (A1c < 8%, BP < 130/85, or LDL < 130mg/dl). Non-parametric Data Envelopment Analysis(DEA) was used to model the relationship between resource utilisation and quality of care, to rank MGs in terms of efficiency of diabetes care, and to identify performance benchmarks for MGs.

Results: MGs with fewer than 30 DM patients (n=5) were excluded. The remaining 28 MGs averaged 109 sampled DM patients (range: 174 to 38). Median per patient costs were \$19,045 with MG-specific medians ranging

from \$8,822 to \$38,842. 73% of all patients (n=1,824) achieved two or more goals with MG-specific range from 57% to 82%. After controlling for patient age and comorbidities, three MGs were identified as relatively efficient “benchmarks”, four were classified as outliers, and twenty-one were found inefficient. If inefficient MGs performed at benchmark levels an estimated 35% decrease in resource use OR an 8% increase in patients achieving two or more goals could be realized.

Conclusions: There is considerable variation in efficiency of diabetes care across the medical groups in this study. Health plans or national health care systems can use existing data sources to assess efficiency of diabetes care across medical groups. Improved efficiency of diabetes care could lead to either cost reduction or quality improvement and could have substantial benefits for both patients and payers.

EuroAction: the achievement of lifestyle and risk factor targets in high risk individuals and their partners

K. Kotseva¹, S. B. Connolly¹, C. Jennings¹, A. Mead¹, J. Jones¹, A. Holden¹, T. Collier², D. De Bacquer³, G. De Backer³, D. A. Wood¹;

¹Cardiovascular Medicine, Imperial College, London, United Kingdom,

²Epidemiology and Public Health, London School of Hygiene and Tropical medicine, London, United Kingdom,

³Public Health, University of Ghent, Belgium.

Background and Aims: EuroAction is a cluster randomised controlled trial of a nurse-led multi-disciplinary preventive cardiology programme which aims to manage high risk patients and their partners to the European lifestyle, risk factor and therapeutic targets for cardiovascular disease prevention.

Materials and Methods: In each of 6 European countries, pairs of comparable general practices were randomised to provide the EuroAction cardiovascular prevention programme (INT) or to be monitored for usual care (UC). High risk individuals ≥ 50 years with no history of cardiovascular disease were identified in 3 groups: (I) at high multifactorial risk (HeartScore $\geq 5\%$ over 10 years); (II) treated hypertension/dyslipidaemia; and (III) diabetes mellitus < 3 years. Patients and their partners were invited to attend the EUROACTION programme with a follow up assessment at one year. Using random effects meta-analysis (REML estimation) differences in proportions achieving goal were compared.

Results: 1019 patients in INT and 1005 patients in UC attended the one year assessment. 225 partners (63% of those contactable) in INT and 335 partners in UC (67% of those contactable) attended the one year assessment. Despite patients in Groups I and II being proactively screened for diabetes, there was no significant difference in the overall prevalence of diabetes at one year (32.5% INT, 26.8% UC, $p=0.46$). There was a trend towards a higher prevalence of impaired glucose tolerance in INT compared with UC (10.0% INT, 2.0% in UC, $p=0.08$). Tables 1 shows the proportions of patients and their partners achieving the European lifestyle, risk factor and therapeutic targets.

Conclusion: Although EUROACTION programme did not result in significant reduction in central obesity, it did help high risk individuals and their partners to significantly increase their physical activity levels in comparison with usual care. In addition, there was a significant improvement in their blood pressure control with a trend towards improved glycaemic control. There was also an improvement in the use of cardioprotective medication particularly ACE inhibitors/ARBs and statins in high risk patients. Therefore EUROACTION achieved its overall aim in raising standards of preventive cardiology care for high risk patients and their partners in everyday clinical practice.

Proportions of patients and partners achieving European targets at one year

Proportions achieving target	Patients INT	Patients UC	Partners INT	Partners UC
Waist circumference: M< 94 cm, W< 80 cm	27	21	34	30

HbA_{1c}: the gap between guidelines and clinical reality across eight countries

E. S. Kilpatrick¹, C. Ørskov², K. Berntorp³, T. Koblik⁴;

¹Clinical Biochemistry, Hull Royal Infirmary, United Kingdom,

²Novo Nordisk A/S, Copenhagen, Denmark,

³Endocrinology, Malmö University Hospital, Sweden,

⁴Clinic of Metabolic Diseases, Jagiellonian University, Krakow, Poland.

Background and Aims: Expert guidelines highlight that good glycaemic control is vital to improve quality of life and reduce the risk of complications in patients with diabetes. Despite this, glycaemic control is sub-optimal, with HbA_{1c} levels $>6.5\%$ in the majority of patients. For example, 83% of patients in India have reported HbA_{1c} levels $>7\%$ and approximately half of patients in the UK have levels $\geq 7.5\%$. We present data from a recent, global survey that evaluated HbA_{1c} awareness, attitudes and behaviours among healthcare professionals (HCPs) and patients across 8 countries, with the aim of identifying factors responsible for the gap between guidelines and clinical reality.

Materials and Methods: 185 HCPs and 95 patients with type 2 diabetes in Canada, Poland, Russia, Sweden, Turkey and the UK (Aequus Research), China (Synovate) and India (AC Nielsen) took part in 1-hr face-to-face interviews to provide qualitative data on the underlying causes of the difference between the guidelines and clinical reality. A larger sample of HCPs (n=1357) and patients (n=1006) participated in 20-min telephone interviews to obtain quantitative data, including medication, information sources, glycaemic control and frequency of consultation. Patients and HCPs had tailored questions.

Results: The patient interviews showed differences between countries in terms of awareness of HbA_{1c} (Table) and communication with their HCP. Patient awareness of HbA_{1c} ranged from 15% in China and 19% in India, to 92% in Sweden, with 62% of Swedish patients regarding HbA_{1c} as very important on a scale of 1 to 5 (5 being ‘very important’). These findings suggest that the least HbA_{1c} awareness seemed to occur in countries likely to experience largest growth in diabetes numbers. The interviews also showed that patients in China have only 5–10 mins to consult with their HCPs, compared with 19 mins in India (defined as length of time explaining HbA_{1c} test) and 30 mins on average in Sweden. In China approximately 80% of HCPs stated that they routinely tested HbA_{1c}, while approximately 25% of patients reported having their HbA_{1c} levels tested at every 3-month visit. Other findings from the HCP interviews were more positive. In Sweden, 70–87% of HCPs regarded HbA_{1c} as highly important, and took frequent measurements (2–3 times a year). Similarly, in Canada, India and the UK, the HCPs reported taking 2–4 measurements a year on average.

Conclusion: These findings indicate a need for greater awareness of the importance of HbA_{1c} among patients, and for changes in the way many HCPs and patients think and act with respect to this measurement. The next step will be to identify what practical solutions are needed to facilitate these changes

and address the gap between guidelines and clinical reality. Data from some countries, for example Sweden and the UK, indicate that improvements are achievable.

Table

Patterns of glycaemic control across Europe: has clinical practice kept pace with recommended targets for blood glucose management?

P. D. Ambery¹, B. Pandya¹, M. Benford², M. Evans³;

¹Metabolic Centre of Excellence, Glaxosmithkline, Uxbridge, United Kingdom, ²Adelphi Europe, Adelphi, Bollington, United Kingdom, ³Department of Medicine, University of Cardiff, United Kingdom.

Introduction: Liebl described in 2002 that more than 2/3rds of patients were missing the HbA_{1c} target of 6.5%. Since then this target has been reiterated by IDF guidelines, and regular HbA_{1c} testing 3–4 times/year has been endorsed. This independent patient record study, (Adelphi Diabetes Tracker 2006), examines parameters relating to glycaemic control across 5 major European Countries.

Methods: 622 randomly selected Primary Care Physicians (PCPS) in UK, France(Fr), Germany(Ger), Italy(It) and Spain(Sp) submitted questionnaires on management of their 8 most recent consulting T2DM patients receiving OAD therapy +/- insulin. Most recent actual HbA_{1c} was recorded along with an individualised target HbA_{1c}, frequency of HbA_{1c} testing during previous year (12/12) and previous and current therapies.

Results: See results table, P for UK differences shown in the table <0.001. In addition we found that 29% of UK patients had HbA_{1c} >8%, (14% across other 4 countries) and that 68% of oral monotherapy patients across all 5 countries have HbA_{1c} > 6.5%.

Conclusion: Glycaemic control across Europe remains sub-optimal, with over 2/3rds of patients receiving oral hypoglycaemic monotherapy failing to achieve target HbA_{1c}. Whilst the frequency of HbA_{1c} testing across all 5 countries gives grounds for optimism, aspirations for HbA_{1c} achievement are above 6.5% in every country apart from Italy. This is associated with achieved mean HbA_{1c} levels above 7% in every case. If we are to impact on the future burden of complications in type 2 diabetes then more aggressive intensive management in line with guidelines is essential.

Results Table

Country	Number Evaluable HbA _{1c} tests	Average Target HbA _{1c}	Mean achieved HbA _{1c}	Average number HbA _{1c} tests prev year
UK	515	7.1	7.7	2.0
France	588	6.8	7.3	3.1
Spain	353	6.7	7.2	2.8
Germany	594	6.6	7.2	2.9
Italy	481	6.2	7.2	2.5

Do we correctly follow type 2 diabetes mellitus therapeutic guidelines in daily clinical practice?

A. Calderón¹, V. Barrios², G. Romero³, V. Pérez¹;

on behalf of the Post-Adelante study group,

¹Family Medicine, CS Rosa de Luxemburgo, Madrid, ²Cardiology Institute, Hospital Ramon y Cajal, Madrid, ³sanofi-aventis S.A., Barcelona, Spain.

Background and Aims: The guidelines for the diagnosis and treatment of patients with type 2 diabetes (T2D) are based on algorithms derived from randomized controlled clinical trials. Currently, it is not known if these guidelines are followed and applied in daily clinical practice. Accordingly, we sought to determine profiles of patients with T2D poorly controlled with two or more oral antidiabetic agents (OAD) who would benefit from initiating insulin treatment according to the 2005 ADA/EASD guidelines included in the Post-Adelante study, as well as evaluating the degree of compliance with the guidelines.

Materials and Methods: The Post-Adelante study is a 4-month observational multicentre study, designed to examine the metabolic and cardiovascular profiles of patients with T2D inadequately controlled with OADs who initiated insulin therapy. It aims to evaluate the efficacy of adding insulin to OADs after 4 months in a primary care setting. The study was approved by a local Ethics Committee. All patients completed a written consent form.

Results: Of 1714 patients included, 1500 were valid for the analysis. 55.8% were women, age 64.7 ± 10.8 years, body mass index 29.2 kg/m², HbA_{1c} 8.6 ± 1.1%, morning fasting plasma glucose (FPG) 10.5 ± 2.8 mmol/L (189.9 ± 50 mg/dL), and duration of T2D was 10.5 ± 6.6 years. Metformin (Met) was the most used drug (80.6% of patients) followed by sulfonylureas (SU) (75.3%), α-glucosidase inhibitors (GI) (22.1%), rapid-acting secretagogues (RAS) (9.2%) and glitazones (GTZ) (5.6%). The most frequent daily dose of Met was 2550 mg (47% of patients taking Met), SU: 15 mg of glibenclamide (40.8% of patients taking SU), GI: 300 mg acarbose (59.05% of patients taking GI), RAS: 6 mg of repaglinide (49.6%), and GTZ: 4 mg rosiglitazone (29.4%). 17.3% of patients used one (46.2% of them Met, 43.1% SU), 69.3% two and 13.2% three OADs. The most frequent combinations were Met + SU for double therapy (70.5% of patients using 2 OADs) and Met + SU + GI for triple therapy (72.1% of patients using 3 OADs). Although 71.2% of patients had HbA_{1c} ≥8% and 87% had FPG >7.8 mmol/L (>140 mg/dL), only 13.2% were on intensive therapy with three OADs.

Reasons why physicians altered treatment were: bad glycaemic control (97.7% of cases); poor compliance (18.4%); hypoglycaemia (6.6%); and treatment change initiated at the patient's request (4.0%). Upon insulin initiation, 28.4% of patients discontinued OAD therapy, 44.4% of patients used basal insulin (BI) added to one OAD, 25.4% used two OADs + BI, 1.6% used three OADs + BI and 0.08% used four OADs + BI. In addition to insulin, Met was used by 57.9% of patients, SU by 30.7%, GI by 9.9%, RAS by 5.4% and GTZ by 3.0%. The most frequent daily dose of Met was also reduced to 1.7 mg (42.8% of patients taking Met), while no changes were observed in relation with the most frequent dose of the other OADs. The most frequent therapies were Met + BI (31.3% of patients), followed by BI (28.4%), Met + SU + BI (17.3%) and SU + BI (6.9%).

Conclusion: According to ADA/EASD 2005 guidelines, the choice of OADs and dosages were correct, however, in order to achieve adequate glycaemic control, the add-on treatment effect was clearly insufficient. According to the new ADA/EASD 2006 guidelines, it appears necessary to add or change the choice of drugs and the combination strategy when starting basal insulin.

Evaluation of a complex intervention: a cluster randomised controlled trial of enhanced diabetes care – the United Kingdom Diabetes Study (UKADS)

N. T. Raymond¹, S. Bellary^{2,3}, P. J. O'Hare¹, S. Mughal², A. Szczepura¹,

S. Kumar¹, A. H. Barnett^{2,3}; on behalf of the UKADS Study Group,

¹Health Sciences Research Institute, Warwick Medical School, Coventry,

²Diabetes, Heart of England NHS Foundation Trust, Birmingham,

³Diabetes, University of Birmingham, United Kingdom.

Background and Aims: Intensive management in type 2 diabetes can improve clinical outcomes, but delivering healthcare to achieve targets remains a

challenge for health care professionals. Within a complex interventions framework and following a pilot study, we investigated the effectiveness of a culturally sensitive enhanced care package designed to improve cardiovascular risk factors in patients of South Asian ethnicity with type 2 diabetes.

Materials and Methods: In Coventry and Birmingham, UK, 21 practices were randomised to either intervention (protected practice nurse time, link worker sessions and diabetes specialist nurse support) or standard, care groups. Treatment protocols, including detailed prescribing algorithms for control of diabetes, blood pressure and lipids were provided for both groups. Outcome measures were blood pressure, total cholesterol, HbA1c and proportions of patients achieving internationally recommended and Quality and Outcomes Framework (QOF) targets after 1 year. Analyses used multiple linear and mixed regression methods to estimate intervention effects allowing for confounding factors and cluster randomisation.

Results: 1494 consenting patients of South Asian ethnicity with type 2 diabetes were included in analyses. Baseline differences between intervention and control groups were significant for systolic and diastolic BP, gender and diabetes duration. After one year, significant decreases in systolic blood pressure (4mmHg), diastolic blood pressure (2mmHg), total cholesterol (0.3mmol/l) and proportions of patients achieving blood pressure and total cholesterol targets were achieved for the whole study group. With adjustment for confounding factors, the intervention group achieved statistically significantly lower systolic (-2.1mmHg (-3.7 to -0.4), $P=0.013$) and diastolic (-1.4mmHg (-2.4 to -0.4), $P=0.004$) blood pressures. After adjustment for clustering, only diastolic blood pressure remained significant. There were no significant differences between groups for total cholesterol or HbA1c. In the sub-group of patients with blood pressure $>145/85$ mmHg at baseline, the intervention group achieved significantly greater reductions in systolic (-4.7 , -8.2 to -1.1 , $P=0.012$) and diastolic (-2.3 , -4.6 to -0.1 , $P=0.041$) blood pressures after adjustment for confounding factors and clustering.

Conclusion: Whilst improvements in blood pressure and cholesterol were achieved, limited effects of the intervention were observed. There were no significant improvements in glycaemic control, despite the QOF initiative plus our intervention. In high risk groups, there was some evidence of added benefits from our culturally sensitive initiative. Innovative measures to motivate patients and evidence based clinical targets may be needed to maximise healthcare outcomes in patients of South Asian ethnicity.

INSTIGATE Study: Differences in initial insulin regimes initiated in patients with type 2 diabetes in 5 European countries

S. Cleall¹, L. Timlin¹, M. Benroubi², A. Charles³, A. Tynan⁴;

¹Eli Lilly, Windlesham, United Kingdom, ²Diabetes Centre, Athens General Hospital, Greece, ³Dept de Recherche, INSERM, Paris, France,

⁴Eli Lilly, Surrey, United Kingdom.

Background and Aims: The objectives of the INSTIGATE study are to assess the direct costs, resource utilisation and clinical outcomes associated with the first 6 months of insulin therapy in people with type 2 diabetes and to observe patient outcomes over the first 24 months of insulin therapy. This abstract presents data on initial insulin regimes prescribed to enrolled patients in five European countries.

Materials and Methods: INSTIGATE is an ongoing prospective observational study in five European countries (UK, Germany, Greece, Spain and France) studying patients with type 2 diabetes who have initiated insulin as part of usual care. Patients were enrolled into the study following the independent clinical decision to initiate insulin. Data on medications for diabetes, clinical outcomes, health related quality of life and resource use are collected when patients initiate insulin and at regular intervals over the following 24 months.

Results: 1172 patients were enrolled across 5 countries. At insulin initiation mean (SD) HbA1c was 10.2 (1.7)% in the UK, 9.2 (2.0)% in Germany, 9.6 (1.6)% in Greece, 9.2 (1.6)% in Spain and 9.6 (1.9)% in France. Insulin regimes were summarised into five categories; long or intermediate acting alone, mixture alone, short acting alone, basal/bolus and other. The initial insulin regimes prescribed varied across countries as can be seen from table 1. Long or intermediate insulin alone and mixture alone were the two most commonly prescribed regimes in UK, Greece, Spain and France. Between 77.6% and 99.1% of the study patients in these countries received one of these regimes. Short acting insulin alone and a basal bolus regime were the two most commonly prescribed regimes (excluding "other") in the German sample, accounting for 55.6% of starting regimes prescribed. Overall the highest starting insulin dose, mean (SD) 0.420 (0.20) IU/kg, was prescribed to patients initiated on a basal/bolus regime. The lowest starting insulin dose, mean (SD) 0.219 (0.13) IU/kg, overall was for a long or intermediate only regime.

Conclusion: The observed initial insulin regimes prescribed across the 5 participating European countries varied substantially with simpler regimes of long/intermediate insulin alone or mixtures alone preferred as starter insulin regimes in most countries. More complex multi-injection regimes were prescribed less frequently as starting regimes in most countries. The opposite is observed in Germany with short acting alone and basal/bolus regimes initiated in the majority of patients. Further investigation is required as to how much the choice of starter insulin regime is influenced by patient characteristics and how much by country specific guidelines and site preferences. (Tab. 1)

Supported by Eli Lilly and Amylin

1033

Cost-effectiveness of detemir based basal-bolus therapy versus NPH for type 1 diabetes in a Spanish settingJ. A. Ray¹, W. J. Valentine¹, G. Goodall¹, M. Aagren², R. W. Kotchie³;¹Health Economics Department, IMS Health, Basel, Switzerland,²Novo Nordisk A/S, Bagsvaerd, Denmark,³Health Economics Department, IMS Health, London, United Kingdom.

Background and Aims: A meta-analysis of results from three clinical trials in type 1 diabetes patients showed that insulin detemir (IDet) based basal-bolus treatment compared to protamine Hagedorn human (NPH) based basal-bolus therapy in type 1 patients led to improved HbA_{1c} (0.13% points lower), a decrease in hypoglycaemic events (by 4%) and lower body mass index (BMI) (0.21 kg.m⁻²).

Materials and Methods: A published, validated, peer-reviewed computer simulation model of diabetes (the CORE Diabetes Model) was used to project short-term results obtained from the fixed-effects (weighted average) meta-analysis to long-term clinical and cost outcomes (including life expectancy, quality adjusted life expectancy, incidence of complications, and direct medical costs) for IDet versus NPH in type 1 diabetes patients, when used in combination with either insulin aspart (IAsp) or human soluble insulin (HIS) as the bolus component of therapy. Probabilities of complications were derived from landmark clinical and epidemiological studies and the costs of treating complications in Spain were retrieved from published sources. Total direct costs (complications + treatment costs) for each arm were projected over patient lifetimes from a Spanish Health Service perspective. Both costs and clinical outcomes were discounted at 3.5% annually.

Results: Improved glycaemic control, decreased hypoglycaemic events and lower BMI with IDet-based basal/bolus therapy led to fewer diabetes-related complications, an increase in quality-adjusted life expectancy of 0.173 years, increased total lifetime costs/patient of €4,254, and an incremental cost-effectiveness ratio of €24,616 per quality-adjusted life years (QALYs) gained. Results were stable under variation in a range of reasonable assumptions.

Conclusion: Short-term improvements seen with IDet versus NPH as part of a basal-bolus regimen were projected to lead to decreased complications, improvements in QALYs, and reductions in complication costs leading to a cost-effectiveness ratio which fell within a range considered to represent excellent value for money (<€50,000/QALY gained).

Supported by Novo Nordisk A/S

1034

Cost-effectiveness of pioglitazone in type 2 diabetes in Switzerland based on the PROactive studyM. Brande¹, W. Valentine², G. Goodall³, N. Dumont³, F. Pang⁴, M. Massi Benedetti⁵;¹Division of Endocrinology and Diabetes, Kantonsspital St Gallen, Switzerland, ²Center for Outcomes Research, IMS Health, Allschwil, Switzerland, ³Takeda Pharma AG, Lachen, Switzerland,⁴Takeda Global Research & Development, London, United Kingdom, ⁵Dipartimento di Medicina Interna, Università di Perugia, Italy.

Background and Aims: Type 2 diabetes is recognised as a chronic progressive disease that exerts a considerable burden on healthcare resources due to the increased risk of macrovascular and microvascular complications. The PROspective pioglitazone Clinical Trial In macroVascular Events (PROactive) Study is the first large-scale outcomes study to investigate prospectively the effect of a PPAR γ -agonist on macrovascular outcomes in patients with type 2 diabetes with a history of cardiovascular disease and demonstrated that pioglitazone (PIO) was associated with a 10% reduction in the primary endpoint ($p=0.09$) and a 16% reduction in the key secondary endpoint ($p=0.03$) vs placebo (PLB) when administered in addition to existing diabetes and CV therapies, including statins. The objective of this health economic analysis was to determine the cost-effectiveness of PIO versus PLB over a lifetime horizon from the Swiss healthcare perspective using a validated modelling framework – the CORE Diabetes Model (CDM).

Materials and Methods: The CDM was modified to accommodate patient-level data from PROactive and included 18 relevant disease and procedure specific interdependent Markov sub-models to extrapolate costs and effects over time beyond the duration of the trial. Direct medical costs (treatment, management and complication) were derived from published Swiss sources

and expressed in 2005 Swiss Francs (CHF). Health utilities were taken from the Cost of Diabetes in Europe – Type 2 study of diabetes (CODE-2). Clinical and economic outcomes were discounted at 2.5% *per annum* in line with the Swiss Federation Office of Social Security guidelines, and univariate and probabilistic sensitivity analyses (PSA) were performed to estimate the impact of uncertainty surrounding input parameters on the results.

Results: Over a lifetime horizon, PIO treatment was projected to have an additional life expectancy (discounted) of 0.258 years over PLB at an additional direct cost of CHF10,914 giving an incremental cost-effectiveness ratio (ICER) of CHF42,274 per life year gained. PIO was also associated with an additional 0.180 QALYs generating an ICER of CHF60,596 per QALY gained. Probabilistic sensitivity analysis demonstrated that, at a willingness to pay of CHF80,000 per QALY gained, there was a 62.5% probability of PIO being cost-effective. Univariate sensitivity analyses demonstrated that the results were most sensitive to the time horizon and duration of PIO benefit.

Conclusion: The addition of pioglitazone to existing therapy in patients with type 2 diabetes at high risk of further cardiovascular events is a cost-effective treatment option and represents good value for money in the Swiss setting.

1035

Cost of treatment and metabolic profile of patients with type 2 diabetes during the last decade

S. Papaioikonomou, S. Liatis, S. Dimopoulos, P. Thomakos, I. Tombrou, N. Katsilambros;

First Department of Internal Medicine, Athens University Medical School Laiko Hospital, Athens, Greece.

Background and Aims: During the last decade, several new agents have been introduced for the treatment of type 2 diabetes, and at the same period of time, a multifactorial approach including more strict control of glycemia, blood pressure (BP) and lipid profile as well as the frequent use of antiplatelet agents has been established. Aim of the present study was to compare the metabolic and BP profile of type 2 diabetic patients between the years 1998 and 2006 and to estimate the change in the cost of medications used for their treatment.

Materials and Methods: We compared the files of a random sample of patients ($n=244$) who visited the Diabetes outpatient Clinic of our Department during 1998 with a sample of 336 patients matched for sex, age and duration of diabetes who visited our Clinic during 2006. The cost of medications was calculated in Euros, using the 01-01-2006 official Greek market prices (as indicated in each medication's label).

Results: The total cost of drug treatment increased by 245% (from 23.08 Euros per patient/month in 1998 to 79.84 Euros per patient/month in 2006, $P<0.001$). The expenses for antidiabetic medications increased by 124%, for hypolipidemic medications by 1,105%, for antihypertensive agents by 162% and for antiplatelet agents by 3,930% ($P<0.00001$ for all comparisons). The median number of medications taken per patient, increased from 2 (min 0, max. 7) to 4 (min 0, max. 9), mainly due to an increase in the use of statins (from 7.8% of patients in 1998 to 49.8% in 2006) and antiplatelet agents (from 14.8% of patients in 1998 to 41.7% in 2006). The mean value of HbA_{1c} decreased from 7.39 ± 1.36 in 1998 to 6.95 ± 1.05 in 2006 ($P<0.001$). This difference was significant for insulin treated patients (7.91 ± 1.36 vs. 7.27 ± 1.08 , $P=0.001$), whereas for patients receiving only OADs, the difference was not significant (7.11 ± 1.25 vs. 6.90 ± 0.97 , $P=0.09$). LDL-cholesterol decreased from 144.63 ± 49.73 mg/dL to 110.54 ± 36.33 mg/dL but no significant difference was observed in triglycerides and HDL-C. There was no significant difference in systolic BP, but diastolic BP decreased from 81.12 ± 8.91 mmHg to 75.15 ± 10.82 mmHg.

Conclusion: In our Diabetes Outpatient Clinic, the cost spent for antidiabetic, hypolipidemic, antihypertensive and antiplatelet medications of type 2 diabetic patients increased by 245% during the last 8 years. At the same time we observed a significant reduction in HbA_{1c} of insulin treated patients and a significant reduction in LDL-C and diastolic blood pressure.

1036

Economic evaluation of improved diabetes care to patients of South Asian ethnicity: the United Kingdom Asian Diabetes Study (UKADS)

A. Gumber¹, A. Szczepura¹, N. Raymond², J. O'Hare³, S. Bellary⁴, S. Mughal⁴, S. Kumar¹, A. Barnett⁴;

¹Clinical Sciences, Warwick Medical School, Coventry,

²Health Sciences, Warwick Medical School, Coventry, ³Clinical Education, Warwick Medical School, Coventry, ⁴Heartlands Hospital, Heart of England NHS Trust, Birmingham, United Kingdom.

Background and Aims: Diabetes affects over 2 million people in England and accounts for nearly 9% of the annual NHS budget, or £5.2 billion per year. The South Asian population raises major challenges for type II diabetes care due to higher disease incidence, early onset, higher risk of developing complications, and cultural & language barriers to accessing care. The United Kingdom Asian Diabetes Study (UKADS) is assessing the costs and benefits of a community-based, culturally sensitive enhanced care package specifically designed to improve general practice (GP) care for South Asian patients with type II diabetes. A national Quality and Outcomes Framework (QOF) has also been introduced into general practices in the UK. The QOF sets practice targets linked to financial incentives, with 39% of payments for diabetes care associated with achievement of designated blood pressure (BP), HbA_{1c} and cholesterol levels. In 2004/5 an estimated £98.6 million was spent in England on QOF payments to GP practices for diabetes.

Method: 21 general practices in two English cities (Coventry and Birmingham) were randomised to either UKADS intervention (protected practice nurse time, South Asian link-worker sessions and diabetes specialist nurse support) or standard care. Treatment protocols provided for both groups included prescribing algorithms for control of diabetes, BP and lipids. Clinical outcomes were measured after 1 year to include BP, total cholesterol and HbA_{1c}. Health related quality of life (HRQL) assessed using EQ5D. Intervention costs were calculated to include staff time, capital (accommodation & equipment), overheads and consumables (including prescribing costs), and QOF payments. Cost-effectiveness was assessed by comparing incremental costs and marginal benefits.

Results: Data from 1,494 South Asian patients with type II diabetes showed significant decreases in systolic BP (4.6mmHg), diastolic BP (2.3mmHg) and total cholesterol (0.3mmol/l) after 1 year for the whole study group. After adjusting for confounding factors and clustering, the control group achieved 11mmHg fall in systolic BP in high risk patients (>145/85mmHg), while the intervention group achieved a further decrease of 5mmHg. There was no significant net difference in HRQL between intervention and control group. UKADS intervention costs were estimated at £105 per patient per year (including prescribing). Average QOF payment for diabetes were approximately £57 per patient per year. Initial analysis estimates a cost-effectiveness ratio of approximately £5.2 per mmHg fall in BP for QOF incentives plus treatment protocol; and an incremental cost-effectiveness ratio for the tailored intervention is £21.0 per additional 1mmHg fall in BP. Further results will be presented.

Conclusions: Our results confirm decreased cardiovascular risk factors (BP, cholesterol) for South Asian patients with type II diabetes following the introduction of QOF financial incentives. Also, that further improvements can be achieved at a reasonable cost through use of a tailored community intervention for this disadvantaged population. However, changes in glycaemic control remain a major challenge, as do improvements in HRQL. *Supported by various pharmaceutical industries*

1037

Cost-effectiveness analysis of medical intervention in patients with early detection of diabetic foot in a tertiary care hospital in Bangladesh

S. H. Habib¹, K. B. Biswas², S. Akter³, A. K. Azad Khan¹;

¹Health Economics Unit, DAB, ²Dept of Physiology & Molecular Biology, BIRDEM, ³Dept of Biochemistry & Cell Biology, BIRDEM, Dhaka, Bangladesh.

Background and Aims: The economic burden resulting from diabetic foot complications consume a major portion of resources allocated for health-care services. Cost-effectiveness of various interventions on diabetic foot & its complications have relatively been well explored in developed countries, but these are almost absent in developing countries. The present study was

undertaken to assess the cost-effectiveness of medical intervention in patients with diabetic foot.

Materials and Methods: Two hundred patients with diabetic foot, with at least 1 yr of follow-up, were purposively selected from BIRDEM (tertiary diabetes care hospital) of Bangladesh. Of them 100 were late in detection & poorly managed (Late diabetic foot or LDF) and 100 were early detected & properly managed (Early diabetic foot or EDF). The degree & extent of complications like peripheral neuropathy, retinopathy, cardiopathy and vasculopathy, treatment outcome, clinical effectiveness of interventions and direct, indirect & incremental cost of complications were calculated. Comparison was made between the groups. Cost included drugs, hospitalizations, diagnostics & visits.

Results: A total of 200 patients were considered for an average of 365 days, amounted to 651 person-yrs of observation in total. The mean±SD total cholesterol of the groups was 205.5±41.6 mg/dl in LDF & 103.2±34.5 mg/dl in EDF, HDL cholesterol was 56.2±20.3 & 39.0±14.1 mg/dl and HbA_{1c} was 8.2±1.5% & 4.9±1.3% respectively. About 19% patients in LDF & 36% in EDF were free of diabetic complications other than diabetic foot. In LDF, 32% had one complication, 29% had two & 20% had more than two complications. On the other hand, in EDF the corresponding values were 48%, 10% & 6% respectively. The most frequent complication was peripheral neuropathy, which affected 33% patients in LDF & 27% in EDF, followed by cardiopathy 21% & 18%, retinopathy 17% & 13%, and vasculopathy 10% & 6% respectively. The average annual cost of care was US\$ 26846 (direct US\$ 17893 & indirect US\$ 8953), with an average US\$ 134 per patient. Among the average annual cost LDF consumed US\$ 18918 (US\$ 189 per patient) and EDF US\$ 7929 (US\$ 79 per patient). 50% (US\$ 13473) of costs were attributable to drugs for both groups of which US\$ 10419 (77%) was for LDF & US\$ 3054 (23%) for EDF, 29% (US\$ 7653) to hospitalisations of which US\$ 4914 (64%) for LDF & 2739 (36%) for EDF. In case of diagnostics and visits the corresponding values were US\$ 1953 (55%) & 1580 (44%) and US\$ 1631 (75%) & 556 (25%) for LDF & EDF respectively. The annual medical costs increased with the number of complications from US\$ 1,320 to 2,296 & to 3,989 in LDF with one, two & more than two complications (other than diabetic foot) which is increasing at a rapid speed and US\$ 917 to 1556 & to 2372 in EDF respectively, increasing at a diminishing marginal rate. The regression equation showed that medical cost is significantly related to complications tested in both univariate ($P < 0.0001$) & multiple linear regression analyses ($R^2 = 0.51$; $F=81.5$, $P < 0.0001$). **Conclusion:** Proper management with regular follow up substantially reduces the expenditure related to care of patients with diabetic foot & related complications even in a developing country. Strategies aimed at preventing & early detection of the onset of foot complications will reduce medical costs in a substantial way.

Impact of increasing body mass index on medical resources for people with type 2 diabetes – a retrospective analysis in United States

M. Aagren¹, H. Colclough², M. Hammer³;

¹Novo Nordisk A/S, Virum, Denmark, ²Adelphi Group, Bollington, United Kingdom, ³Novo Nordisk A/S, Bagsvaerd, Denmark.

Background and Aims: The risk of developing cardiovascular and other life threatening diseases is strongly linked to increased body weight. This is particularly relevant to people with type 2 diabetes (T2D) of whom over 80% are overweight or obese. However, limited data exist on the impact on obesity on the medical resources and lost productivity. The aim of this study was to investigate the annual use of medical resources (drug use and outpatient visits) and lost productivity (days off work) for people with T2D with increasing BMI.

Materials and Methods: A retrospective analysis was conducted in United States based on a random sample of T2Ds from the Adelphi Metabolic Syndrome Disease Specific Programme (a large cross sectional study) in 2006 with 643 people diagnosed with T2D, aged between 35 to 64 years and a BMI ≥ 20 kg/m² (based on physician reported height and weight). People were stratified according to their BMI; normal/overweight (20–29.99 kg/m²; n=110), obese (30–34.99 kg/m²; n=178); very obese (35–39.99 kg/m²; n=170) and morbidly obese (>39.99 kg/m²; n=185). The cohort had an average age of 53 years, 58% were male, and 69% were Caucasians.

Results: For people with T2D with a BMI of 20 to 29.99 kg/m², mean number of total drugs used for any condition was 4.7 and 5% used more than 2 diabetes drugs. The number of annual visits to health professionals (primary

care physician, cardiologist, diabetes specialist, diabetes nurse, other doctor/nurse) was 5.9. The rate ratio i.e. the mean annualized resource utilization relative to the utilization in the normal/overweight group for people with T2D with a BMI of 30–34.99 kg/m², 35–39.99 kg/m² and ≥39.99 kg/m², respectively, were 1.08, 1.15 and 1.32 for total drug use, 1.75, 2.37 and 3.37 for percentage of people using more than 2 diabetes drugs, and 1.18, 1.23 and 1.37 for annual number of visits to health professionals. People not retired had an average annual number of days off work due to CV or diabetes complications of 1.5 for the normal/overweight group, with 3.2 for the obese group (BMI ≥30 kg/m²).

The proportion of people achieving HbA1c < 7% (ADA target for good glycaemic control) was 54% among the normal/overweight, and 45% in the morbidly obese group (≥39.99 kg/m²). Furthermore statistical tests showed that people in the normal/overweight group had statistically significant better glycaemic control (p<0.05) than people in the morbidly obese group (≥39.99 kg/m²).

Conclusion: These findings suggest a positive correlation between BMI and medical resources. The impact of obesity on resource use is particularly evident in people with T2D in the high obesity groups where a significantly lower glycaemic control also is seen.

Hyperglycaemia-related complications and medical care costs of intermediate hyperglycaemia

G. A. Nichols¹, B. Arondekar², W. H. Herman³;

¹Center for Health Research, Kaiser Permanente, Portland,

²GlaxoSmithKline, Inc, Philadelphia, ³Endocrinology and Metabolism, University of Michigan, Ann Arbor, United States.

Background and Aims: There is a lack of published studies that estimate the overall disease and economic burden of intermediate hyperglycemia (impaired fasting glucose [IFG] or impaired glucose tolerance [IGT]). The objectives of this study were to identify the prevalence of hyperglycemia-related complications and compare the medical care costs of IFG and/or IGT and its associated complications.

Materials and Methods: We used laboratory test results from Kaiser Permanente Northwest, a large HMO in Northwestern USA, to identify patients who had both a random and fasting plasma glucose (FPG) test result no more than 365 days apart between 1 January 1998 and 31 December 2004. Those with evidence of diabetes (chart diagnosis, FPG > 125mg/dl, or use of an anti-hyperglycemic), cancer, chronic renal failure or pregnancy were excluded. We then applied a validated algorithm that uses random glucose to screen for dysglycemia and results from the FPG test to assign patients to one of four categories: 1) isolated IFG (FPG 100–125mg/dl but did not screen as dysglycemic, n=5,713); 2) isolated IGT (FPG < 100mg/dl but screened as dysglycemic, n=2,552); 3) IFG/IGT (FPG 100–125mg/dl and screened as dysglycemic, n=2,217); 4) normoglycemia (FPG < 100mg/dl and did not screen as dysglycemic, n=15,629). Using electronic medical records, we identified and compared the prevalence of hyperglycemia-related complications. We then constructed multivariable regression models to compare age and sex adjusted annual medical costs across the four groups and to estimate the costs associated with the complications.

Results: Subjects averaged 62.5 years of age and 41% were male. Mean annual age/sex adjusted costs were \$6208, \$6171, \$7250, and \$7003 for normoglycemic, isolated IFG, isolated IGT, and IFG/IGT subjects, respectively. Compared to normoglycemics, age/sex adjusted complications were more prevalent among each of the dysglycemic groups, and were greatest among the isolated IGT and the IFG/IGT groups (see table). Presence of complications added significantly and independently to costs, ranging from \$993 for estimated GFR < 60ml/min to \$5324 for peripheral vascular disease. After controlling for complications, costs among the isolated IGT group were \$489 higher than those with normoglycemia. No other comparisons were significantly different.

Age/Sex Adjusted Prevalence and Costs of Complications

	Normo-glycemia	Isolated IFG	Isolated IGT	IFG/IGT	Estimated Annual Cost
Cardiovascular Disease	17.5%	21.5%	23.2%	22.8%	\$2669
Stroke	7.4%	7.9%	9.8%	8.6%	\$2262
Peripheral Vascular Disease	2.5%	3.1%	3.2%	2.8%	\$5324
Congestive Heart Failure	5.2%	6.7%	8.6%	10.5%	\$4479
Any Macrovascular Complication	25.0%	30.0%	33.6%	33.3%	\$4020
Retinopathy	0.2%	0.2%	0.4%	0.3%	\$4005
Macular Edema	0.3%	0.3%	0.3%	0.5%	\$2334
Peripheral Neuropathy	4.5%	4.8%	5.0%	5.1%	\$3014
GFR < 60ml/min per 1.73m ²	12.3%	13.7%	17.5%	16.8%	\$993
Any Microvascular Complication	16.2%	18.0%	21.5%	21.2%	\$1945
Any Complication	33.9%	39.1%	44.1%	44.4%	\$3700

Conclusion: Intermediate hyperglycemia is associated with increased medical costs. Hyperglycemia-related complications are highly prevalent among patients with intermediate hyperglycemia. Medical costs are correspondingly greater, especially when macrovascular complications are present. The highest costs were found among those with isolated IGT, a form of intermediate hyperglycemia that would seldom be identified. Complications did not fully account for the cost differences between this group and those with normoglycemia.

Estimating the cost of complications of diabetes in Sweden using administrative hospitalization data and the National Diabetes Register

P. M. Nilsson¹, U. Gerdtham², P. Clarke³, A. Hayes³, B. Eliasson⁴, S. Gudbjörnsdottir⁴;

¹Medicine, Clinical Sciences, Malmö, Sweden, ²Health Economy, Clinical Sciences, Malmö, Sweden, ³Health Economy, School of Public Health, Sidney, Australia, ⁴Medicine, Diabetes Centre, Göteborg, Sweden.

Background and Aims: Diabetes is a major public health problem with large, but varying financial costs at different stages of the disease. We aimed to estimate acute and long-term costs of hospitalization in Sweden for major diabetes-related complications, using administrative health care data.

Materials and Methods: The costs were estimated using administrative information on hospital data from the Swedish National Board of Health Welfare which have been linked to the Swedish National Diabetes Register (NDR). Data were available for a total of 179,749 patients with diabetes in Sweden from 1998–2003 (mean duration of 5.9 years of follow-up). Costs of inpatient admissions was based on Nordic Diagnostic Related Groups (DRG). Multiple regression analysis was used to estimate inpatient care costs controlling for age, sex and co-morbidities. The data on hospitalisations were converted to costs (€ 2004) using exchange rates.

Results: For a male aged 70 years the average annual costs associated with inpatient admissions in the year when the event first occurred were for coma: €6,275 (95%CI: 3,500, 9,050); heart failure: €6,432 (5,359, 7,505); non-fatal myocardial infarction (MI) €6,863 (5,642, 8,084); non-fatal stroke €7,706 (6,580, 8,832); renal failure €9,371 (7,097, 11,644); ischaemic heart disease €9,524 (8,452, 10,596); chronic leg ulcer €10,261 (7,301, 13,221); dialysis €13,686 (10,722, 16,651); and amputation €16,174 (14,316, 18,033). The costs were on average higher when also taking co-morbidities into account. For example, a diagnosis of MI with a co-morbidity was twice as costly as for MI alone.

Conclusion: Estimates of the hospitalization costs associated with diabetes-related complications can be used in modelling the long-term costs of diabetes and in evaluating the cost-effectiveness of improving care.

Using the chronic care model as a framework to improve diabetes care in a large U.S. health system

L. M. Siminerio¹, F. X. Solano², J. Zgibor³, G. Piatt⁴;

¹Endocrinology, University of Pittsburgh, ²Center for Quality Improvement and Innovation, University of Pittsburgh, ³Graduate School of Public Health, University of Pittsburgh, ⁴University of Pittsburgh Medical Center, United States.

Background and Aims: A Chronic Care Model (CCM) organised around elements (health system, community, decision support, clinical information systems, self-management, and delivery system design) has been shown to improve outcomes. It was our objective to use the CCM as a framework to improve quality and outcomes for the University of Pittsburgh Medical Center (UPMC), a large US health system, by gaining organisational and community support; implementing American Diabetes Association (ADA) medical and education standards for decision support; using clinical information systems to characterise target populations and track outcomes for continuous quality improvement (CQI), and integrating diabetes educators to provide point of service education in primary care practices for system re-design.

Materials and Methods: UPMC health system leadership provided organizational support for tracking of outcomes, negotiating with insurers and physician education. Programs were promoted through public awareness campaigns throughout all communities served by the health system. Target populations were characterised and CQI outcomes improved throughout the health system from 2/02 – 9/06.

Results: The proportion of patients in the health system with A1c levels < 7% (60.4% to 72%, $p < 0.0001$) and LDLc levels < 100 mg/dL (42.6% to 52.3%, $p < 0.0001$) significantly increased over time, as did the proportion of patients on statin (36% to 48%, $p < 0.0001$) and ace inhibitor (48.1% to 50.7%, $p < 0.0001$) therapy. Additionally, improvements in mean A1c (7.6% to 7.3%, $p < 0.0001$) and LDLc (116.7 mg/dL to 100.6 mg/dL, $p < 0.0001$) levels occurred over time (2/03-6/03) in patients receiving education in the primary care setting. Additionally, a significantly greater proportion of people accessed diabetes education when provided at point of service in the primary care office than in the traditional hospital-based setting (14.5% vs. 10.4%, $p < 0.0001$).

Conclusion: Using the CCM as a framework to improve diabetes care in a large health system resulted in organizational and community attention, ability to establish an effective system for monitoring ADA standards and CQI, and provided a novel approach for access. By using and coordinating the many resources of the health system, there have been significant improvements in health delivery processes and outcomes.

Cost-effectiveness of self-monitoring of blood glucose for the management of patients with non-insulin treated type 2 diabetes: economic evaluation of the DiGEM trial

J. Simon¹, A. M. Gray¹, A. N. Wade², H. A. W. Neil³, A. J. Farmer⁴;

¹Department of Public Health, University of Oxford, United Kingdom,

²Johns Hopkins Bayview Medical Centre, Johns Hopkins University School of Medicine, Baltimore, United States, ³Division of Public Health and Primary Care, University of Oxford, United Kingdom, ⁴Department of Primary Health Care, University of Oxford, United Kingdom.

Background and Aims: Current guidelines promote the use of self-monitoring of blood glucose (SMBG) for patients with non-insulin treated diabetes without robust clinical and economic evidence. Although the additional resources required for the technology have long been recognised, no previous study has attempted to estimate the real health care cost impact of the intervention. The aim of this economic evaluation is to assess the incremental cost-effectiveness of using SMBG either alone (less intensive monitoring) or with training in interpretation of the results of testing (more intensive monitoring) compared to standardised usual care for patients with non-insulin treated type 2 diabetes.

Background and Aims: Current guidelines promote the use of self-monitoring of blood glucose (SMBG) for patients with non-insulin treated diabetes without robust clinical and economic evidence. Although the additional resources required for the technology have long been recognised, no previous study has attempted to estimate the real health care cost impact of the intervention. The aim of this economic evaluation is to assess the incremental cost-effectiveness of using SMBG either alone (less intensive monitoring) or with training in interpretation of the results of testing (more intensive monitoring) compared to standardised usual care for patients with non-insulin treated type 2 diabetes.

Materials and Methods: Patient level resource use information was collected retrospectively at baseline and prospectively for the 12-month trial period for 453 patients in the randomised, controlled DiGEM study. Data were available on frequency of blood glucose testing, nurse involvement, diabetes and non-diabetes related medications, and primary and secondary health care use. Costs (UK £, £1 ≈ €1.47) were calculated from a health care perspective using national-level unit cost data for the year 2004/05. Costing was carried out on an intention-to-treat basis. Within-trial health care costs were compared between the three trial arms and to baseline costs where applicable. The within-trial change in the level of HbA1c is used to predict the long-term health outcomes and health care costs using the UKPDS outcome model.

Results: The DiGEM trial showed a mean difference of -0.14% in HbA1c level between the less intensive monitoring and the control arms, and a mean difference of -0.17% between the more intensive monitoring and the control arms. The overall intervention costs, including the costs of SMBG and nurse time, were £160 (SD 45.95), £267 (SD 60.70) and £264 (SD 81.09) in the control, less intensive and more intensive monitoring arms respectively. Only the difference between the control and the less intensive monitoring arms (£107, 95% C.I. £95 to £119) and between the control and the more intensive monitoring arms (£104, 95% C.I. £88 to £119) were significant ($p < 0.001$). There was also significant increase in the costs of both diabetes-related and other medications compared to baseline in all three trial arms. The size of increase, however, was independent of the type of intervention received.

Conclusion: The increase in the overall medication costs compared to baseline is likely to be a consequence of the closer follow-up of patients in the trial compared with their previous management. No differences are shown in the cost of diabetes medications between patients using SMBG and those receiving standardised usual care. Analysis of the effect of SMBG on other health care resource use, long-term life expectancy, quality-adjusted life years and health care costs, and estimation of cost-effectiveness, is in progress.

Long-term clinical outcomes of insulin detemir versus NPH based basal-bolus therapy for type 1 diabetes patients in Germany: A modeling analysis using results from a meta-analysis of three clinical trials

R. W. Kotchie¹, M. Aagren², W. J. Valentine³, G. Goodall¹;

¹IMS Health, London, United Kingdom, ²Novo Nordisk A/S, Bagsvaerd, Denmark, ³IMS Health, Basel, Switzerland.

Background and Aims: The aim of this study was to estimate the long-term clinical outcomes of type 1 diabetic patients treated with detemir (IDet) based basal-bolus therapy versus NPH based basal-bolus therapy in a German setting using the short-term results from a meta-analysis of three clinical trials.

Materials and Methods: A published and validated diabetes model was used to project long-term cumulative incidence (CI) of complications, life expectancy, quality-adjusted life expectancy, and time to onset of complications in a German setting. The model comprises a series of semi-Markov sub-models that simulate the long-term incidence and progression of diabetes-related complications and utilized second order Monte Carlo simulation. The probabilities of complications were derived from landmark clinical and epidemiological studies. Baseline cohort characteristics (mean age 40.3 years, duration of diabetes 16.3 years, HbA1c 8.3%, BMI 25.2 kg.m⁻²) and intervention effects were derived from a fixed-effects (weighted average) meta-analysis of three clinical trials (n = 1555) where patients received either human insulin (neutral protamine Hagedorn, NPH) or insulin detemir as the basal component of their therapy. Clinical benefits were discounted at a rate of 5% annually.

Results: Treatment with IDet was projected to improve discounted life expectancy by approximately 0.05 years (12.27±0.13 versus 12.22±0.12 years) and quality-adjusted life expectancy by 0.14 quality-adjusted life years (QALYs) (6.23±0.07 versus 6.09±0.06 QALYs) compared to NPH. Improved glycaemic control with IDet based basal-bolus therapy led to a delayed onset of the first diabetes-related complication, approximately 0.04 years (0.90 versus 0.86 years). IDet was associated with a reduction in the CI of diabetes-related complications; a 2.0% reduction of the CI of end stage renal disease (from 20.73% to 20.32%), and a 4.6% reduction of proliferative diabetic retinopathy (from 19.87% to 18.96%). In addition IDet was also associated with a 3.5% reduction in the CI of peripheral vascular disease (from 14.63% to 14.12%), but a projected increase of CI of stroke events of approximately

1.0% (from 12.20% to 12.27%). This increase in stroke events was due to the survival paradox, whereby patients living longer on IDet were exposed to the risk of stroke for a longer period than those on NPH.

Conclusion: Projections based on short-term (3-month) improvements in glycemic control and reduced weight gain with IDet versus NPH basal insulin in a recent meta-analysis indicate that IDet can be reasonably expected to yield long-term survival benefits, reduce the incidence of complications and improve quality-adjusted life expectancy. The data from this modeling study suggest that use of IDet as the basal component of a basal-bolus regimen in German type 1 diabetes patients will lead to long-term clinical benefits, making it an attractive treatment option for this patient group.

Quality of metabolic control in geriatric patients with diabetes mellitus

A. Braun, A. Abel, C. Wittmann-Jennewein, T. Zieschang, P. Oster; Department of Geriatrics at the University of Heidelberg, Bethanien Hospital, Germany.

Background and Aims: For elderly people with diabetes mellitus maintenance of autonomy is an important therapeutic goal influencing quality of life. Objective: Systematic assessment of the diabetes treatment quality and perceptions of elderly patients admitted to an acute geriatric hospital from different home environments (nursing home residents, home care, family carer, auto-sufficient).

Research Design and Methods: Quality of diabetes treatment, metabolic control (HbA1c), nutrition, patients perceptions, treatment satisfaction and level of dependency (Barthel activities of daily living) were assessed in 130 patients with diabetes (age 81.2±6.5y, HbA1c 7.6±1.7%, diabetes duration 9.8 (0.01–51.7)y, body-mass-index 25.7±4.8 kg/m², waist-hip-ratio 0.99±0.08). 42 patients were on diet therapy, 38 received oral antidiabetics (OAD), 38 insulin therapy and 12 insulin+ OAD therapy.

Results: Eighty-six out of 130 patients (66.2%) showed an HbA1c ≤ 8% according to the guidelines for ageing people with diabetes of the German Diabetes Association (DDG). Compared to patients living independently at home (n=28), the metabolic control in nursing home residents (n=36) (nursing home residents vs. autosufficient: HbA1c 7.6±1.6% vs. 8.0±2.0%, n.s.) and their treatment satisfaction (26.9±6.8 vs. 30.8±5.2points, n.s.) were as good. They had a higher degree of dependency though (Barthel 5 (0–80) vs. 65 (5–100) points, p<0.001), more strongly impaired mobility (Tinetti 1(0–17) vs. 11(0–27) points, p<0.01), less knowledge about diabetes knowledge (2.1±2.9 vs. 5.1±3.3 points, p<0.001), inferior cognitive performance (MMSE, SPMSQ, p<0.01) and a higher prevalence of depression (GDS) (p<0.01). Better cognitive function correlated with better diabetes knowledge (r=0.49; p<0.001), but not with better metabolic control.

Conclusion: Metabolic control of nursing home residents seems to be as good as that of patients caring for themselves at home. 66% of the nursing home residents showed HbA1c ≤ 8% according to the national guidelines.

Does intensive treatment of people with screen-detected diabetes improve outcomes? Impact on cardiovascular risk factors at one year in the ADDITION (Cambridge) trial

S. J. Griffin¹, T. Prevost², A. L. Kinmonth², K. M. Williams², N. J. Wareham¹; ¹Epidemiology Unit, Medical Research Council, ²Public Health and Primary Care, University of Cambridge, United Kingdom.

Background and Aims: A key determinant of the cost-effectiveness of screening for type 2 diabetes is the magnitude of cardiovascular (CVD) risk reduction associated with early detection and treatment of diabetes and related risk factors. However, there are few published data concerning the effects of simultaneous treatment of multiple risk factors, and none among patients with diabetes detected by screening. We assessed the effects on cardiovascular risk factors of a program of screening and intensive, multi-factorial treatment compared with a program of screening followed by routine general practice care.

Materials and Methods: In a pragmatic, parallel group, cluster randomised trial, 55 general practices in East Anglia were allocated to screening and intensive treatment (IT:28), or screening followed by routine care according to local and national guidelines (RC:27). Six practices were unable to commence the study (IT:2, RC:4). Stepwise screening of 135,825 people aged 40–69 years included a risk score, random capillary blood glucose and HbA1c tests (24,654), fasting capillary test, and finally oral glucose tolerance tests (1,481). 867 people were diagnosed with diabetes (1999 WHO criteria). 13.9 months (SD:2.9) post-diagnosis, 85% of patients returned for re-measurement by staff unaware of study group. In the IT group, management of blood glucose, blood pressure, cholesterol and microalbuminuria was optimised through practice-based educational meetings, guidelines, target setting, academic detailing, audit and feedback, alongside provision of a pack of theory-based educational materials for newly diagnosed patients.

Results: Patients with screen-detected diabetes had high levels of cardiovascular risk factors at diagnosis which improved over the first year. Reduction in levels of risk factors was significantly greater in the intensive treatment group.

Conclusion: Screening for type 2 diabetes is feasible and identifies people with high levels of modifiable cardiovascular risk factors which can be improved through routine general practice diabetes care. Optimisation of intensive multi-factorial treatment was associated with clinically important improvements in intermediate outcomes 14 months after diagnosis. Whether such a program will be a cost-effective means of reducing CVD events over five years is being addressed in the ADDITION (Europe) study in Denmark, the Netherlands and the UK. (Tab. 1)

Supported by Wellcome Trust, MRC, NHS R&D

Tab. 1

Cardiovascular risk factors at diagnosis and follow-up (13.9 months)

	Routine care group		Intensive treatment group		Difference in change (95% CI)	P value
	Mean (SD) at diagnosis	Mean (SD) at follow-up	Mean (SD) at diagnosis	Mean (SD) at follow-up		
HbA1c (%)	7.33 (1.65)	6.62 (0.95)	7.35 (1.77)	6.42 (0.77)	-0.20 (-0.33 to -0.06)	0.009
BMI (kg/m ²)	33.6 (5.9)	32.6 (6.0)	33.1 (5.3)	31.9 (5.2)	-0.26 (-0.55 to +0.03)	0.084
Systolic BP (mmHg)	142.1 (20.0)	138.0 (18.6)	141.5 (19.8)	134.6 (18.3)	-3.18 (-6.26 to -0.11)	0.048
Diastolic BP (mmHg)	81.4 (10.3)	79.6 (9.9)	82.1 (10.4)	77.9 (9.2)	-1.81 (-3.30 to -0.32)	0.022

Clinical utility of indentifying metabolic syndrome (MetS) in patients with type 2 diabetes for primary cardiovascular disease (CVD)**prevention: a population-based study**

U. Bulugahapitiya^{1,2}, S. Siyambalapatiya^{1,2}, J. Sithole³, D. J. S. Fernando^{1,2}, I. Idris^{1,2};

¹Diabetes and Endocrinology, Sherwood Forest Hospitals Foundation Trust, Nottinghamshire, ²Academic Unit of Diabetes, Endocrinology and Metabolism, University of Sheffield,

³Trent RDSU, University of Nottingham, United Kingdom.

Background and Aims: In patients with type 2 diabetes (T2D) without overt cardiovascular disease, we aimed to determine whether identifying patients with MetS (IDF criteria) would affect the decision to prescribe statin for primary CVD prevention, based on currently available public health guidelines

Materials and Methods: We analysed last recorded CVD risk profiles obtained from The Health Improvement Network (THIN) primary care database which contains imputed patients dataset using the shared VISION software from 229 GP practices in England and Wales. Out of 60258 patients with diabetes, 11005 (10%) men and women aged 30–74 years fulfil criteria for primary CVD prevention and were not on lipid lowering drugs. Outcome data was extrapolated to an estimated national diabetes prevalence of 3.6%.

Results: The prevalence of MetS is 67.3%. Females, but not males with MetS have a significantly higher LDL-cholesterol compared with non-MetS patients. Mean framingham 10-year CVD risk was significantly higher in MetS as was the proportion of patients with 10-year risk >20% (56% vs. 34.5%, pearson chi square 0.2, $p < 0.001$). Identifying MetS in this group of patients would produce an additional 29,536 (8.4%) and 104,288 (29.6%) patients nationally, who would require statin therapy based on the Joint British Society (JBS -treat all patient above the age of 40 years) and the National Institute of Clinical Excellence (NICE – treat all patient whose 10-year CVD risk exceeds 20%) guidelines respectively.

Conclusion: Framingham risk-score appears to reflect the heightened CVD risk among patients with T2D and MetS. However, identifying patients with MetS may further increase the use of statins in this high risk group of patients.

1047

Acute complications continue as a major cause of death for children and young adults with type 1 diabetes

R. G. Feltbower¹, H. J. Bodansky², C. R. Stephenson¹, R. C. Parslow¹, C. C. Patterson³, P. A. McKinney¹;

¹Paediatric Epidemiology Group, University of Leeds, ²Paediatric Epidemiology Group, The General Infirmary at Leeds, ³Department of Epidemiology & Public Health, Queen's University Belfast, United Kingdom.

Background and Aims: There is a paucity of information on cause of death in subjects diagnosed with type 1 diabetes (T1D) between 15–29 years of age compared with that available for individuals diagnosed aged 0–14 years. The aim of the study was to examine mortality rates and cause of death amongst subjects diagnosed with T1D between the ages of 0–29 years.

Materials and Methods: Subjects were identified from the population-based Yorkshire Register of Diabetes, a high quality database with a 98% ascertainment rate. Patients were selected with T1D aged 0–14 years at diagnosis from all Yorkshire (1978–2004) and 15–29 years from West Yorkshire only (1991–2004). Subjects were traced on the UK National Health Service Central Register to provide details of death notifications. Deaths were coded according to ICD-9 (1979–2000) and ICD-10 (2001–2005) classification schemes. A person-years at risk analysis calculated expected numbers of deaths using UK mortality rates. Standardised mortality ratios (SMR) with 95% confidence intervals were derived using the Poisson distribution.

Results: 3,349 and 897 patients diagnosed aged 0–14 years and 15–29 years represented 50,471 person years of follow-up. Mean length of follow-up was 12.6 years for 0–14 and 9.1 years for 15–29 year olds. Only ten patients (0.2%) were untraceable. Overall 107 (2.5%) patients died, of whom 76 (71%) were male. 73 (2.2%) deaths occurred in the younger diagnosed group and 34 (3.8%) occurred in the older group. The SMR was 4.6 (95%CI 3.8–5.6) overall and identical for males and females. The SMR rose with increasing duration of diabetes: 3.7 for a duration of 0–4 years compared with 6.8 for 15–19 years. Only 11 deaths occurred in children before age 15, with the

majority occurring between 20–39 years of age, most likely due to increasing disease duration. 47 deaths (44% of the total) occurred from diabetes complications: 32 acute and 15 chronic. Acute complications comprised 14 from DKA, 2 from hyperglycaemia (excluding DKA), 8 from hypoglycaemia and 8 unspecified cases. Males constituted 25/32 (78%) deaths from acute complications. Acute complication fatalities occurred evenly throughout the cohort by age at death. Deaths associated with chronic complications included: 6 from ischaemic heart disease, 1 stroke and 8 renal (6 deaths being female). 24 out of the 107 (22%) deaths were attributed to accidents or violence (SMR 2.1; 95% CI 1.4–3.2), 5 of which were suicides. Within this group, the SMR was non-significantly higher for females (3.4; 1.4–6.9) compared to males (1.9; 1.1–3.0). 10% of all deaths (11/107) were related to drug misuse compared to 6% in the general population ($p = 0.09$). There were 19 deaths of other or unknown causes: SMR = 3.3 (2.1–5.2).

Conclusion: Follow-up of subjects diagnosed under 30 with T1D since the 1970s has shown a four-and-a-half-fold excess mortality risk compared to the background population, an effect which was similar for males and females although increased with disease duration. Almost half the deaths (44%) were due to acute or chronic complications of T1D and with continued vigilance and education most of such future deaths should be preventable. There may be an emerging trend for young people with T1D to misuse drugs which warrants further investigation.

Direct costs of diabetic ketoacidosis in children and adolescents with diabetes

A. Rewers¹, M. Rewers²;

¹Department of Pediatrics, University of Colorado, Denver,

²The Barbara Davis Center for Childhood Diabetes, University of Colorado, Denver, United States.

Background and Aims: DKA remains the costliest complication of diabetes in young people. The goal of this work was to estimate the direct cost of managing diabetic DKA among children and adolescents and to provide national estimates.

Materials and Methods: Administrative hospital data were analysed for all cases of DKA treated at The Children's Hospital in Denver, between 1995–2006. DKA was defined by the ICD-9 diagnosis code 250.10–250.13, validated by chart review (pH <7.35 arterial or <7.30 venous or bicarbonates <15 in presence of hyperglycemia and ketonuria). Direct medical cost of DKA included hospital charges and professional fees. The cost was adjusted for inflation using the U.S. consumer price index and expressed in 2006 dollars. The cost estimates for specific patient groups were compared using Kruskal-Wallis test.

Results: There were 1093 DKA events in 777 patients during the study period. Median age at DKA was 12 yrs (range 0–19); 55% of the patients were females. DKA at onset of diabetes accounted for 49% of the episodes. Overall 23% of the patients were treated only in emergency department, 12% in an observation unit (<24 h) and 65% were hospitalised for a median of 1 day (range 1–61 days). Insurance status included private/HMO insurance in 66%, government/indigent coverage in 27% and 7% the patients had no insurance. The median cost of the DKA treatment was higher ($p < 0.0001$) at the onset of diabetes – \$10890 (interquartile range \$6830–16023) than in patients with long standing diabetes – \$8010 (\$3656–13237). In multivariable regression analysis, the cost of DKA at onset of diabetes was 67% (95% CI 45%–93%) higher than that of DKA in established patients adjusting for age and gender. Median cost of DKA increased 20% between 1995–96 (\$8836) and 2005–06 (\$10551) ($p = 0.008$), adjusting for inflation. We previously reported prevalence of DKA in newly diagnosed youth (25.5%) and DKA incidence in patients with established diabetes (8/100 person-year). Using these estimates, the SEARCH estimates of the incidence and the prevalence of diabetes in the U.S. youth and the U.S. census population data we calculated the cost of DKA in the U.S. population younger than 20. In 1995, direct medical cost of DKA in the U.S. youth (expressed in 2006) dollars was \$184 million (\$48 million at onset and \$136 million in established cases), increasing to \$258 million (\$73 million and \$185 million, respectively) in 2006.

Conclusion: In conclusion, children with newly diagnosed diabetes incur higher cost of DKA treatment and longer LOS, probably due to more severe presentation and lower family resources for transition to outpatient management. The economical burden of DKA among children and adolescents with is very high and increasing.

Depressive symptoms increase the risk of all-cause mortality in men with high postload glucose levels: results of a 30 year prospective study

J. Kruse¹, N. Schmitz², K.-H. Ladwig³, J. Heinrich³;

¹Psychosomatic Medicine and Psychotherapy, University Duesseldorf, Germany, ²Douglas Hospital Research Centre, McGill University, Montreal, Canada, ³Department of Epidemiology, GSF, München, Germany.

Background and Aims: About 25% of people with diabetes have coexisting depressive symptoms. The aim of the present study was to evaluate the effect of depressive symptoms on all cause mortality among men with and without postload hyperglycemia (PH) over a period of 30 years.

Materials and Methods: We examined mortality in the population based Erfurt cohort study in Germany. Between September 1973 and August 1975, 1160 men aged 40–59 years were surveyed. At baseline a 1-hour postload venous blood sample was obtained after an oral glucose tolerance test. Depressive symptoms were assessed by an exhaustion scale. The mortality follow up continued until death or the end of 2003.

Results: Over 30 years, 595 study participants (51.3%) died. Mortality rates were highest in men with depressive symptoms and coexisting postload hyperglycemia. Hazard ratio for mortality was 0.81 (95%CI 0.64–1.02) for men with depressive symptoms alone, 1.29 (95% CI 0.96–1.73) for men with postload hyperglycemia alone, and 2.02 (95% CI 1.24–3.30) for men with both, postload hyperglycemia and depressive symptoms. These associations remained significant even after controlling for age, smoking, body mass index, education, hypertension, and cholesterol level.

Conclusion: The results suggest that the coexistence of depressive symptoms and postload hyperglycemia is associated with an increased risk of mortality in men.

1050

Influence of diabetes on cognitive function and physical impairments in the elderly

M. Lechleitner, U. Benvenuti-Falger, M. Kufner;
Internal Medicine, Hospital Hochzirl, Zirl, Austria.

Background and Aims: The prevalence of type 2 diabetes increases with increasing age. Diabetes seems to be related to an earlier manifestation of cognitive dysfunction and physical impairments, resulting in a worse metabolic control, loss of autonomy and thus quality of life. Published study results of systematic and comprehensive test programs for elderly are hardly available for diabetic patients. We have applied the routinely performed geriatric assessment test program to study the impact of diabetes on cognitive and motoric abilities in elderly diabetics and an age-matched non-diabetic population.

Patients and Methods: A total of 506 patients participated in the evaluation, 112 with diabetes (mean age 80.5±6.7 years) and 394 without diabetes (mean age 78.7±0.0 years). In order to study an age-dependency of the impairments 3 subgroups were created, group I: ≤74.9 years, group II: 75.0–84.9 years, group III: ≥85 years. In addition to clinical and laboratory routine controls all patients underwent a structured test program summarised as the geriatric assessment (Mini Mental State Examination (MMSE), geriatric depression scale, Activity of Daily Living (ADL), Mobility Tests).

Results: The mean HbA1c value of all diabetic patients was 7.2±1.4%. Compared with non-diabetic patients diabetics revealed a less favourable outcome in the various tests of the geriatric assessment. Especially in group II (age 75.0–84.9 years) ADL score (66.7±22.1 points), MMSE (25.8±3.8 points) and mobility tests (Tinetti score with 13.8±6.2 points and Up and Go test with 67.7±48.8 seconds) were significantly worse than in non-diabetic patients (ADL-score 77.0±18.0, p<0.001; MMSE 26.8±3.0 points, p<0.041; Tinetti score 16.8±5.2, p<0.001; Up and Go test 43.9±32.8 seconds, p<0.0001). Diabetic patients in group II revealed similar results as non-diabetic patients, who were 10 years older (group III ≥85 years). The depression score in all diabetic patients was 30% higher than in non-diabetic patients (p<0.005).

Conclusion: Elderly diabetic patients are at an increased risk for a more pronounced manifestation of age-associated impairments, especially with respect to mobility, cognitive function and depressive disorders. Test

programs, like the geriatric assessment, should thus belong to clinical routine care in order to modify the therapy according to the individual need of the elderly diabetic patient.

1051

Cardiovascular risk factors and cognitive impairment in type 2 diabetes

L. A. Chugunova¹, I. Semenova¹, E. Tarasov¹, A. Vorontsov², L. Nikankina³, P. Kamchatnov⁴, A. Chugunov⁴, M. Shestakova⁴;

¹Nephrology, National Research Center for Endocrinology,

²Radiology, National Research Center for Endocrinology,

³Biochemistry, National Research Center for Endocrinology,

⁴Neurology, Russian State Medical University, Moscow, Russian Federation.

Background and Aims: Over the past years the cerebrovascular disease was identified as the major cause of mortality and disability, particularly in type 2 diabetes. Patients with type 2 diabetes have a 2–6 fold increased risk of developing cerebrovascular disease not only strokes but also cognitive impairment. This study evaluated the relationship of cardiovascular risk factors, neuropsychological tests for cognitive impairment and cerebral MRI scan in type 2 diabetics.

Materials and Methods: The examination included glycosylated haemoglobin (HbA1c), body mass index (BMI), systolic (SBP) and diastolic blood pressure (DBP) by 24-h ambulatory blood pressure monitoring (24-h ABPM), homocysteine plasma levels, cerebral MRI scan (T1 and T2 weighted), neuropsychological tests: Frontal Assessment Battery (FAB), Mini Mental State Examination (MMSE), Global Deterioration Scale (GDS), Clock Drawing Test (CDT). The study involved 91 (40 men and 50 women) patients with type 2 diabetes.

Results: Mean age of patients was 61±8.4 years. Mean duration of diabetes was 9.2±4.2 years. Mean HbA1c was 8.3±1.8%. The most of MRI scan abnormalities were subcortical and periventricular white matter lesions – 49%. GDS scores showed significant correlation with total area of white matter lesions (R=0.514; p=0.003). MMSE showed a significant negative correlation with diabetes duration (R=0.408; p=0.019). FAB scores were negatively associated with diabetes duration (R=0.355; p=0.049), BMI (R=0.271; p=0.041), SBP (R=0.402; p=0.028) and homocysteine plasma levels (R=0.353; p=0.048). CDT scores exhibited a significant negative correlation with homocysteine plasma levels (R=0.459; p=0.021). Association between HbA1c and neuropsychological test scores was not estimated.

Conclusion: Our study confirms strong association of cognitive impairment in type 2 diabetes with vascular MRI abnormalities, cardiovascular risk factors, especially SBP, BMI, diabetes duration and homocysteine plasma levels as marker of endothelial dysfunction.

1052

Increased glucose levels are associated with episodic memory in non-diabetic women

O. Rolandsson¹, A. Backeström¹, S. Eriksson², L.-G. Nilsson³;

¹Department of Public Health and Clinical Medicine, Family Medicine,

Umeå, ²Department of Community Medicine and Rehabilitation, Geriatric

Medicine, Umeå, ³Department of Psychology, Stockholm, Sweden.

Background and Aims: Patients with type 2 diabetes have an increased risk of a reduction in cognitive function. We investigated the hypothesis that plasma glucose is associated with a reduction in episodic and/or semantic memory already in nondiabetic subjects.

Materials and Methods: We linked and matched two large population based data sets in Sweden. First, the Västerbotten Intervention Program, a health survey with subjects aged 40, 50 and 60 years. It includes measuring of fasting and 2-hour plasma glucose, and other risk factors for diabetes and cardiovascular disease. The second database was the Betula study where a random sample from the population aged 35–85 years was investigated for cognitive function by an elaborate memory testing including episodic and semantic memory. We identified 411 (M/F 179/232, mean age 50.6 ±8.0 years) nondiabetic subjects, free from dementia who had participated in the two surveys within six months (mean time difference between surveys 14 ±68 days).

Results: Women had better episodic and semantic memory compared to men ($p < 0.001$ for both). Both quartiles of fasting (figure 1) and 2h plasma glucose (figure 2) among women were correlated to episodic memory. In a multivariate linear regression fPG ($B -0.195$, $SE 0.067$, $Beta -0.206$, $p=0.004$) and 2hPG ($B -0.071$, $SE 0.031$, $Beta -0.170$, $p=0.025$) were significantly negatively associated to episodic memory among women, but not in men. This was found after adjustment for age, systolic and diastolic blood pressure, hypertension, total cholesterol, body mass index, educational level, depression, smoking and history of cardiovascular disease. The association was not found in relation to semantic memory.

Fig. 1. Mean (95% CI) episodic memory (z-store) among women by quartiles of fasting plasma glucose.

Fig. 2. Mean (95% CI) episodic memory (z-store) among women by quartiles of 2h plasma glucose.

Conclusion: We conclude that an increase in plasma glucose is associated with impairment in episodic memory in women. This could be explained by a negative effect on hippocampus by raised plasma glucose levels.

Diabetes, chronic diseases and well-being: the WHO 5 into practice

G. Hochberg;

DELF, Paris, France.

Aims: In 2001, the Dawn Study helped for the first time to understand more fully diabetic patient attitudes worldwide in order to improve their outcomes. In the same perspective, French Dawn experts decided in 2005 to use the

WHO 5 questionnaire as a barometer to have a clearer picture of the well-being state of diabetic patients in comparison with patients suffering from other chronic diseases (CD) and through the results, to make practitioners more aware of psychosocial aspects of diabetes.

Methods: The WHO-5 Questionnaire was proposed to 4965 general practitioners and 1702 diabetologists in hospitals and cities for distribution to their chronic patients. The practitioners' geographic area was specified. Patients were also invited to give socio-demographic and medical information as sex, age, type of CD, type of diabetic treatment (insulin or not), then to answer a question on the possible link between their well being and their CD. Patients fulfilled questions alone and returned questionnaires back directly.

Results: 2253 were returned, 2213 could be analysed. 49% males, 51% females. 41% suffered from diabetes, 34% from diabetes and other CD, 25% from other CD than diabetes. 57% of diabetics were treated by insulin. WHO 5: mean score =14.1 (males = 14.97; females = 13.5; $p < 0.001$). 1/3 of patients could be considered as depressed (< 13). Significant difference was found between patients with diabetes alone and patients with diabetes and other CD ($p < 0.005$). Diabetics have better well-being than patients with other CD ($p = 0.002$). Among diabetics only, insulin treatment is associated with worse well-being ($p = 0.03$).

Conclusions: Globally, diabetics seem to have better well-being than patients with other CD. Negative factors influencing well-being are female sex, insulin treatment within diabetics. These results tend to highlight that HCP have to consider more systematically well-being of patients with CD.

Supported by Novo Nordisk

1054

Psychosocial adjustment and outcomes of glycaemic control with basal insulin therapy in patients with type 2 diabetes mellitus (T2DM)

R. J. Tanenberg¹, Q. Zhang², A. Zisman³;

¹Division of Endocrinology, Brody School of Medicine, Greenville,

²sanofi-aventis U.S., Bridgewater,

³Endocrine Center of Aventura, Miami, United States.

Background and Aims: Psychosocial adjustment may influence glycemic control in patients with T2DM using insulin therapy. A 24-week, randomised, open-label study that compared the rate of severe hypoglycemic events (primary endpoint) and the proportion of patients reaching A1C $< 7.0\%$ was used to examine the relationship between poor psychosocial adjustment and increased risk of hypoglycemia. Patients ($N=4163$) with T2DM failing oral therapy (mean A1C=9.2) were randomised to 5 insulin glargine treatment algorithms with target fasting blood glucose of 80, 90, 100, 110, and 120 mg/dL, respectively.

Material and Methods: A 46-item Psychosocial Adjustment to Illness Scale (PAIS) was administered at baseline and end of the study period to assess psychosocial adjustment to diabetes in each of the 7 domains that include health care orientation; vocational, domestic, social environment; sexual and extended family relationships; and psychological distress.

Results: Patients were 55 years, 48% male, 70% white, with mean T2DM duration of 8.3 years and BMI 34.7. Poor psychosocial adjustment was consistently associated with lower risk of hypoglycemia and higher study-end A1C_independent of baseline A1C and BMI. In addition, effect of psychosocial adjustment was constant among titration algorithms (ie, different target fasting blood glucose). Study-end A1C was lower ($P < 0.0001$) in patients with best psychosocial adjustment (7.3 and 7.0 in patients with and without hypoglycemia, respectively) compared with those with poorer adjustment (8.0 and 7.5, respectively). Of the 7 domains, poor adjustment was associated with higher A1C over 6 domain scores ($P < 0.05$). At the item level, poorly-adjusted patients recorded higher A1C in 30 of 46 items and poor adjustment was associated significantly with lower incidence of hypoglycemia in 18 of 46 items ($P < 0.05$). Patients' age, sex, and T2DM duration interacted with hypoglycemia and psychosocial adjustment to yield an impact on A1C. Specifically, the effect of adjustment (poor vs. excellent) to hypoglycemia and A1C control is different in younger individuals with poor adjustment being associated with lower risk of hypoglycemia and lower A1C compared to older individuals, where poor adjustment predicts higher risk for hypoglycemia and higher A1C. Gender also interacted with A1C with a decrease in study-end A1C observed among better vs. worse adjusted female patients (7.9% vs. 7.5%, respectively) and only a minimal impact of adjustment among males (7.3% vs. 7.4%, respectively).

Conclusion: This study demonstrated that better psychosocial adjustment contributed to lower A1C during the treatment of patients with T2DM with basal insulin therapy. Patient treatment plans that incorporate the consideration of psychosocial factors may achieve more desirable glycemic outcomes.

Monitoring health-related quality of life in adolescents with type 1 diabetes improves psychosocial well-being and satisfaction with care

M. de Wit¹, R. Gemke², J. Bokma³, B. Boersma⁴, A. Derksen⁵, A. Feliuss², K. Haasnoot⁴, M. Houdijk³, E. van Lie-Peters⁴, E. van Mil², M. Reeser⁵, J. Rottevel², T. Sas⁵, H. Delemarre-van de Waal², F. Snoek¹;

¹Medical Psychology, VU University medical center, Amsterdam,

²Pediatrics, VU University medical center, Amsterdam, ³Pediatrics, Spaarne Ziekenhuis, Hoofddorp, ⁴Pediatrics, Medical Center Alkmaar, Alkmaar,

⁵Pediatrics, Juliana Kinderziekenhuis, Den Haag, The Netherlands.

Background and Aims: Systematic monitoring of psychosocial functioning in adolescents with diabetes may help to improve physical and psychosocial well-being and glycaemic control. In an ongoing RCT, we investigate the effects of monitoring health related quality of life (HRQoL) on physical and psychosocial well-being, HbA1c and satisfaction with care in adolescents with type 1 diabetes.

Materials and Methods: Ninety-one adolescents with type 1 diabetes (age 14.9±1.1, HbA1c 8.8±1.7, BMI 21.1±3.2 and duration 6.4±4.2 years) were recruited from four outpatient paediatric diabetes clinics in The Netherlands. Clinics were randomised over either control or monitoring condition. The clinics in the control condition provided care as usual, while in the monitoring condition the patients completed a 3-monthly computerised HRQoL assessment (using the PedsQL) and discussed the outcomes with their paediatrician or nurse. Both groups were followed for 12 months, assessing physical and psychosocial well-being using validated questionnaires (Child Health Questionnaire (CHQ), Center for Epidemiological Studies scale for Depression (CES-D), diabetes specific family conflict (DFCS), satisfaction with care (PEQ-D) and medical data (HbA1c, BMI, treatment regimen, diabetes duration) at baseline and follow-up. MANCOVA analyses, correcting for baseline differences, were used to explore the effect of the intervention in 80 patients. Multiple linear regression was used to identify factors that explained (variation in) HbA1c levels.

Results: A significant improvement was found in the psychosocial and physical summary scales of the CHQ for the adolescents in the monitoring group, compared to those in the control group ($p < 0.001$, $R^2 = 0.37$ and $R^2 = 0.41$). This effect was most profound in reduction of behavioural problems and improvement in self-esteem. There were no changes in HbA1c levels, depression and diabetes-specific family conflict for either of the groups. However, the patients' satisfaction with care significantly improved in the monitoring group in contrast to the control group, which remained the same. For the group as a whole, HbA1c levels at follow up were predicted by glycaemic control at baseline and by the amount of diabetes specific family conflicts ($p < 0.001$, $R^2 = 0.42$).

Conclusion: This is the first study to demonstrate monitoring health related quality of life improves psychosocial and physical well-being in adolescents with diabetes as well as their satisfaction with care but not glycaemic control. Additional targeted interventions are required to decrease HbA1c levels.

1056

The association of weight worry with quality of life and diabetes self-management

M. Peyrot¹, S. E. Skovlund²;

¹Sociology, Loyola College, Baltimore, United States,

²Novo Nordisk, Bagsvaerd, Denmark.

Background and Aims: This study examined the epidemiology of worry about weight among adults with diabetes and whether this weight worry (WW) was associated with lower quality of life and poorer diabetes self-management.

Material and Methods: Participants were 5104 adults with type 1 or type 2 diabetes from the multi-national DAWN study. Random samples of approximately 500 were obtained from each of 11 countries/regions in Asia, Australia, Europe, and North America. All measures were self-reported data obtained during structured interviews. 32.8% of participants had type 1 diabetes, 26.9% had insulin-treated type 2 diabetes, 40.4% had non-insulin treated type 2 diabetes. Median age was 55 years, median duration of diabetes was 10 years, median age at termination of education was 17 years. 21.8% lived in a rural area. 54.0% were female.

Results: 50.2% of participants reported some WW; 25.1% reported high WW. The study did not contain a measure of obesity, but there were measures of several obesity risk factors. High WW was significantly ($p < .05$) higher among women (31.0%), those with type 2 diabetes (27.0% of those not on insulin, 30.3% of those on insulin), those who had diabetes less than 10 years (26.9%) and those who were older than 54 (27.8%), less physically active (no regular exercise, 26.1%) and terminated education before age 18 (28.7%). In the full study population high WW was associated with significantly ($p < .05$) more diabetes-related distress, more diabetes related symptoms, lower self-rated health, lower vitality, poorer psychological well-being, and more psychological treatment. High WW was associated with significantly ($p < .05$) lower diet and exercise adherence and poorer self-rated diabetes control. The only significantly ($p < .05$) positive correlate of high WW in the full study population was appointment-keeping. Among insulin-naïve respondents high WW was associated with significantly ($p < .05$) more worry about starting insulin and more self-blame about having to start insulin. Among those taking anti-hyperglycaemic medication, high WW was associated with significantly ($p < .05$) more worry about hypoglycaemia. Among those whose only anti-diabetic medication was insulin, high WW had a complex relationship with medication adherence; among type 1 patients WW was associated with significantly ($p < .05$) lower insulin adherence, among type 2 patients WW was associated with significantly ($p < .05$) higher insulin adherence.

Conclusion: Weight worry was common among adults with diabetes. Although it was not possible to examine the relationship between weight and weight worry, those at greater risk for being overweight experienced higher levels of weight worry. Weight worry was associated with a plethora of negative outcomes, including multiple indicators of diabetes-related distress, poor physical and psychological well-being, and regimen non-adherence. Weight worry is associated with worry about starting insulin and having hypoglycaemia, which may lead patients to resist initiation of insulin therapy. These findings suggest that health care providers should assess weight worry among their patients with diabetes, and take steps to prevent negative impacts on patient outcomes.

Can a theory-based behaviour change programme improve outcomes for people with recently diagnosed type 2 diabetes? – the ADDITION Plus trial

A. L. Kinmonth¹, N. J. Wareham², S. Sutton¹, W. Hardeman¹, T. Prevost¹, K. M. Williams¹, S. J. Griffin²;

¹Public Health and Primary Care, University of Cambridge, ²Epidemiology Unit, Medical Research Council, Cambridge, United Kingdom.

Background and Aims: Recent trials emphasise the value of intensive treatment of multiple risk factors among people with diabetes. This consists of poly-pharmacy, combined with efforts to achieve healthy behaviours, and presents a considerable burden to patients and a challenge to practitioners. In an explanatory, parallel group, individual randomised trial we assessed the efficacy of a theory-based intervention to promote health-related behaviours (physical activity, dietary change, medication adherence and smoking cessation) and to achieve clinically important changes in cardiovascular disease (CVD) risk factors, among patients with diabetes detected by screening, or recently clinically diagnosed, and offered intensive drug treatment.

Materials and Methods: 239/422 patients newly diagnosed through a step-wise screening program in primary care, and 239/684 patients clinically diagnosed within the previous three years were recruited from 34 general practices in the east of England. Following baseline measurement participants were independently randomised to intervention (I:239) or control (C:239) groups using a partial minimisation procedure to balance covariates. Intensive drug treatment of all study patients and general support in self-management was facilitated through practice-based educational meetings,

guidelines, target setting, academic detailing and educational materials for patients. Intervention patients also received a theory-based behavioural intervention delivered by trained and quality-assured facilitators at six practice-based appointments over 10 months. After 13.2 months (SD:1.6) 93% of participants attended for objective measurement of the principal outcomes: physical activity (individually calibrated heart rate monitoring), diet (plasma Vitamin C), medication adherence (serum drug levels) and smoking status (serum cotinine); self-reported health behaviours, clinical, biochemical, functional status and psychological outcomes.

Results: CVD risk factors (secondary outcomes) improved among intensively managed patients in both study groups. There was no additional benefit associated with the behavioural intervention. Newly diagnosed patients demonstrated a small advantage for the intervention group for bmi (difference (95%CI): -0.49kg/m^2 (-0.91 to -0.07), $p=0.021$), and HDL cholesterol ($+0.05\text{mmol/l}$ ($+0.004$ to $+0.10$), $p=0.034$).

Conclusion: A theory-based intervention to promote changes in health behaviours was not associated with improvements in CVD risk factors among recently diagnosed patients over and above that achieved through educational materials and intensive general practice management. Behavioural interventions may be more successful if delivered soon after diagnosis. Results for principal behavioural outcomes will be presented. (Tab. 1)

Disordered eating behaviour and metabolic control in young subjects with type 1 diabetes transferred from a paediatric to an adult diabetes unit

I. Conget¹, M. Lara¹, M. Vidal¹, M. Jansa¹, J. Castro², M. Giménez²;

¹Endocrinology and Diabetes Unit, ²Paediatric Psychiatry-Psycology Unit, Hospital Clinic i Universitari/IDIBAPS, Barcelona, Spain.

Background and Aims: Eating disorders are a significant health problem in young people and they could be especially troublesome and a determinant factor to achieve an optimal metabolic control in young subjects with type 1 diabetes (T1D) transferred to adult diabetes units. Our study aimed to evaluate the prevalence of disordered eating behaviour and its relationship with metabolic control among young subjects with T1D transferred from a paediatric to an adult diabetes unit.

Subjects and Methods: Seventy-four consecutive young subjects with T1D (aged 17.6 ± 1.4 years, 40 women, T1D duration 9.0 ± 1.3 years) transferred from a paediatric to an adult diabetes unit were included. In addition to clinical and physical exam, we evaluated: the metabolic control, the Eating attitude Test (EAT), the eating behaviour, the self-management abilities and knowledge (DKQ2 test), the Diabetes Quality-of-Life questionnaire (DQoL) and the SF-12 health survey questionnaire.

Results: At entry HbA_{1c} was $8.7\pm 1.6\%$. EAT score was significantly correlated with HbA_{1c} ($r=0.32$, $p<0.008$) and it was higher in girls than in boys (12.2 ± 6.0 vs. 5.7 ± 3.1 ; $p<0.000$). In 10 subjects (9 girls) we found a highly/moderately disordered eating behaviour and in those subjects HbA_{1c} tended to be higher (9.3 ± 2.3 vs. $8.5\pm 1.4\%$, $p=0.178$). DQoL Diabetes-related issues worrying subscale score was significantly higher in girls (9.1 ± 2.9 vs. 7.5 ± 2.1 ; $p<0.015$). The perception of health assessed by SF-12 test and DKQ2 score were better in boys than in girls ($p<0.015$ and $p<0.05$, respectively).

Conclusion: At the time of transfer of young people with T1D from a paediatric to an adult diabetes unit the presence of a significant disordered eating behaviour is far from uncommon, particularly in girls, and it is related with a worse metabolic control.

Tab. 1

Cardiovascular risk factors at baseline and follow-up

	Control group		Intervention group		Difference in change (95% CI)	P value
	Mean (SD) at baseline	Mean (SD) at follow-up	Mean (SD) at baseline	Mean (SD) at follow-up		
HbA1c (%)	7.01 (1.23)	6.67 (0.95)	7.23 (1.62)	6.66 (0.94)	-0.10 (-0.24 to +0.04)	0.17
BMI (kg/m ²)	32.8 (5.7)	32.3 (5.7)	32.7 (5.3)	32.1 (5.2)	-0.16 (-0.46 to +0.14)	0.29
Systolic BP (mmHg)	134.4 (19.3)	128.2 (17.2)	138.2 (19.1)	132.1 (17.4)	+1.96 (-0.67 to +4.59)	0.14
Diastolic BP (mmHg)	79.1 (10.9)	75.1 (9.8)	81.6 (10.0)	77.7 (8.8)	+1.40 (-0.09 to +2.90)	0.066
Total cholesterol (mmol/l)	4.90 (1.16)	4.31 (0.86)	4.96 (0.98)	4.33 (0.91)	-0.01 (-0.15 to +0.14)	0.94

Characteristics and eating habits of diabetic patients during the fasting month of Ramadan

Y. Altuntas, S. Ucak, H. Tokel, T. Erdem, O. Basat, T. Saler, A. Kol; Endocrinology&Metabolism, Sisli Etfal Research and Training Hospital, Istanbul, Turkey.

Background and Aims: Ramadan is an absolute fast (no food or water) month between dawn and sunset. Duration is 1 lunar month in a year. It is a Holy Month for Muslims. The aim of this study was to evaluate the characteristics and eating habits of patients with type 2 diabetes during Ramadan.

Materials and Methods: This was a single-centre, retrospective study. A total number of 300 patients attending to our diabetes outpatient clinic were screened. They were under follow and applied for their routine visit during the month of Ramadan. All patients were type 2 diabetics and at least 35 years of age. A standard questionnaire-based interview was conducted by the physician. Interviews were made one to one and face to face. Patients were asked if they were fasting during Ramadan. And also sweet food intake frequency in a month, hypoglycemic episodes, duration of diabetes mellitus, treatment, change in treatment during Ramadan were questioned. For qualitative data group comparisons were performed using chi-square test, otherwise Fisher's exact test was performed. For quantitative data analysis of variance or nonparametric tests were performed. A p value less than 0.05 was considered significant.

Results: A total number of 300 diabetic patients were recruited for the study. During Ramadan 51.7% of patients fasted. 168 patients treated with OAD's and 132 patients treated with insulin. In OAD group there were 123 female and 45 male patients while there were 91 female and 41 male patients in insulin group. In OAD group 69.6% of subjects and in insulin group 21.2% of subjects fasted ($p<0.01$). In OAD group 107 patients (63%) and in insulin group 84 patients (63%) ate sweet foods during Ramadan. In OAD group 23.8% of patients had baklava (a special Turkish desert), 35.1% of patients had cookies, 47.6% of patients had dry persimmon (high glycaemic index), 19.6% had honey and 31% had jam. In insulin group 48% of patients had baklava, 34.8% had cookies, 34.8% had dry persimmon and 18.2% had jam. Hypoglycemia rate was greater in insulin group than OAD group (40.2% vs. 9.5% $p<0.01$). Duration of disease was longer in insulin group (10.45 ± 7.05 vs. 5.22 ± 5.10 , $p<0.01$). Patients in insulin group were fasting longer than in OAD group (5.40 ± 4.51 vs. 3.87 ± 3.15 , $p<0.05$). Only 10 patients in insulin group and 5 patients in OAD group made changes in their treatment during Ramadan. Although in insulin group HbA1c levels did not change significantly 3 months after Ramadan, in OAD group HbA1c levels decreased significantly after 3 months (6.47 ± 1.15 vs. 6.10 ± 1.16 , $p=0.001$).

Conclusion: A high number of patients with diabetes mellitus still fast during the month of Ramadan. Especially patients using OAD's seem to fast more. Although fasting may cause dangerous conditions in insulin treated patients, they persist on fasting. Patients with diabetes mellitus also consume large amounts of sweet foods in contrary to physicians advices. Although fasting does not seem to effect metabolic control in patients using OADs, more time and effort should be put in on patients education impressing the importance of lifestyle changes in the management of diabetes.

Multifactor approach associated with orlistat for 2 years weight loss maintenance

V. Makoundou¹, F. Habicht¹, E. Harsch-Bobbioni¹, J.-P. Gachoud², A. Golay¹;

¹S.E.T.M.C., Geneva University Hospital, Geneva 14, Switzerland,

²Roche Pharma, Reinach, Switzerland.

Background and Aims: Weight loss maintenance management over time after weight loss is difficult and important. We have considered a multifactor approach in order to achieve weight loss maintenance: diet and physical activity counseling associated with a cognitive-behavioral therapy and an orlistat “on-off” treatment program when the weight relapse is higher than 2.5%.

Materials and Methods: 50 obese patients (mean BMI 36.4 kg/m²) were enrolled in the weight loss maintenance study after a weight loss of more than 10% (mean -17%). Patients came to the clinic every 2 months for the first year and then every 3 months until year 2. In order to maintain their weight loss, patients received a diet and physical activity counseling during the study. If a weight relapse of $\geq 2.5\%$ was measured during a study visit, the following procedures were added: food questionnaire for the patient, cognitive-behavioral therapy, orlistat 120mg tid. This procedure was maintained as long as the weight relapse was of $\geq 2.5\%$ (“on-off” treatment program). In order to manage so called risky situations on special occasions such as birthdays, restaurants, social events, orlistat was also prescribed at patient request. Body weight was measured and weight relapse (if any) calculated at each visit, body composition and self assessment eating questionnaire (EDI2) were performed once a year; anxiety and depression, physical activity self-assessment questionnaires were performed every 6 months.

Results: At baseline the mean age was 43 \pm 11 years, and BMI 30.1 \pm 5.7 kg/m². Five patients dropped during the study. After 2 years, the mean body weight was very well maintained: 80.7 kg \pm 17.1 at 2 years compared to 82.1 kg \pm 15.6 at baseline. 58% of the patients had at least an additional weight loss of > 2.5% or stable weight and 38% had at least one episode of weight gain of > 2.5% during the 2 years of follow up. The orlistat was prescribed in 48% for special occasions only, in 34% for special occasions and continuous intake, in 8% for continuous intake only and in 10% no intake. 18% of the patients had at least once a cognitive behavioral therapy, 22% physical and diet motivational workshops, 16% new diet counseling. For body composition, EDI2, HAD, parameters, no change were observed after the 2 years weight loss/maintenance program.

Conclusion: This new multifactor approach with an “on-off” orlistat program appears to be promising. These results should be confirmed with the weight loss maintenance program at 4 years which is actually ongoing.

Short-term effects of an educational program on health seeking behavior for infections in patients with type 2 diabetes: a randomized controlled trial in primary care

K. J. Gorter, L. M. A. Venmans, E. Hak, G. E. H. Rutten;

Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, The Netherlands.

Background and Aim: Patients with type 2 diabetes mellitus (DM2) have an increased risk of urinary tract infections (UTIs) and lower respiratory tract infections (LRTIs). Also, common infections may be more difficult to treat, often recur and diabetes increases the risk of hospitalization and mortality from infections. However, results of focus group interviews and a questionnaire study showed that patients with DM2 are lacking basic background knowledge about risk factors and symptoms of infections and risks are underestimated. Together with barriers like being afraid that insulin will be prescribed, this may cause substantial delay in health seeking behavior and consequently lead to increased morbidity and mortality in patients, economic costs for health care and loss of productivity to society. Based on these findings, we developed an educational program on common infections in diabetes. This study aims to assess the short-term effects of an educational program on health seeking behavior for UTIs and LRTIs in patients with DM2.

Material and Methods: In a randomised controlled trial 1,124 patients with DM2 aged between 44 and 85 years participated. The intervention consisted

of an educational program with an interactive meeting, a leaflet, a website and a consult with the diabetes care provider. The program focused on the patients' needs, apparent from a prior focus group and questionnaire study. The primary outcome measure was an indicator of health seeking behavior for UTI and LRTI, defined as the proportion of participants with a positive score on at least seven out of nine determinants of health seeking behavior according to the Health Belief Model and the additional domains knowledge, need for information and intention. Variables were measured with questionnaires at baseline and after five months. Before-after comparisons were made according to the intention-to-treat and on-treatment principle by use of General Equation Estimation modeling to account for baseline levels and clustering.

Results: The mean age of the patients was 64 years (SD 9), 53% of the participants were male, co-morbidity was present in 44% of the patients and insulin was used by 13% of the patients. Mean duration of diabetes was 6 years (SD 7). Complete outcome data were available for 468 intervention group patients and 472 control patients. In all, 68% of the intervention group patients attended the meeting. At baseline, 28% of the participants of the intervention group had a positive score on seven of the nine determinants, compared to 27% of the controls. After the educational program, these percentages were 53% and 32%, respectively ($p < 0.001$). In the intervention group, especially knowledge about symptoms of LRTI (31%, compared with 4% in controls) and UTI (11% compared with 0%) improved. Besides, there was an improvement in the perception of an increased risk of infections (18% compared with 7%).

Conclusion: Our educational program positively influenced determinants of health seeking behavior for common infections in patients with DM2. Especially knowledge and risk perception were improved. Besides, the proportion of participants with a positive score on seven of nine determinants of health seeking behavior increased significantly. By improving this behavior, complications of common infections in patients with DM2 may be prevented. *Supported by Public Health Fund, The Hague; Diabetic Fund, Amersfoort, The Netherlands*

Predicting return for a long-term follow-up diabetes self management education visit following a chronic care model based diabetes care intervention

G. A. Piatt¹, J. C. Zgibor²;

¹University of Pittsburgh Diabetes Institute, University of Pittsburgh Medical Center, Pittsburgh, ²Epidemiology, University of Pittsburgh Graduate School of Public Health, Pittsburgh, United States.

Background and Aims: Evidence supports the effectiveness of diabetes self-management education (DSME) in the short term; however mixed results are reported with follow-up greater than one year, possibly due to attrition. We therefore aimed to determine the patient factors that best predict return for a long term follow-up DSME visit (FUV) following a Chronic Care Model based intervention (CCMI) that took place in an underserved community between 2002 and 2003.

Materials and Methods: Eleven primary care practices, along with their patients, (mean age: 66.6 yrs, 47.6% male, 10.7% non-white) were randomly assigned to 3 groups: patient and provider education (CCM) (n=30), provider education only (PROV) (n=38), and usual care (UC) (n=51). CCM received all elements of the CCMI. Subjects were followed for 3 years post CCMI.

Results: 54% (57 of 105) subjects (mean age: 66.4 \pm 8.7, 49.1% male, 8.8% non-white, 19.3% insulin user), who were evaluated at one year post CCMI, chose to be reevaluated at three year post CCMI. Follow-up rate was similar when examined by intervention group (CCM: 56%, PROV: 56%, UC: 52%). Overall, a significantly greater proportion of subjects who returned for a FUV were not using insulin (56.1% vs. 29.7%, $p = 0.008$) and had not seen a healthcare provider in the previous 12 months (61.8% vs. 38.5%, $p = 0.02$). Additionally, those who returned for a FUV had higher diabetes knowledge test scores (72 \pm 14.4 vs. 60.9 \pm 19.2, $p = 0.002$) and lower systolic blood pressure levels (138.9 \pm 18.5 mmHg vs. 145.9 \pm 19.3 mmHg, $p = 0.06$). Multivariate analyses controlled for age and insulin use at study entry and intervention group. Significant associations remained as subjects not taking insulin were more likely to return for a FUV (OR=0.18, 95% CI: 0.06, 0.54). Additionally, with every 5% increase in diabetes knowledge test scores (OR=1.3, 95% CI: 1.1, 1.5) and every 5 mmHg decrease systolic blood pressure (OR=0.87, 95% CI: 0.76, 0.99), the likelihood of returning for a FUV increased significantly.

Conclusion: These results demonstrate that a variety of factors predict return for a FUV. This type of information may aid researchers in targeting specific

populations, and may be translated into the clinical practice setting to guide changes in scheduling patterns or to recognise patients appropriate for additional diabetes or non-diabetes related interventions to change behavior. *Partially sponsored by funding from the US Air Force administered by the US Army Medical Research Acquisition Activity, Fort Detrick, Maryland*

1063

Cardiovascular risk awareness and metabolic control are correlated with disease specific knowledge in patients with type 2 diabetes

A. H. Pfützner¹, C. Hohberg¹, G. Lübben², E. Karagiannis², S. Gauer³, W. Roth¹, T. Forst¹, A. Pfützner¹;
¹IKFE Institute for Clinical Research and Development, Mainz, ²Takeda Pharma, Aachen, Germany, ³Health Care, BKK, Hannover, Germany.

Background and Aims: A high incidence of cardiovascular disease (CAD) in type 2 diabetes mellitus is seen even in patients with good glycemic control. Increasing the CAD risk awareness may be a helpful tool to implement an acceptance for life style changes and other therapeutic measures in routine health care.

Materials and Methods: In order to evaluate the risk awareness of diabetic patients and their physicians in correlation with patients knowledge about their disease, we performed a brief 9-item diabetes knowledge and CAD risk estimation test in 157 patients with type 2 diabetes (49 women, 108 men, age(mean±SD): 65±8 years, disease duration: 9±8 years) and applied other clinical and laboratory means for CAD risk assessment (e.g. Intima-media-thickness (IMT), PROCAM-Score, UKPDS risk score).

Results: Based on the tertiles of the knowledge test, patients were stratified into low (LK, 64 pts., 40%), medium (MK, 45 pts. 29%) and high knowledge (HK, 49 pts. 31%) groups. The knowledge test outcome was independent from the intensity of previous diabetes trainings as reported by the patients. The HK patients had a better HbA1c and lower IMT than the LK group (HbA1c: 6.7±0.8 vs. 7.1±1.5%, p<0.05; IMT: 0.774±0.128 mm vs. 0.864±0.181 mm, p<0.05). They also had a lower HOMA_{IR} score (4.7±1.5 vs. 7.1±3.2, p<0.05) and better metabolic profile with regard to lipids and other laboratory risk markers. When the individual risk for a CAD/stroke event was estimated by the patients and their physicians, the agreement was better in the HK group than in the LK or MK group. The UKPDS-risk engine revealed a low CAD risk in 8.8%, 13.8%, and 13.8% (LK, MK, HK; Procam: 8.3%, 15%, and 17.8%). LK patients underestimated their CAD risk to a much higher extend (no risk: 40.3%), than MK (25.6%) or HK patients (8.3%). The treating physicians estimated that 12.2%, 9.1% and 6.1% of the patients in the three groups had no current CAD risk.

Conclusion: Patients who had more knowledge about their disease were better controlled and had a better understanding of their own vascular risk. Their risk assessment was in better agreement with the risk estimate by their physicians and with the UKPDS risk engine or the PROCAM score. The findings of our evaluation that were independent from the previous diabetes training status, nevertheless, underline the importance of a constant flow of patient education to increase the knowledge level of the diabetic patient and to increase the risk awareness, which is in our opinion of major importance to achieve adherence to therapeutic measures of any kind.

1064

Structured treatment and teaching programmes (DTTP) are very efficient tools to improve glucose metabolism in insulin treated younger and older patients with diabetes type 2 – an analysis of data from AKD (Arbeitsgemeinschaft Klinische Diabetologie) hospitals from 1999 to 2006 one year after participation in a DTTP

C. S. Kloos¹, A. Sämman¹, N. Müller¹, D. Tessmann², H. Fischer³, U. A. Müller¹;

¹Internal Medicine, Klinikum für Innere Medizin III, Jena,

²Internal Medicine, Medizinische Klinik Passau,

³Internal Medicine, Krankenhaus Düren, Germany.

Background and Aims: Structured teaching in small groups is the standard intervention and basis to improve blood glucose in diabetes. In Germany, DTTP are an essential part of disease management programmes. We

examined, if DTTP are equally effective in younger and older patients with diabetes type 2.

Materials and Methods: The AKD is a nationwide circle to assure treatment quality in Germany. Participation is on a voluntary basis. An unselected sample of at least 50 (till 2003) or 60 (from 2004 on) patients is examined personally 12 to 15 months after participation in a DTTP. Markers of treatment quality (HbA1c, blood pressure, body weight) and further information to characterise treatment modalities (e.g. number of injections, age) are collected. Data of 67 AKD-hospitals with a total of 5985 patients from 1999 to 2006 are analysed. All patients were treated with insulin. The data were divided in equally distributed thirds (all data before participation in the DTTP) Third 1(n=2021): mean age 50years, body weight 93.8kg, BMI 32.3kg/m², RR syst. 138.5, RR diast. 82.8mmHg, Diabetes duration 8.1y; Third 2(n=1927): mean age 61.9y, body weight 87.8kg, BMI 30.6kg/m², RR syst. 142.6, RR diast. 81.7mmHg, diabetes duration 11.3years; Third 3(n=2037): mean age 71.9y, body weight 81.6kg, BMI 29.1kg/m², RR syst. 144.9, RR diast. 80.4mmHg, diabetes duration 13.5 years. The thirds of the youngest and oldest patients were compared. In those thirds body weight, BMI, Diabetes duration and RR were significantly different (p<0.01). Not all variables were complete.

Results: HbA1c improved in both groups significantly without any difference between younger and older patients (Third 1: from 8.5%* to 7.2%*/ Third 3: from 8.5%* to 7.3%*; p<0.001). Younger as well as older patients experienced a weight gain (Third 1: +1.8kg/+0.5kg/m²; Third 3: +0.7kg/+0.4kg/m²; p<0.001). Blood pressure in younger patients was normal and remained normal. Blood pressure in older patients before DTTP was significantly higher compared with the younger patients and improved in older patients performing blood pressure self-control (Third 3: from 142.9/80.1mmHg to 138.9/78.4mmHg;p<0.001) but not if the measurements were carried out by the medical staff.

Conclusion: Structured teaching and treatment programmes (DTTP) are very efficient tools to improve glucose control. The effectiveness is independent from age.

*HbA1c DCCT normalised

1065

Factors driving medication satisfaction in the patient with diabetes: an analysis using the Perceptions About Medications for Diabetes Questionnaire

B. Curtis¹, R. P. Hayes¹, P. O. Monahan², K. A. Lane², D. G. Marrero³;

¹Eli Lilly and Company, Indianapolis, ²Department of Medicine, Indiana University School of Medicine, Indianapolis, ³Division of Endocrinology & Metabolism, Indiana University School of Medicine, Indianapolis, United States.

Background and Aims: Treatment satisfaction has been shown to be associated with adherence, and in turn with better glycemic control. The purpose of this study was to investigate factors that are associated with patient satisfaction with diabetes medication.

Materials and Methods: To validate The Perceptions About Medications for Diabetes (PAM-D) Questionnaire, 67 items developed from 18 focus groups of patients with diabetes were administered via a mailed survey to 1000 randomly selected inner-city patients in Indianapolis, Indiana. Psychometric analysis indicated 10 clinically meaningful PAM-D subscales: flexibility of timing, convenience of transport, negative impact of diabetes medications (i.e., hassle, interferes with daily life, takes too much time), medication effectiveness, trouble remembering medications, perceived (gastrointestinal, hypoglycemic, and weight/edema) physical side effects, and perceived (mood impact and cognitive distress) emotional side effects. The survey included questions about demographics, types of diabetes medications, and 5 items on a 7-point scale measuring satisfaction with aspects of diabetes medications (e.g., ease of taking) summed to create a treatment satisfaction scale (Cronbach's alpha=0.91). A step-wise linear regression model with treatment satisfaction as the dependent variable included any demographic variables and PAM-D subscales as independent variables that were univariately significant at alpha = .25.

Results: Response rate was 36% (n = 362); 5% of respondents had type 1 diabetes (mean age at diagnosis 25.0±14.3 yrs), 95% had type 2 diabetes (mean age at diagnosis 47.7±12.8 yrs). 49% of patients reported use of oral medication alone, 22% insulin alone, and 26% a combination of oral medication and insulin. 71% of subjects were female and 40% were Caucasian.

The best predictors of treatment satisfaction were four PAM-D subscales; medication effectiveness ($R^2 = 0.13$), followed by negative impact (R^2 change = 0.05), perceived mood side effects (R^2 change=0.01), and flexibility of timing (R^2 change = 0.01), for a total $R^2 = 0.20$ (all $p < 0.05$). No other variables including demographics, duration of disease, bodily pain, vitality, mental health, or health distress reached significance for inclusion in the final model. After adjusting for these four significant predictors, no significant differences were found between medication groups ($p = 0.42$) in mean satisfaction scores (95% CI): oral medications alone 26.3 (25.0 to 27.6); insulin alone 25.6 (23.7 to 27.5), oral medications and insulin 24.8 (23.0 to 26.6).

Conclusions: These results indicate that patients with diabetes are more likely to be satisfied with medications that have clinical effectiveness, less negative impact such as interfering with daily life, lower perceived mood side effects, and greater flexibility of application timing. Treatment satisfaction may, in turn, drive adherence to treatment regimens and thereby improve glycemic control.

Monitoring individual needs in persons with diabetes: results of an ongoing, nurse-led well-being assessment as part of the annual review

N. Zandbelt¹, M. de Wit¹, C. H. C. Lubach², N. Breas², F. J. Snoek¹;

¹Medical Psychology, ²Diabetes Centre, VU University Medical Centre, Amsterdam, The Netherlands.

Background and Aims: International guidelines advocate systematic monitoring of well-being as integral part of diabetes care. In previous research we demonstrated feasibility and effectiveness of a nurse-led computer-assisted assessment procedure. The aim is to implement and evaluate pc-assisted monitoring of psychological well-being by the diabetes nurse specialist (DNS) as integral part of ongoing outpatient care for adults with diabetes. Data on well-being and glycaemic control of the first 301 patients included in this ongoing project, are presented here.

Materials and Methods: A computerised assessment programme was developed, including the WHO-5 Well-being Index and the Problem Areas in Diabetes (PAID) scale. The DNSs received training to interpret and discuss psychological outcomes. The computerised assessment takes 5–7 minutes and is scheduled as part of the annual review, prior to the consultation with the DNS. A report on psychological status is automatically generated and discussed with the patient. All adult outpatients with diabetes type 1 or 2 are eligible.

Results: So far, 308 diabetes patients participated in the period between September 2005 and October 2006. Five patients dropped out (1.6%; reasons: language problems or new patients), and 2 patients (0.6%) came for their second annual review, resulting in a total of 301 patients (N=301; mean age was 52.3 years±15.7, 50.2% male, 47.2% type 1). Overall mean HbA_{1c} was 7.9%±1.1 (range: 5.1 – 11.5%). No significant differences in HbA_{1c} were found between males and females nor between type 1 and type 2 diabetes. Seventy patients (23.3%) reported poor well-being (WHO-5 score ≤ 50), and 23 patients (7.6%) had scores indicative for depression (WHO-5 score ≤ 28). Fifty-nine patients (19.6%) reported seriously elevated diabetes distress (PAID ≥ 40). WHO-5 and PAID showed a significant but moderate correlation ($r = -0.457$, $p < 0.01$). In total, 32 patients (10.6%) had high diabetes-specific distress (PAID score ≥ 40) and low emotional well-being (WHO-5 score ≤ 50), while 14 patients (4.7%) had high diabetes-specific distress (PAID score ≥ 40) and likely depression (WHO-5 score ≤ 28). Psychological functioning was not significantly associated with HbA_{1c}. Patients who indicated low well-being and/or high diabetes-distress did not have significantly higher (or lower) HbA_{1c}'s. From PAID/WHO-5 scores, 14 'cases' (4.7%) were identified, of whom 2 patients were already known and had received psychological support prior to the assessment. Nine patients were referred for professional psychological treatment as a result of the monitoring. Four of them had not (yet) agreed to psychological counselling although they had high depression and distress scores.

Conclusion: Monitoring well-being as part of ongoing diabetes care is feasible and well appreciated by both health care professionals as well as patients. It provides valuable information on patient's psychological status. Approximately 1 in 4 patients has (serious) psychological issues, warranting attention. Glycaemic control is not a good marker for psychological functioning, underscoring the need to assess well-being next to clinical parameters. An international collaborative study (DAWN MIND) has just started to promote further dissemination of this procedure in secondary care.

No relation between treatment modality and quality of life in type 1 diabetes after 11-year follow-up

S. J. J. Logtenberg¹, N. Kleefstra^{1,2}, E. G. Gerrits¹, E. van Ballegooye^{2,3}, H. J. G. Bilo^{1,4};

¹Diabetes Research Centre, Isala Clinics, Zwolle, ²Langerhans, Medical Research Group, Zwolle, ³Internal Medicine, Bethesda General Hospital, Hoogeveen, ⁴Internal Medicine, UMCG, Groningen, The Netherlands.

Background and Aims: Over the last decades intensified insulin therapy with multiple daily injections (MDI) or continuous insulin infusion (CII) has become the treatment of choice in patients with type 1 diabetes mellitus (T1DM). CII improved health related Quality of Life (QoL) in randomized trials with limited follow-up. The purpose of this study is to evaluate metabolic control and QoL in a T1DM population in relation to intensive insulin regimens during an 11-year follow-up.

Materials and Methods: As part of a prospective cohort study that was initiated in 1995, a cohort of patients with T1DM was examined annually according to protocol. To determine long term changes in QoL (as assessed with the SF-36 questionnaire) and metabolic control (HbA_{1c}) data from 184 subjects who completed baseline and follow-up measurements were analysed. Paired t-tests and analysis of variance were used for comparisons with correction applied for multiple testing.

Results: Final follow-up measurements were performed in 2005 and 2006 (follow-up 11.1±0.3 years). Baseline characteristics (% or mean±SD): 57.6% male, age 37.5±10.9 years, diabetes duration 16.0±9.7 years.

Significant changes (mean Δ (95% CI)) in HbA_{1c} (-0.25 (-0.50, -0.01) and QoL (Physical Component Summary (CS); -3.5 (-4.7, -2.2), Mental CS; -2.0 (-3.6, -0.4)) over time were observed (table). Regarding mode of therapy, 50 patients progressed from MDI to CII at some point during follow-up (median time on CII in 2006 6.8 years). 87 patients remained on MDI and 45 remained on CII throughout follow-up. Two patients discontinued CII in favour of MDI. There were no significant differences in change or final follow-up measurements of metabolic control and QoL parameters between patients that remained on either therapy or patients that switched from MDI to CII (ANOVA; $p > 0.05$). At baseline, no differences in HbA_{1c} were observed that could possibly identify patients that would progress in the years to come from MDI to CII. However, at baseline some SF-36 subscores and the Mental CS were lower in patients that would switch in the following years (time on CII > median) compared to patients that would switch later in follow-up ($p < 0.05$).

Values at baseline and 11-year follow-up in cohort of patients with type 1 diabetes (n=184)

Parameter	Baseline	Follow-up	Mean Δ (95% CI)	p-value
HbA _{1c} (%)	8.0±1.7	7.7±1.0	-0.25 (-0.50, -0.01)	0.04
Total cholesterol (mmol/L)	4.9±0.9	4.9±0.9	0.06 (-0.08, 0.20)	0.40
eGFR (mL/min)	109.2±25.5	97.7±27.1	-11.5 (-13.8, -9.1)	<0.001
Systolic blood pressure (mm Hg)	138.4±17.4	134.5±17.2	-3.8 (-6.8, -0.9)	0.01
Body mass index (kg/m ²)	24.8±3.1	26.9±4.4	2.1 (1.7, 2.6)	<0.001
SF-36: Physical Component Summary	53.1±6.5	49.6±8.5	-3.5 (-4.7, -2.2)	<0.001
SF-36: Mental Component Summary	52.3±8.8	50.3±9.8	-2.0 (-3.6, -0.4)	0.01

Conclusion: These long term results show improved metabolic control over time in patients with T1DM, regardless of treatment mode and regardless of treatment intensification during the years. Interestingly, differences in QoL between treatment modes could not be identified in this cohort at long term follow-up. Prospective trials will need sufficient follow-up time to verify their results of improving QoL with CII. If not verified, improvement of QoL with CII could be a short term effect, which could also be due to bias because of the impossibility of blinding.

PS 106 Neuropathy: diagnosis and prevalence

1068

A comparison of the new indicator test for sudomotor function (Neuropad®), the vibration perception threshold and the clinical examination in the diagnosis of peripheral neuropathy in type 2 diabetic patients

N. Papanas¹, K. Papatheodorou¹, D. Papazoglou¹, C. Monastiriotes¹, D. Christakidis², E. Maltezos¹;

¹Second Department of Internal Medicine, Democritus University of Thrace, Alexandroupolis,

²Diabetic Department, University Hospital of Alexandroupolis, Greece.

Background and Aims: Peripheral neuropathy remains a major cause of morbidity and a cardinal factor in the pathogenesis of diabetic foot ulceration. Clinical examination is the cornerstone of diagnosis. The Vibration Perception Threshold (VPT) is a reliable tool not only for the diagnosis of neuropathy, but also for the estimation of the risk for foot ulceration. Thus, the aim of the present study was to evaluate the new indicator test for sudomotor function (Neuropad®) in the diagnosis of peripheral neuropathy in patients with type 2 diabetes mellitus, as compared with clinical examination and with the VPT.

Materials and Methods: This study included 154 type 2 diabetic patients (76 men, 78 women) with a mean age of 64.3±7.3 years and a mean diabetes duration of 12.8±4.3 years. Recruitment was consecutive and performed in a tertiary care setting. Neuropathy was diagnosed clinically using the Neuropathy Disability Score (NDS). The VPT was measured with a neurothesiometer (Horwell Scientific Laboratory Supplies, London, UK) whose tractor was applied vertically on the pulp of the hallux. The test was repeated three times and the mean voltage was recorded. The VPT was considered abnormal in patients with a VPT > 25 Volts. Patients were also examined with the indicator test, applied on the plantar aspect of the feet. Time until complete colour change of the test was recorded and sudomotor impairment was diagnosed in patients with time until complete colour change exceeding 10 minutes in at least one foot.

Results: Neuropathy was diagnosed in 90 patients (58.4%). Sudomotor impairment was diagnosed in 88 patients (97.8%) with neuropathy and in 21 patients (32.8%) without neuropathy ($p < 0.001$). Sensitivity of the indicator test for diagnosing neuropathy was 97.8% and specificity was 67.2%, while positive and negative prognostic values were 80.7% and 95.6% respectively. Abnormal VPT was detected in 71 patients with neuropathy and 9 patients without neuropathy ($p < 0.001$). Sensitivity, specificity and positive and negative prognostic values of VPT were 78.9%, 84.4%, 88.8% and 74.3% respectively. Time until complete colour change of the indicator test was 21.8±6 minutes in patients with neuropathy and 9.1±3.6 minutes in patients without neuropathy ($p < 0.001$). A significant correlation was shown between time until complete colour change and VPT (Spearman's rank coefficient $r_s = 0.889$, $p < 0.001$).

Conclusions: Both the indicator test and the VPT have a high sensitivity for neuropathy. Sensitivity is slightly higher with the indicator test, but specificity is higher with VPT. Time until complete colour change of the indicator test shows a positive correlation with VPT. These results suggest that, while VPT is a validated test to estimate the risk of foot ulceration, Neuropad may prove valuable as an additional diagnostic tool of neuropathy in type 2 diabetes. Neuropad appears to be suitable for screening, self-examination and education. Its potential contribution to the estimation of risk for foot ulceration could only be investigated in a prospective study.

1069

Evaluation of the self-administered indicator plaster neuropad for the diagnosis of neuropathy in diabetes

N. Tentolouris, V. Achtsidis, K. Marinou, S. Liatis, E. Diakoumopoulou, N. Katsilambros;

1st Department of Propaedeutic Medicine, Athens University Medical School, Laiko General Hospital, Greece.

Background and Aims: Chronic peripheral sensorimotor neuropathy (PN) is a common complication of diabetes and it is the main cause for foot problems. Sudomotor dysfunction develops early in the course of diabetes. Previous

data demonstrated that sudomotor dysfunction-assessed with the use of the indicator plaster neuropad (IPN)-has a high sensitivity and specificity for the diagnosis of the PN. The advantage of the IPN is that it is an easy to perform test by the patient. In the present study we evaluated the inter-rater reliability of the IPN between patient and provider sensory evaluations.

Materials and Methods: A total of 156 consecutive subjects (age 59.6±15.4 years, duration of diabetes 13.8±9.2 years) with both type 1 and type 2 diabetes were recruited from the outpatient diabetes clinic of our hospital. Inclusion criteria required that they were able to read and understand the written instructions on the use and evaluation the IPN. Patients with dyschromatopsia or severe visual loss as well as severe peripheral vascular disease (ankle-brachial pressure index < 0.5) were excluded. Participants were assessed for neuropathy at the first visit. Diagnosis of neuropathy was based on neuropathy symptom score, neuropathy disability score, and vibration perception threshold. The IPN was applied for 10 min and evaluated as normal or abnormal by the doctor at the same visit. Afterwards, the IPN together with written instructions for its use and evaluation at home were given to the patient. In addition, a special questionnaire was provided asking for the easiness to understand the instructions, the easiness to use and the easiness to evaluate the IPN (visual analogue scales 0–10, with 0 the most difficult and 10 the easiest for each question). All participants returned the results of the IPN and the completed questionnaires in a second visit to another participating doctor, who was blind to results of the tests of the first visit.

Results: Neuropathy was diagnosed in 93 subjects (59.6%). The sensitivity of the IPN for the diagnosis of PN was 87% and the specificity 68.9%. The agreement between patient and doctor in the evaluation of neuropad as normal or abnormal was 90.3% (in 141 out of 156 subjects). The k statistic to measure overall agreement between patients and health-care provider was very good: 0.88 (95% confidence intervals 0.85–0.91). Also, the evaluation of the instructions and the test by the patients was as follows: easiness to understand the instructions 9.1±1.4, easiness to use the IPN 9.0±1.5, and easiness to evaluate the test as normal or abnormal 8.9±1.4.

Conclusion: Self-administered IPN provides patients an opportunity to share in the responsibility for the identification of the PN. The test can be used easily by the patients when clear, written instructions for its use and evaluation are provided.

1070

In vivo corneal confocal microscopy and nerve growth factors in the assessment of microvascular complications in diabetic patients

J. Nam¹, J. Park¹, M. Cho¹, H. Kim¹, H. Chung¹, E. Kang¹, Y. Lee¹, C. Ahn¹, Y. Song², B. Cha¹, E. Lee¹, S. Lee¹, K. Kim¹, H. Lee¹;

¹Internal Medicine, Yonsei University Medical College, Seoul,

²Internal Medicine, NHIC Hospital, Koyang, Republic of Korea.

Background and Aims: *In vivo* corneal confocal microscopy (IVCCM) is being recognised as a non-invasive, early diagnostic tool for diabetic neuropathy, for it provides a clear image of corneal subbasal nerve plexus in detail. Nerve growth factors (NGF) are believed to regulate peripheral and central nervous system, neuronal differentiation, and regeneration of damaged nerves, and their role in diabetic neuropathy is being emphasised these days. Moreover, NGFs and receptors are also expressed in retina and renal mesangial cells, suggesting their possible role in the common pathogenesis of diabetic microvascular complications. We plan to examine corneal structures of diabetic patients and compare those with conventional tools and analyze their serum and tear NGF levels.

Materials and Methods: IVCCM, nerve conduction velocity (NCV), and serum, urine, and tear samplings were done in 42 diabetic patients. From IVCCM, we measured corneal nerve density, branch, and tortuosity, total corneal/epithelial thickness, and the number of endothelial/keratocyte cells, and we checked patients' biochemical profiles and serum and tear NGF levels.

Results: Patients with more severe neuropathy had less corneal endothelial cells (3105±218 vs. 2537±142 vs. 2350±73 vs. 1914±465, $P = 0.02$), higher serum NGF (35.51±15 vs. 59.86±57.66 vs. 79.67±57.63 vs. 109±60.81, $P = 0.39$) and tear NGF levels (135±11.94 vs. 304.29±242.22 vs. 538.5±251.92 vs. 719.5±92.63, $P = 0.01$). There was a positive correlation between neuropathy and corneal nerve tortuosity ($r^2 = 0.479$, $P = 0.044$) and negative correlation between neuropathy and endothelial cell count ($r^2 = -0.709$, $P = 0.002$). Interestingly, similar changes were seen in other microvascular complications as well.

Conclusion: Our results provide a possibility of using novel tools, IVCCM and NGF, as common diagnostic tools for diabetic microvascular complications, but it should be followed by a large population study.

Assessment of the risk of falling in postmenopausal women with diabetes using a foot mat system

S. L. Hyer¹, M. Plank¹, A. Rodin¹, S. Patel²;

¹Diabetes, ²Rheumatology, St Helier University Hospital, Surrey, United Kingdom.

Background: Older women with diabetes have an increased risk of falls which is only partly explained by known risk factors.

Objective: To assess postural stability in women with diabetes compared with healthy controls

Methods: Post-menopausal women were randomly selected from a hospital-based diabetes database and invited to participate. We studied 147 patients (aged 55–91) with diabetes and 18 age-matched controls. All subjects were assessed for neuropathy and falls risk from detailed history, clinical examination and vibration perception threshold (VPT). Postural stability (sway) was assessed by the motion of the centre of force (COF) during quiet standing on a foot mat system (Tekscan[®]). Force transducers in the foot mat detect pressure changes under the foot from which COF trajectories can be displayed.

Results: Mean VPT (volts) in those who had fallen 3 or more times (22.7±2.3) was greater than in those who had not fallen at all in the last 12 months (18.4±0.9); $p=0.05$. Mean (SD) COF centroid area (area of sway) (mm²) was significantly increased in the diabetic group versus controls; 505 (317) vs. 360 (128); $p<0.05$ and was highest in the 65 neuropathic patients; 513 (273). Asymmetric loading with lateralisation of the COF to one side was observed in 19 patients with diabetes and only 1 control. Mean time (hours) on feet was inversely correlated with severity of neuropathy and sway area ($r=-0.28$; $p=0.01$).

Conclusion: Increased postural sway and hence postural instability occurs frequently in older women with diabetes even when VPT is below the conventional threshold for significant neuropathy (i.e. <25 V). Patients with instability adopt a strategy of spending less time on their feet in order to reduce their risk of falling. Assessment of postural stability in addition to clinical examination and VPT measurement provides useful additional information on falls risk in this group of patients.

Supported by grant from R&D department at Epsom and St Helier University Hospitals

1072

Diagnostic aspects of diabetic somatic and sudomotor neuropathy in general practice

Z. A. Kamenov, V. G. Christov, T. Yankova, V. N. Karamfilova;
Medical university, Clinic of Endocrinology, Sofia, Bulgaria.

Background and Aims: Epidemiological data for the most common late diabetic microvascular complication – diabetic neuropathy (DN) vary considerably among different studies depending on the method. Large questionnaires and sophisticated electrophysiological testing are inappropriate for everyday practice. Simple devices are usually used for somatic DN, but autonomic DN is often under diagnosed. A new diagnostic test – Neuropad[®] has been developed as a simple tool for early detection of sudomotor neuropathy and for early recognition of the diabetic foot syndrome.

The aim of this study was to evaluate the utility of Neuropad and to compare the results with other tests for DN.

Materials and Methods: In this cross-sectional study were included 264 consecutive diabetic men/women (126/138) with mean age±SD 55.4±12.0 years, diabetes type 1 or 2 (61/203) and diabetes duration of 9,3±7,1 years. The patients were divided according to the presence or absence of neuropathic symptoms. For somatic DN a modified Neuropathy Disability Score (NDS) was used including vibration perception (VP) with 128-Hz graduated in 8 stages Rydel-Seiffer tuning fork; temperature perception (TP) (Thio-Term, Germany); 10g monofilament (MF); Achilles reflex (AR). The maximum

NDS was 10 points (5 points for each foot). For sudomotor DN Neuropad was used – an adhesive indicator test that changes color when applied to the skin of the sole. The color change was rated as normal – group 0 – complete change from blue to pink (n= 81), borderline – group 1 – mottled blue/pink color (n= 164), abnormal – group 2 – no color change (n= 19).

Results: 187 (70.8%) from all patients had neuropathic symptoms. Of them positive for DN were only: for VP (≤6/8)–158 patients (84.5%); TP (no feeling)–109(58.3%); MF (no feeling)–80(42.8%); AR (abnormal)–165(88.2%); NDS (≥ 6 points)–123(65.8%); NDS (≥1point)–182(97.3%); Neuropad (≥ 1)–152(81.3%). On the contrary, in the group of 77(29.2%) asymptomatic patients positive neuropathic tests had VP-42 (54.5%); TP-26 (33.8%); MF-13 (16.9%); AR-47 (61.0%); NDS(≥ 6)- 22 (28.6%); NDS(≥1)- 58 (75.3%); Neuropad-44(57.1%) The three Neuropad-groups differed significantly in their NDS and in each test in particular.

Conclusion: The objective differences in test results, caused by separate neuronal modality engagement, require a complex diagnosis of DN in the general practice, including medical history, use of simple devices for somatic DN, and examination for autonomic neuropathy with tests like Neuropad.

We would like to thank our colleagues Stefan Dimitrov, Victoria Andreeva and Petya Staikova for technical assistance. The diagnostic test Neuropad was a kind gift from miro Verbandstoffe GmbH.

1073

The prevalence and current therapeutic management of painful polyneuropathy in diabetes clinics in Belgium

K. Van Acker¹, I. Colin², D. Bouhassira³, S. Weiss⁴, K. Matthys⁴, H. Raemen⁴, C. Mathieu⁵;

¹Endocrinology and Diabetes, St. Jozefkliniek, Bornem, Belgium,

²Endocrinology, CHR. St.-Joseph-Hôpital de Warquignies, Mons, Belgium,

³Centre d'Evaluation et de Traitement de la douleur, CHU Ambroise Paré, Paris, France, ⁴Pfizer Inc., Brussels, Belgium,

⁵Endocrinology and diabetology, UZ gasthuisberg, Leuven, Belgium.

Background and Aims: Painful diabetic polyneuropathy (DPN) is a common and debilitating, but still under-recognized and undertreated complication of diabetes. The aim of this study was to evaluate the prevalence of DPN and painful DPN (PDPN) in diabetes clinics throughout Belgium. In addition, PDPN-associated conditions, impact on quality of life (QoL) and current therapeutic management of neuropathic pain were investigated.

Materials and Methods: A cross-sectional multi-centre study including 1111 patients (767 type 2, 344 type 1) in 40 diabetes clinics was carried out. Validated tools were used for the diagnosis of DPN (Neuropen[®]-diagnosed sensory loss) and PDPN (score ≥ 4 on DN4 questionnaire applied in patients with DPN and pain in the legs). Pain intensity was measured by a Visual Analog Scale (VAS). Participants completed the Short Form-12 (SF-12) to evaluate the physical and mental QoL. Multivariate models were used to analyse patient data.

Results: The prevalence of both DPN and PDPN increased with age and diabetes duration ($p<0.0001$), not with gender or HbA1C. Prevalences were 43% for DPN and 14% for PDPN, with a significantly higher prevalence in type 2 than in type 1 (DPN 43,5% vs. 38,4% and PDPN 15,4% vs. 10,8% resp.). Multivariate analysis showed that age, diabetes duration, nephropathy, obesity, low HDL-C and high triglycerides were all independently associated with PDPN. In the subgroup of patients with pain in their legs (n=531), the prevalence of PDPN proved to be 30%. The median VAS score was twice as high in patients with neuropathic pain vs. non-neuropathic pain (50 vs. 25mm, $p<0.0001$). Multivariate analysis of the impact on QoL showed that PDPN independently affected the physical QoL, next to age, BMI, nephropathy and sensory loss neuropathy. PDPN also affected the mental QoL, next to female gender, smoking, BMI and sensory loss neuropathy. Further adjustment for pain intensity did not alter these findings.

Nearly half of the PDPN patients (46,3%) were treated for their pain. Only 25,7% of those treated for pain received anticonvulsants or antidepressants.

Conclusion: PDPN is a frequent long-term complication of diabetes, especially in type 2 patients with metabolic syndrome characteristics. It profoundly diminishes the quality of life in affected persons. Diagnosis can be easily made with cheap tools, not requiring special expertise and should therefore be used more extensively. More adequate treatment of neuropathic pain should be considered in PDNP patients.

1074

Does motor nerves impairment predominate in children with short duration type 1 diabetes and poor metabolic control?E. Piontek¹, M. Wysocka-Mincewicz¹, I. Gromek², J. Skwarzec¹;¹Department of Metabolic Diseases, Endocrinology and Diabetology,²Department of Neurology and Epileptology, The Children's Memorial Health Institute, Warsaw, Poland.

Background and Aims: Diabetic neuropathy is serious and burdensome and with no effective treatment till now. The aim of the study was to detect early abnormalities to distinguish the group of risk developing peripheral neuropathy.

Materials and Methods: 45 children with type 1 diabetes were included in the study (25 girl and 20 boys, mean age 14,68 years+/-3,07SD, mean HbA1c 8,38%+/-1,63SD, mean duration of diabetes 4,96+/-3,28). In all cases neurologic examination and nerve conduction studies of motor (median, ulnar, tibial and peroneal) and sensory nerves (median, ulnar and sural) with standard techniques were done. Chi-square frequency analysis were performed.

Results: In the studied group polyneuropathy was recognised in 8 children (17,8 %, in 5 person motor, and in 3 sensory-motor), with only 2 person showing no clinical signs and symptoms. Abnormalities in conduction tests of 31,1% of peroneal nerves, 24,4% tibial, 6,7% in sural nerves and 4,4% in sensory ulnar and 2,2% in motor median, were recorded. In motor nerves primary axonal changes with decreasing of potential amplitude were detected (abnormalities in 37/180 tested nerves, 20,5%) and elongation of wave F latency, which indicates injury of nerves trunk (50/180, 27,8%). In sensory nerves decrease of conduction velocity (22/135, 16,3%) was dominant. Significant differences between frequency of motor and sensory nerves impairment were recorded (26/180 vs. 5/135 respectively, p<0,005) and nerves of legs and arms (28/135 vs. 3/180 respectively, p<0,00001).

Conclusion: In poor metabolic controlled children with type 1 diabetes with short duration of diabetes axonal changes and trunk damage of motor nerves were predominating. In sensory nerves demyelinating lesions with the decrease in conduction velocity were observed.

Methods: Two hundred and fifty five asymptomatic patients, aged 10–20 years diagnosed with type 1 DM and a control group of fifty two healthy age-matched subjects participated in the multicentre study, during 2005 / 2006. The patients included in the study had been diagnosed as type 1 DM for more than one year, without any evidence of neurological illness, and drugs that would disturb the nerve conduction velocity, without cetoacidosis or severe hypoglycaemia in the last 6 month before and at the moment of the study. Clinical examination: weight, height, BMI (body mass index) pubertal stage (Tanner), alcohol and tobacco consumption in both. In patients with DM we considered: duration of disease (years), HbA1c (mean value of the previous 12 months), insulin dose (U/kg). Microangiopathic complications: microalbuminuria and retinopathy.

Michigan tests: 1) examination of the foot appearance (skin lesion, hallux), 2) foot ulceration, 3) vibration perception (128hz tuning fork), 4) sensibility (10 grams Semmes Weinstein monofilament pressure), 5) Achilles tendon reflex. Classification score: < 3: normal; 4-5: risk score; > 6 pathologic.

In addition, thermal sensibility (warm, cool), pedals pulses, muscle strength testing (assessing finger spread) and associated symptoms were evaluated.

Results: Michigan normal: DM: 97.2% vs. control: 100%; risk score: 1.96% pathologic score: 0.78%.with more than 9 years duration of disease (or: 11.28-p= 0.003) Associated symptoms were cramps with normal score 23.8% risk score 40% and in pathologic score 100%. The decrease of muscle strength on the 13.3% and pedal pulse abnormal: 2.8%; abnormal thermal sensibility for cold, 5.5 %warm: 5.9% vs control:0%. Characteristics of the diabetic and control populations in table 1

Conclusions: While it is an uncommon problem during childhood, it needs to be considered in adolescents with long duration of diabetes. Michigan score is a simple method, easy to apply and has high effectiveness in order to diagnose DM neuropathy.

1075

Diabetic neuropathy in children and adolescents: a multicentre studyL. Caracotche^{1,2}, S. Segal¹, L. Trifone¹, M. Ferraro³, I. Moreno⁴, A. Figueroa Sobrero⁵, S. Lopez⁶, M. Rópolo⁷, G. Freijoo⁸, D. González⁹, L. Tartaglino¹⁰, D. Fernandez¹¹;

Ma. Trinidad, Córdoba, ⁸Children Hospital Jesús of Praga, Salta, ⁹Regional Hospital de Neuquén, ¹⁰Minister Health, Posadas, Misiones, ¹¹Hospital Enrique V. Barrios, La Rioja, Argentina.

Background: Neuropathy is well recognized as a major complication of type 1 diabetes mellitus in adults, resulting in significant morbidity and mortality. Symptomatic peripheral neuropathy is uncommon in children and adolescents with type 1 diabetes mellitus, although a high prevalence of subclinical peripheral nerve conduction abnormalities has been reported in these patients. Michigan neurophatic inspection is a clinical examination easy to use in the detection of neuropathy, and has been validated in epidemiological studies in adults.

Aims: To asses the availability of a clinical method screening (Michigan test) to detect peripheral neuropathy in children and adolescents with type1 Diabetes Mellitus (DM), and to estimate the prevalence and associated risk factors.

Background and aims: Ultrasound (US) measured intrarenal resistance index (RI) predicts renal function in several conditions. No standard cut-offs have been identified to date; however values above 0.75–0.85 have been associated with chronic kidney disease and deterioration of renal function over time. The use of RI in routine clinical practice for the identification and prediction of diabetic nephropathy (DN) is virtually unexplored, particularly in patients with normoalbuminuria. Aims of the study are: 1) to compare the distribution of RI in control subjects and in type 2 diabetic patients; 2) to validate the use of RI in the identification and prediction of DN

Methods: Design: observational, prospective. Participants: 88 type 2 diabetic patients aged 40 to 70 and 37 non diabetic controls age and gender matched; both groups included people with moderate hypertension and normal renal function. Measurements: BP, fasting glucose, lipids, creatinine, HbA_{1c}, urinary albumin and creatinine on spot collection; creatinine clearance and urinary albumin excretion rate (AER) were calculated. RI was measured by US with a standard protocol. Diabetic patients were re-examined after 48±5 months; the progression of albuminuric state was defined as – i.e. transition from baseline normoalbuminuria to micro/macroalbuminuria at follow-up or from baseline normo/microalbuminuria to macroalbuminuria at follow-up.

Results: Diabetic patients had significantly higher RI than controls (0.69±0.04 vs. 0.59±0.05, $p < 0.001$). RI values were normally distributed in both groups with little overlapping: ranging from 0.61 to 0.80 and from 0.48 to 0.67 respectively in diabetic and non diabetic participants. We used the 80th percentile of the distribution in diabetic patients (i.e. ≥ 0.73) to define high RI; this value is lower than arbitrary cut-offs used in previous studies. Patients with high RI had significantly higher AER (48.9±74.8 vs. 31.7±45.3 $\mu\text{g}/\text{mg}$, $p < 0.001$). Age, HbA_{1c}, lipids, smoking habits and use of renin/angiotensin system inhibitors were not significantly different in the two groups. At follow-up AER increased significantly more in patients with high RI (follow-up minus baseline was 290.8±469.4 vs. 34.9±140.3 $\mu\text{g}/\text{mg}$, $p < 0.001$). Progression of the albuminuric state was observed in 52.9% and 9.5%, $p < 0.001$, of those with high or low RI respectively. Unadjusted Odds Ratio for progression was 10.7 (95%CI 3.0–38.0) for patients with $\text{RI} \geq 0.73$ vs. < 0.73 . After correction for established predictors of DN (i.e. age, BP, renin/angiotensin system inhibitors, HbA_{1c}, microalbuminuria and creatinine clearance) multivariate OR calculated by exponentiation of regression coefficients was 6.0 (95% CI 1.7–21.2). By confining the analysis to patients with normoalbuminuria, OR for progression was 7.2 (95% CI 1.6–32.3) for patients with $\text{RI} \geq 0.73$ vs. < 0.73 .

Conclusions: Ultrasound measured RI is associated with clinical signs of DN and predicts its progression overtime. Values above 0.73 predict progression of albuminuric stage in the total group as well as in normoalbuminuric patients. Thus RI is an early and reliable marker of risk of DN

Intrarenal arterial resistance index is a good predictor of chronic kidney disease in type 2 diabetes

A. P. S. Kong^{1,2}, E. K. H. Liu³, W. C. W. Chu³, W. Y. So¹, P. C. Y. Tong¹, J. C. N. Chan¹;

¹Medicine and Therapeutics, ²Li Ka Shing Institute of Health Science, ³Diagnostic Radiology and Organ Imaging, The Chinese University of Hong Kong, Shatin, Hong Kong.

Background and Aims: Intrarenal arterial resistance index (RI) is associated with various renal diseases, notably obstructive uropathy and hypertensive

renal disease. Despite the growing incidence of diabetes-associated chronic kidney disease (CKD), there is a paucity of data of RI in diabetes. We examined the relationship between RI and CKD and defined its optimal cut-off value to predict CKD in a consecutive cohort of Chinese male patients with type 2 diabetes.

Materials and Methods: 113 Chinese men with type 2 diabetes (mean age=54.7±9.9 years, mean body mass index (BMI)=25.9±5.2 kg/m^2) had RI measured by real-time Doppler ultrasound in addition to detailed phenotyping. Estimated glomerular filtration rate (eGFR) was calculated using Modified Modification of Diet in Renal Disease (MDRD) formula calibrated for Chinese.

Results: RI was correlated with eGFR ($r = -0.61$, $p < 0.001$), urinary albumin-creatinine ratio (ACR) ($r = 0.38$, $p < 0.001$) and serum creatinine levels ($r = 0.49$, $p < 0.001$) using Pearson's correlation analysis. There was progressive increase of RI with advancing stages of CKD (p for trend < 0.001). After adjustment for age, BMI, disease duration, hypertension, dyslipidaemia and urinary ACR, RI remained an independent predictor for CKD ($< 60 \text{ ml}/\text{min}/1.73\text{m}^2$). Using Receiver Operating Characteristics (ROC) curve analysis, the cutoff value of $\text{RI} \geq 0.75$ had a sensitivity of 82% and a specificity of 89% to predict CKD.

Conclusion: RI is an independent predictor of CKD in Chinese men with type 2 diabetes and is potentially useful to identify high risk subjects for close monitoring.

Performance of the new '175' MDRD equation using 'gold standard' creatinine values in persons with newly diagnosed type 2 diabetes

R. A. Chudleigh, J. N. Harvey, G. Dunseath, R. Peter, S. Luzio, D. R. Owens; Diabetic Medicine, Diabetes Research Unit, Cardiff, United Kingdom.

Introduction: The Modification of Diet in Renal Disease (MDRD) equation has been revised for use with Isotope Dilution Mass Spectrometry (ID-MS) traceable 'gold standard' creatinine values. This revision is proposed to improve the performance of four variable-MDRD equation. We compared the performance of the traditional '186' MDRD and new '175' MDRD equations to predict Glomerular Filtration Rate (GFR) measured by ⁵¹CrEDTA in a cohort of newly diagnosed persons with type 2 diabetes.

Methods: 293 subjects newly diagnosed with type 2 diabetes were recruited and studied fasting at 0830 hours. Serum creatinine concentration was measured on a Vitros analyser using OCD dry slide method. Creatinine was aligned to ID-MS traceable values using United Kingdom National External Quality Assessment Service (UK NEQAS) recommendations. Estimated Glomerular Filtration Rate (eGFR) was calculated by the '186' MDRD equation using non aligned creatinine values, and the '175' MDRD equation using ID-MS traceable creatinine values. GFR was measured by single plasma injection clearance of 1MBq of ⁵¹CrEDTA using the four sample method.

Results: In the study population 75% of subjects were male with a mean (SD) age of 55.2 (9.4) years, BMI of 31.52 (5.58) kg/m^2 , fasting plasma glucose of 9.67 (3.04) mmol/l and HbA_{1c} of 7.79 (2.00) %. 89% of subjects had normoalbuminuria.

Mean (SD) creatinine and ID-MS traceable creatinine values for the study population were significantly different at 80.0 (14.8) and 73.0 (14.9) $\mu\text{mol}/\text{l}$ respectively ($p < 0.05$). Mean (SD) Isotopic GFR of the population was 115 (22) $\text{ml}/\text{min}/1.73\text{m}^2$, this was significantly underestimated by the '186' MDRD and '175' MDRD equations at 89 (19) and 95 (22) $\text{ml}/\text{min}/1.73\text{m}^2$ respectively ($p < 0.05$). The '186' MDRD equation had a significantly greater negative bias than the '175' MDRD equation, mean [SE] bias were -25.0 [1.0] and -20.1 [1.0] $\text{ml}/\text{min}/1.73\text{m}^2$ respectively ($p < 0.05$). The '186' MDRD equation was less accurate than the '175' MDRD equation with 79% [2%] of results within 30% of measured GFR compared with 86% [2%] using the '175' MDRD equation.

Conclusion: In persons with newly diagnosed type 2 diabetes using ID-MS traceable creatinine values in the '175' MDRD equation improves performance of the MDRD equation to estimate GFR.

1079

Both Cockcroft-Gault and MDRD4 estimated GFR are markedly lower than 24hr creatinine clearance in subjects with diabetes mellitus type 2A. G. Lieve¹, S. J. J. Logtenberg², N. Kleefstra^{2,3}, R. T. Gansevoort⁴, H. J. G. Bilo^{2,5};¹Internal Medicine, Maxima Medical Centre, Eindhoven,²Diabetes Centre, Isala Clinics, Zwolle, ³Langerhans, Medical Research Group, Zwolle, ⁴Nephrology, UMCG, Groningen,⁵Internal Medicine, UMCG, Groningen, The Netherlands.

Background and Aims: Decreased renal function has been identified as a risk indicator for both cardiovascular mortality and all cause mortality in subjects with diabetes mellitus (DM) type 2. In national and international guidelines, it is advised for reasons of practicality to abandon measurement of 24hr creatinine clearance (CrCl), and to estimate renal function by using either the Cockcroft-Gault (CG) formula or the four-component Modification of Diet in Renal Disease (MDRD4) formula. Furthermore, it is advised to consider referral of subjects with an estimated glomerular filtration rate (eGFR) < 60 to an internist or nephrologist. We compared estimates of GFR obtained with both formulas to GFR as calculated with CrCl in a population of patients with DM type 2.

Materials and Methods: As part of the local protocol for medical care of the diabetes outpatient clinic of the Maxima Medical Centre in Eindhoven, 24hr urine samples and venous blood samples are collected. For the purpose of this study analysis was performed on data from 1087 consecutive patients who visited the clinic between June 2005 and December 2006. Serum and urinary creatinine was measured using the enzymatic method. To estimate GFR, CrCl was calculated from 24hr urine samples, and by using the CG formula and the MDRD4 formula. Body surface area (BSA) was calculated using the method of Mosteller.

Results: Patient characteristics (mean±SD): Age 61.1±13.3 years, body mass index 28.7±5.7 kg/m², BSA 2.0±0.2 m² and HbA_{1c} 6.9±1.2%. 56% was male.

Mean eGFR±SD was with CrCl 115±50 mL/min, with CG 99 ± 42 mL/min, and with MDRD4 82±27 mL/min/1.73 m². Figure 1 shows boxplots of the 3 methods. Mean difference (95% confidence interval) was for CrCl and CG 16.4 (14.4, 18.5), for CrCl and MDRD4 32.6 (30.4, 34.9) and for CG and MDRD4 16.2 (14.6, 17.8); all p<0.01. When using CrCl as proxy for GFR 12% should be considered for referral, whereas these numbers are considerably higher when GFR is estimated according to the CG (17%, p<0.01 vs. CrCl) or MDRD4 formula (20%, p<0.001 vs. CrCl).

Conclusion: Practical tools to estimate renal function are needed in the care for patients with DM. However, our results show marked differences in estimated GFR when formulas are used compared to CrCl calculated from 24hr urine samples. This could maybe be expected for the MDRD4 due to its BSA correction, but is also true for the standard CG. This results in large differences in numbers of diabetic patients to be considered for referral. In our opinion, the changes in methodology for assessing renal function advocated

by present clinical guidelines, and the possible consequences attached to the resulting (e)GFR, need careful reconsideration.

Is creatinine clearance valid during renin angiotensin system blockade in diabetic kidney disease?P. Rossing¹, L. Tarnow¹, S. Andersen¹, J. Bröchner-Mortensen², H.-H. Parving^{3,4};¹Steno Diabetes Center, Gentofte, Denmark,²Aalborg Syd: Nuclear Medicine, University of Aarhus, Aalborg, Denmark,³Medical Endocrinology, Rigshospitalet, Copenhagen, Denmark,⁴Faculty of Health Science, University of Aarhus, Denmark.

Background and Aims: It has been suggested that chronic ACE inhibition in patients with diabetic kidney disease increases organic ion clearance e.g. creatinine. This implies that creatinine based indices of kidney function would give different results from true GFR based indices in patients treated with an ACE inhibitor. Consequently, it is possible that at least some of the benefit attributed to therapy blocking the renin angiotensin system (RAS) may be related to improved tubular secretion of creatinine rather than a beneficial effect on renal function. Our aim was to perform a post hoc analysis of studies of type 1 diabetic patients with diabetic nephropathy randomised to ACE inhibition (lisinopril 10–20 mg/day) or calcium channel blocker (CCB) (nisoldipine 20–40 mg/day) and followed for 4 years (4 investigations) and type 2 diabetic patients with microalbuminuria randomised to placebo on top of conventional antihypertensive treatment or angiotensin II receptor blocker (ARB) (irbesartan 150–300 mg/day) and followed for 2 years with GFR determination at baseline and at the end.

Materials and Methods: 48 type 1 diabetic patients with diabetic nephropathy randomised to ACE inhibition or CCB and 46 type 2 diabetic patients with microalbuminuria randomised to placebo or ARB on top of conventional antihypertensive treatment. The main outcome measure was change in GFR (51Cr-EDTA plasma clearance) and Cockcroft Gault estimated creatinine clearance (CrCl) (s-creatinine measured with enzymatic method, results adjusted for body surface area)

Results: In the type 1 diabetic patients the mean baseline GFR was 85 (26) (SD)ml/min/1.73 m² (ns between groups) and CG CrCl 96 (30) (ns). For patients treated with nisoldipine the rate of decline in GFR was 6.0 (1.2) (SE) ml/min/year and decline in CG CrCl 6.1 (1.2), for lisinopril group it was 6.8 (1.1) and 6.5 (1.3) respectively (ns between groups and methods). In type 2 diabetic patients GFR was 110 (25) (SD) in 15 patients randomised to placebo and 117 (21) in 31 patients randomised to ARB. CrCl was 104 (31) and 115(35) respectively. For patients treated with ARB the change in GFR was 16 (2) (SE) ml/min/1.73 after 2 years and in CrCl 10 (3), and in patients treated with placebo it was 14 (2) vs 7 (2) respectively (ns between groups). If all patients were combined (decline in GFR-decline in CrCl) was 1.3 (0.7) ml/min/year in non-RAS vs. 1.7 (0.8) ml/min/year in patients treated with ACE inhibitor or ARB (p=0.70).

Conclusion: estimated creatinine clearance is valid during chronic RAS blockade in diabetic kidney disease.

1081

Both eGFR and albuminuria are predictors of mortality in type 2 diabetes mellitus: 6-year follow-up of the ZODIAC studyL. J. Ubink-Veltmaat¹, S. J. J. Logtenberg², G. W. D. Landman³, S. T. Houweling⁴, N. Kleefstra^{2,4}, H. J. G. Bilo^{2,5};¹General practice, Huisartsenpraktijk, t Veen, Hattem,²Diabetes Centre, Isala Clinics, Zwolle, ³Internal Medicine, Isala Clinics,⁴Langerhans, Medical Research Group, Zwolle,⁵Internal Medicine, UMCG, Groningen, The Netherlands.

Background and Aims: Micro- or macroalbuminuria are considered as an indicator for the risk on cardiovascular complications in patients with type 2 diabetes mellitus (T2DM). Recently, decreased renal function has been added as a potentially important risk indicator for all cause mortality. We investigated the impact of the presence of micro- or macroalbuminuria and renal function separately and combined on all cause mortality in a cohort of subjects with T2DM treated in primary care.

Materials and Methods: The ZODIAC study (Zwolle Outpatient Diabetes project Integrating Available Care) started in 1998. A group of 1145 patients with T2DM was seen annually, and data on mortality were assessed 5.8 years later on average. Data of 1142 subjects were available at follow-up. Presence of micro- or macroalbuminuria at baseline was assessed by albumin creatinine ratio (ACR); ACR was considered normal when <3.5 mg/mmol in females and <2.5 mg/mmol in males. Baseline renal function was assessed by estimating glomerular filtration rate (eGFR) using the Cockcroft-Gault formula (CG); CG was considered normal when ≥ 60 mL/min. Comparisons of mortality were made for the total group and between age categories (< 70 and ≥ 70 years). Data were analysed using Chi-square test.

Results: Baseline characteristics: age 68.7 \pm 11.5 years, 42% male, median (P25, P75) diabetes duration 5.3 (2.5, 10.4) years, serumcreatinine 96 \pm 22 μ mol/l. Baseline eGFR could be calculated for all subjects; baseline ACR was available for 1096 subjects (96%), with 34% microalbuminuria and 8% macroalbuminuria.

Both low eGFR (CG < 60 mL/min) and the presence of micro- or macroalbuminuria were associated with increased mortality (table). When combining both risk indicators, the all cause mortality rate further increased to 56% compared 14% in patients without these two risk factors.

6 year mortality	CG		ACR		ACR + CG	
	normal	abnormal	normal	abnormal	normal	abnormal
total	138/744 18%	195/398 49%**	143/503 21%	171/459 37%**	66/456 14%	108/194 56%**
< 70 yrs	48/497 10%	9/51 18%	24/355 7%	31/180 17%**	22/324 7%	7/22 32%**
≥ 70 yrs	90/247 36%	186/347 54%**	110/282 39%	140/279 50%*	44/132 33%	101/172 59%**

Data presented as ratio and percentage of deceased patients per total patients per group. CG is defined normal ≥ 60 mL/min; ACR was considered normal when <3.5 mg/mmol in females and <2.5 mg/mmol in males. Chi-square tests; * = $p < 0.01$, ** = $p < 0.001$ normal vs. abnormal

Conclusion: Decreased eGFR and the presence of (micro) albuminuria predict all cause mortality risk in a cohort of subjects with T2DM in primary care. Combined presence of these two "renal" risk factors predicts a poor prognosis in T2DM in primary care.

1082

Development of a prediction model for early onset of microalbuminuria in type 1 diabetes mellitus

S. S. Soedamah-Muthu^{1,2}, Y. Vergouwe¹, J. Zgibor³, N. Chaturvedi⁴, T. J. Orchard³, J. H. Fuller⁵, K. G. M. Moons¹;

¹Julius Center for Health Sciences and Primary Care, UMC Utrecht, The Netherlands, ²Department of Epidemiology and Public-Health, Royal Free and University College London Medical School, United Kingdom, ³Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, ⁴National Heart and Lung Institute, Imperial College London, United Kingdom, ⁵Department of Epidemiology and Public Health, Royal Free and University College London Medical School, United Kingdom.

Background and Aims: Microalbuminuria is an important early marker of risk for diabetic renal disease and for cardiovascular disease in patients with type 1 diabetes. Early prediction of microalbuminuria in patients with type 1 diabetes will help clinicians to target these patients to prevent long-term chronic complications. Prediction models for this purpose have not been developed yet. We therefore developed prediction model to predict the individual risk of developing microalbuminuria in patients with type 1 diabetes.

Materials and Methods: The EURODIAB Prospective Complications Study (PCS, European multicentre study) data were used to develop the prediction model. Microalbuminuria was defined as an albumin excretion rate (AER) between 20 and 200 μ g/min, based on the average of two 24-hour urine collections at follow-up. The model was developed with multivariable logistic regression analysis. Performance of the model was corrected for overoptimism with a bootstrap procedure.

Results: In the EURODIAB PCS, 1134 type 1 diabetic patients were normoalbuminuric (AER < 20 μ g/min) at baseline, out of which 972 patients

were still normoalbuminuric and 143 patients became microalbuminuric (13%) during the follow-up. The prediction equation was as follows: $\log\text{odds}(\text{microalbuminuria}) = -8.59 + 1.66 \cdot \ln(\text{glycated haemoglobin}) + 0.075 \cdot \text{AER} + 1.62 \cdot \text{waist-hip ratio} + 0.058 \cdot \text{body mass index} + 0.30 \cdot \text{ever-smoking}$. This model had a reasonable discriminative value (c -statistic 0.71 after correction for optimism) and good calibration (Hosmer-Lemeshow test p -value=0.42).

Conclusions: With relatively easily obtainable predictors such as glycated haemoglobin, albumin excretion rate, WHR, BMI and smoking the individuals' risk of microalbuminuria can be estimated in patients with type 1 diabetes.

The relation between plasma creatinine level and lactic acid in type 2 diabetic patients with normal renal function

F. Liu¹, J. Lu¹, J. Tang¹, H. Lu², H. Lu¹, X. Hou³, W. Jia¹, K. Xiang¹;

¹Endocrinology & Metabolism, ²Nuclearology, ³Shanghai Research Institute for Diabetes, Shanghai 6th People's hospital, Shanghai, China.

Background and Aims: To study whether the fasting lactic acid(LA) levels change with the creatinine and GFR levels in type 2 diabetic (T2DM)patients with normal renal function, the effect of metformin administration on it and to find a predictive clinical index for hyperlactic acidemia.

Materials and Methods: The whole venous blood was collected from 723 T2DM inpatients (include 275 cases with metformin administration as treatment group and 448 cases without metformin as control group) in the morning without meal and physical activity. The LA was measured with enzyme-electrode assay (EKF diagnostic Company, Germany). The fasting glucose (FPG), fasting insulin (FINS), Creatinine (Cr), alanine aminotransferase (ALT), and HbA_{1c} levels were determined. Total glomerular filtration rate (GFR) was detected by ⁹⁹Tcchnetium isotope scan. BMI was calculated, and HOMA-IR was evaluated based on FPG and FINS levels. The data were analysed with SPSS13.0 software.

Results: 1. The fasting LA levels of 448 cases of control group was 1.17 \pm 0.47mmol/l, and it was in the normal range. 2. The LA levels of treatment group (1.33 \pm 0.57 mmol/l) was higher significantly than control group ($p=0.000$), and the FINS levels ($p=0.003$) and BMI($p=0.000$) decreased significantly. 3. The incidence of hyperlactatemia (9.45%) in metformin group was higher than control group (4.91%), and no lactic acidosis was found in all patients. 4. The LA levels increase with the Cr levels and decrease with total GFR, especially when Cr was over 90 μ mol/l and the latter was below 80ml/min, and the AUC of Cr to predict the LA was 67.2% (95% confidence 0.534~0.810, $p=0.008$) and the cutpoint of Cr level causing hyperlactic acidemia was 95.35 μ mol/l.5. Based on the lactic acid as dependent variable, and the others as independent variable, the correlation analysis showed that the Cr ($r=0.36$, $p=0.000$), ALT($r=0.201$, $p=0.000$) and BMI ($r=0.137$, $p=0.004$) was positively correlated with LA in control group, and GFR was negatively correlated with Cr ($r=-0.30$, $p=0.000$) in these patients.

Conclusion: The LA level of type 2 diabetic patients was similar to healthy adults, it is influenced mainly by the function of renal and liver, BMI, and administration of metformin. The risk of hyperlactic acidemia increase when plasma Cr level is above 95 μ mol/l, and Cr is a good index to predict the hyperlactatemia.

1084

Risk of contrast-induced nephropathy in patients with diabetes mellitus type 2

N. V. N. Zaytseva¹, M. S. Shamkhalova¹, E. N. Drozdova¹, M. V. Shestakova¹, S. T. Matskeplishvili², E. F. Tugeeva², U. O. Buziashvili², A. D. Deev³;

¹Diabetic Nephropathy, Endocrinology Research Center, ²Clinical Diagnostic, Bakoulev Scientific Center of Cardiovascular Surgery, ³Laboratory of Biostatistics, State Research Center for Preventive Medicine, Moscow, Russian Federation.

Background and Aims: To determine the incidence of contrast-induced nephropathy (CIN) after percutaneous coronary intervention (PCI),

characterise independent predictors and determine the prognostic implications of CIN among patients with and without diabetes mellitus (DM) type 2.

Materials and Methods: We have studied 121 patients (98 males, 23 females) with DM and 42 patients (33 males, 9 females) without DM who was under coronarography to determine further intervention on the heart vessels. Mean age was 57.7±0.7 and was not different between groups. The CIN defined as an increase in serum creatinine (SCr) of at least 25% or 44µmol/L over baseline within 48 hours of PCI.

Results: Baseline SCr and glomerular filtration rate (GFR) were similar in diabetics and non-diabetics (90.6±2.2 vs. 91.6±3.3 µmol/L and 80.4±1.9 vs. 80.5±2.8 ml/min, respectively). The incidence of CIN was significantly higher among the diabetics, than non-diabetics (36.4±4.4 vs. 14.3±5.5 percent respectively, $p<.01$). CIN was associated with baseline creatinine, contrast volume administrated – OR=2.57 per 100ml of medium 95%CI (1.59,4.16), low (<40) ejection fraction – OR=3.44 with 95%CI (1.25,9.49), other heart failure indicators, systolic dysfunction, diuretics use –OR=3.09 with 95%CI (1.26,7.59).

Conclusion: Although similar baseline renal function, the overall incidence of CIN after PCI was significantly higher among diabetics in comparison with non-diabetics. Efforts to control risk factors should be intensified to limit the impact of injury and protect them from future adverse events.

⁷Ophthalmology, Chinese PLA General Hospital, Beijing, China,

⁸Cardiovascular Medicine, George Institute for International Health, Sydney, Australia,

⁹Ophthalmology, Erasmus Medical Center, Rotterdam, The Netherlands.

Background and Aims: The ADVANCE Retinal measurement study (AdRem), a sub-study of the international Action in Diabetes and Vascular disease (ADVANCE) clinical trial, provides data on diabetic retinal lesions in a large study population of patients with type 2 diabetes in 14 countries.

Materials and Methods: Seven-field stereoscopic photographs of both eyes were taken at baseline. Lesions were graded in one reading center. Gradable retinal images were received from 1605 patients.

Results: The number of patients with any retinopathy (ETDRS score > 20) was 610 (38.0%, 95%CI 35.6–40.4), of these 35 (2.2%, 1.6–3.0) had severe diabetic retinopathy (ETDRS > 50). Focal arterial narrowing was present in 3.8%, venous beading in 5.1%, and arteriovenous (AV) nicking was found in 9.8%. Prevalence of retinal abnormalities did not differ significantly between men and women. Among participants included in this study, Chinese and South-Asian patients had more retinopathy than Caucasians, as defined both by ETDRS score (49.4%, 46.0%, 31.3%; $p<0.001$ adjusted for age, gender, HbA1c and duration of diabetes) and after comparing specific vascular lesions (e.g. AV nicking 12.3%, 8.5%, 7.5%; adjusted p -value <0.005).

In patients with and without retinopathy (ETDRS score > 20) mean HbA1c levels were 7.6% (SD 1.6) and 7.2% (1.4), duration of diabetes 8.6 (6.4) and 6.5 (5.7) years, and systolic blood pressure 138 (21) and 135 (20) mmHg (all comparisons: $p<0.01$). Focal arterial narrowing was associated with a mean HbA1c difference of 0.3 ($p<0.05$) whereas macular oedema, venous beading and AV nicking were not associated with differences in current HbA1c levels. Systolic and diastolic blood pressure were higher in patients with venous beading and macular edema ($p<0.05$, adjusted for age, gender and duration of diabetes). Smoking was not associated with retinal lesions. All these associations were similar in Chinese, South-Asian, and Caucasians patients.

Conclusion: Using a sensitive diagnostic procedure, more than one third of patients with type 2 diabetes enrolled in a clinical trial had retinal lesions at study entry. HbA1c, diabetes duration, and blood pressure were increased in patients with retinal vascular lesions irrespective of ethnic group.

A diabetic retinopathy screening program detecting non-diabetic eye problems

K. P. Shotliff¹, G. Duncan²;

¹Beta Cell Diabetes Centre, Chelsea and Westminster Hospital,

²Medical Illustration, First Retinal Screening, London, United Kingdom.

Background and Aims: As part of the United Kingdom National Screening Committee's grading criteria for digital retinal photographs in people with diabetes there are several grades for the level of diabetic retinopathy and a single grade of 'O' / 'Other' for all non-diabetic lesion. We wished to see which 'other' diagnoses were most commonly seen and whether any action was needed on the basis of diagnosing them.

Method: A prospective observational study of 4,083 consecutive people offered screening in a community based diabetic retinopathy screening program examined over a 12 month period.(3,659 attended) All images were

dual graded by trained Ophthalmologists to give a diagnosis for these non-diabetic pathology which would all be classified by the UK National Screening Committee as 'O / Other'.

Results: Non-diabetic conditions were found in 1,313 (35.9%) of people or 956 (26.1%) if cataracts were excluded. Only 3% of patients required referral for non-diabetic retinopathy findings alone. The most common conditions seen were media opacities (20.8%), drusen (16.2%), age related macula degeneration (6.1%), pigmented lesions (4.9%) and abnormalities of the optic disc (2.2%).

Conclusion: Non-diabetic conditions were a common finding in this population based diabetic retinopathy screening program. If 35.9% of patients with a non-diabetic lesion were referred rather than the 3% our Ophthalmologist graders felt required referral we would need 140 extra eye clinics per year instead of just 12 clinics. We believe that all individuals grading these images should be aware of the more common non-diabetic conditions seen as this may reduce inappropriate referrals to Ophthalmology Clinics.

1087

Natural history of beta cell destruction in type 1 diabetes influences development and progression of diabetic retinopathy: Protective effect of sustained residual beta cell function

K. Nakanishi^{1,2}, C. Watanabe^{1,2};

¹Dept. of General Internal Medicine and Metabolism, Toranomon Hospital, Kawasaki, ²Dept. of General Internal Medicine and Metabolism, Okinaka Memorial Institute for Medical Research, Tokyo, Japan.

Background and Aims: Presence of residual beta-cell function in type 1 diabetes delayed the development of diabetic retinopathy. However, how long residual beta-cell function needs to exist for protective effect on the development and progression of diabetic retinopathy is not yet known. We investigated time course of retinopathy findings in relation to time course of beta-cell destruction.

Materials and Methods: Subjects were 254 type 1 diabetic patients (men/women: 145/109, age at onset: 34 ± 14 years, mean \pm SD). Serum C-peptide was assessed longitudinally 4.7 ± 3.7 times during 12 ± 11 years. Serum C-peptide level less than 0.017 nmol/l at fasting or 0.033 nmol/l at 2–3 hours after meal was regarded as complete beta-cell destruction. Optic fundi were evaluated longitudinally 21 ± 17 times during 17 ± 9 years. Mean HbA1c value during entire illness was calculated as index of long-term glycemic control.

Results: The patients were stratified into those who lost beta-cell function completely within 20, 15, 10 and 5 years from the onset of diabetes and those who retained residual β -cell function even after the corresponding years from the onset of diabetes (patient number: 104 vs. 42, 84 vs. 76, 60 vs. 105, and 37 vs. 152, respectively). Cumulative incidence of background retinopathy was higher in the patients who lost beta-cell function completely within 20, 15, and 10 years after the onset of diabetes than those who retained residual β -cell function even after the corresponding years (5.41 vs. 4.25/100 patient-years, $P=0.013$; 5.22 vs. 4.18/100 patient-years, $p=0.006$; and 4.77 vs. 4.15/100 patient-years, $p=0.048$, respectively). Cumulative incidence of preproliferative retinopathy was higher in the patients without beta-cell function within 20 years after the onset of diabetes than those with residual β -cell function even after 20 years (2.61 vs. 2.60/100 patient-years, $P=0.031$). Cumulative incidence of any type of retinopathy did not differ between the patients without β -cell function within 5 years and those with residual β -cell function even after the 5 years. Mean HbA1c value was higher in the patients without β -cell function within 20 or 15 years from the onset of diabetes than those with residual β -cell function even after corresponding years (8.46 ± 1.01 vs. 7.87 ± 0.73 %, $p=0.030$, and 8.54 ± 1.03 vs. 8.10 ± 1.02 %, $p=0.042$, respectively), whereas mean HbA1c value no longer differed between the patients without β -cell function within 10 or 5 years and those with residual β -cell function even after the corresponding years. After adjusting possible confounders (sex, mean HbA1c value, age at onset and period until insulin therapy) by Cox's proportional hazards model, complete loss of beta-cell function until 20, 15, and 10 years from the onset of diabetes was an independent risk factor for the development of diabetic retinopathy [relative hazard (95% confidence interval): 1.58 (1.05–2.52), $p=0.029$; 1.47 (1.09–2.00), $p=0.011$; and 1.39 (1.04–1.84), $p=0.024$, respectively].

Conclusion: Sustained presence of residual beta-cell function in type 1 diabetes (more than 10 years) protects the patients from early development

and progression of diabetic retinopathy through the attainment of better glycemic control during a long period.

Retinal thickness changes after insulin therapy initiation in patients with type 2 diabetes. An Optical Coherence Tomography (OCT) based study

F. Gomez-Peralta¹, P. Pujante¹, C. Abreu², E. Santos³, A. Garcia-Layana⁴, A. Salinas⁴, N. Varo⁵;

¹Endocrinology and Nutrition Department, University Clinic of Navarra, Pamplona, ²Endocrinology and Nutrition Department, N.S La Candelaria Hospital, Santa Cruz de Tenerife, ³Endocrinology and Nutrition Department, Complejo Hospitalario, Burgos, ⁴Ophthalmology Department, University Clinic of Navarra, Pamplona, ⁵Center for Applied Medical Research, University Clinic of Navarra, Pamplona, Spain.

Background and Aims: Diabetic macular oedema is a diabetes-related complication with a high risk of vision loss. It is produced by fluid leakage due to blood-retinal barrier breakdown. Macular oedema is more frequent in patients with type 2 diabetes (DM2) after initiation of insulin therapy (IT). Local and systemic factors have been involved in this specific complication of DM. Optical Coherence Tomography (OCT) is the most sensitive, clinically available non-invasive method to measure retinal thickness (RT), able to detect even very small changes. OCT was previously shown to be useful in detecting and quantify diabetic macular oedema.

Aims:

- 1.- Measure changes in retinal thickness (RT) by means of OCT after IT initiation in DM2 patients.
- 2.- Evaluate the relationship of changes in RT with metabolic changes induced by IT.
- 3.- Study the implication of several inflammatory, proangiogenic or growth factors.

Materials and Methods: Prospective study in 12 DM2 patients (8 males, age 62.4 ± 8.2 years). OCT-measured RT and glycosylated haemoglobin; (A1c), lipid profile, blood pressure (BP), IGF-1, IGF-BP3; VEGF y sCD40L were recorded before and 6 months after IT initiation.

Results: Expressed as mean \pm SD, 1: pre, 2:post. A1c1= 9.9 ± 1.8 ; A1c2= 8.2 ± 1.1 (%) ($p=0.039$). Peso1: 75.6 ± 11.7 ; Peso2: 77.8 ± 11.4 (kg) ($p=0.01$). HDL-Col1= 47.3 ± 9.1 ; HDL-Col2= 49.3 ± 8.7 (mg/dl) ($p=0.3$). Tg1: 195 ± 155 ; Tg2: 169 ± 106 (mg/dl) ($p=0.5$). IGF-1(1)= 0.18 ± 0.17 ; IGF-1(2)= 0.26 ± 0.21 ($p=0.043$). IGF-BP3(1)= 40.7 ± 3.4 ; IGF-BP3(2)= 41.7 ± 8.9 (ng/ml) ($p=0.23$). VEGF(1)= 393 ± 42 ; VEGF(2)= 528 ± 48 (pg/ml) ($p=0.23$). sCD40L= 4.9 ± 2.9 ; sCD40L= 0.52 ± 1.7 (ng/ml) ($p=0.35$). Retinal thickness difference: $+7.025$ microns; Retinal volume difference: $+0.025$ mm³. No statistically significant correlation between A1c, BP and RT was observed.

Conclusion: Insulin therapy increases retinal thickness of patients with DM2 in a short time. This change seems to be independent of metabolic and BP improvement. Retinal thickness increase is associated with increases of IGF-1 and VEGF, suggesting a possible role of trophic and proangiogenic effect of insulin therapy in the development of diabetic macular oedema.

A functional magnetic resonance imaging study demonstrating alterations in brain responses to acute pain stimulation in diabetic neuropathy

D. Selvarajah¹, R. A. Gandhi¹, M. D. Hunter², C. J. Emery¹, P. D. Griffiths³, S. Tesfaye¹, I. D. Wilkinson³;

¹Diabetes Research Unit, ²Academic Psychiatry,

³Academic Radiology, University of Sheffield, United Kingdom.

Background and Aims: Chronic distal symmetrical painful diabetic neuropathy (DN) is a common complication of diabetes resulting in significant patient morbidity. There is increasing evidence that the central nervous system is involved although its role remains unclear. This study examines the functional neuroanatomical correlates to acute pain in subjects with type 1 diabetes at different stages of neuropathy.

Materials and Methods: Blood oxygen-level dependent (BOLD) functional magnetic resonance imaging (fMRI) datasets have been acquired in a high

field system (3T) on 12 subjects with diabetes (4 No DN, 4 Painful DN and 4 Painless DN) and 4 healthy volunteers. Heat pain stimulus to the dorsum of the foot was provided by an MR compatible peltier type device (MEDOC TSA-II) in a box-car functional paradigm design. Whole brain fMRI datasets (EPI; TE=35ms, TR=3000ms; 190 time points) were acquired during baseline and hot stimulus presentation over 570sec for each subject. Functional analysis was performed using Statistical Parametric Mapping (SPM2, IoN, UCL).

Results: There was a significantly lower ($p<0.05$) BOLD response to acute heat pain stimulation in the diabetic cohort compared to healthy volunteers. The brain's BOLD haemodynamic response to heat pain also varied between diabetic subject sub-groups ($p<0.05$). Those with No DN showed greater response than those painful and painless DN. And those with painful DN showed significantly greater response than those with painless DN. The neuroanatomical areas that showed a greater response in the painful DN group include the primary somatosensory cortex, lateral frontal and cerebellar regions.

Conclusion: BOLD fMRI can be used to study the spatial distribution of the brain's response to acute heat stimulation in diabetes. This allows further investigations into the physiological CNS responses (plasticity) to alterations of acute pain sensation and perception in DN. Better understanding of these processes will help targeted drug development and also provides an objective tool for monitoring response to interventions.

Patients with clinical manifest vascular disease and diabetes have more atrophy and vascular lesions on brain MRI than non-diabetic patients with vascular disease

A. M. Tiehuis¹, F. L. J. Visseren², A. P. A. Appelman¹, K. L. Vincken³, G. Biessels⁴, L. Kappelle⁴, W. P. T. Mali¹, Y. van der Graaf⁵;

¹Radiology, ²Internal Medicine, ³Image Sciences Institute,

⁴Neurology, ⁵Clinical Epidemiology, University Medical Center Utrecht, The Netherlands.

Background and Aims: Diabetes (DM) can lead to accelerated cognitive decline, dementia and structural brain abnormalities (atrophy and vascular lesions). It is still debated whether these cerebral changes are solely due to co-morbid vascular disease or if other DM-specific factors, such as chronic hyperglycemia, play an additional role.

Materials and Methods: Brain MRI was performed in 1032 participants (217 DM) of the SMART-study, an ongoing cohort study in patients with clinical manifest vascular disease (mean age 58.6 +/- 10.2). Quantitative measurements of brain parenchyma, ventricle and white matter hyperintensities (WMH) volumes were obtained with an automated segmentation technique. The presence of cortical and lacunar infarcts was scored visually. Linear and logistic regression analyses with adjustment for age and gender were performed to estimate the effect of DM on brain MRI abnormalities and to identify determinants for brain abnormalities within the DM group.

Results: Vascular patients with DM had significantly more global (-1.1% brain volume; 95% CI -1.4- -0.7) and subcortical brain atrophy (+0.2% ventricular volume; 95% CI 0.03-0.3) compared with non-DM vascular patients. Moreover, DM patients had larger WMH volumes (0.16 ml (LN); 0.03–0.30). Adjustment for hypertension or excluding patients with cortical infarcts did not affect these associations. Within DM patients, determinants of decreased brain volume were high fasting serum glucose levels (β -0.13 % per 1 mmol/l glucose; -0.23- -0.03), diabetes duration (β -0.05% per 1 diabetes-year; -0.11- -0.002), use of glucose-lowering agents (β -1.43%; -2.73- -0.14) and presence of hypertension (β -0.63%; -1.22- -0.04). Determinants of increased WMH volume were presence of hypertension (β 0.29 ml (LN); 0.03–0.55) and a history of ischemic stroke (β 0.47 ml (LN); 0.17–0.76). Smoking (OR 2.82; 1.21–6.57), history of ischemic stroke (OR 3.59; 1.69–7.66) and carotid artery disease (OR 3.39; 1.36–8.45), or the presence of more than 2 vascular diseases (OR 4.84; 2.12–10.61) increased the risk for lacunar infarcts in DM patients.

Conclusion: In patients with clinical manifest vascular disease, DM has an added detrimental effect on the brain. Within DM patients, diabetes-related factors contribute to brain atrophy, while vascular risk factors are related to both atrophy and vascular lesions.

Diabetes-specific determinants of regional brain volumes and white matter abnormalities in young adults with type 1 diabetes

S. C. Ferguson¹, J. Geddes¹, J. M. Wardlaw², A. Blane², I. J. Deary³, B. M. Frier¹;

¹Department of Diabetes, Royal Infirmary of Edinburgh, ²Department of Clinical Neuroscience, Western General Hospital, Edinburgh,

³Department of Psychology, University of Edinburgh, United Kingdom.

Background and Aims: Type 1 diabetes (T1DM) is characterised by intermittent severe hypoglycaemia, chronic hyperglycaemia and the development of microangiopathy, and frequently develops before neurodevelopment is complete. These diabetes-specific factors may impact upon brain structure. We examined the associations of these factors with aspects of brain structure in young adults with T1DM.

Materials and Methods: 133 normotensive people with T1DM [mean (range): age 32.3yrs (20–45), 51.9% male, diabetes duration 16.1yrs (9–31), onset age 16.1yrs (1–36; 19.8% diagnosed < 8yrs), 36.1% background retinopathy] participated in a cross-sectional study. Participants had no neuropsychological pathology and showed a range of severe hypoglycaemia exposure and microangiopathy status. Correlation was used to identify associations between diabetes-related factors (severe hypoglycaemia, retinopathy, diabetes duration, diabetes onset age) and brain structure (volumetric MRI analysis). Linear Modelling (brain volumes) and Multiple Logistic Regression (atrophy, white-matter abnormalities) techniques identified independent predictors of outcomes.

Results: Mild ventricular atrophy was common (30.8%) but Sulcal atrophy (10.5%) was infrequent. An early diabetes onset age (< 8yrs) independently predicted ventricular atrophy ($p=0.01$) and greater Lateral Ventricular volumes ($p=0.01$). No significant associations were observed between other diabetes-related factors and volumetric measures. Peri-ventricular white-matter lesions were common (60%), mild and not significantly associated with diabetes-related factors. Small Punctate White-Matter Lesions (SPWML) were common (45.1%), located in distinct brain areas [Hippocampus (20.3%), Basal Ganglia (39.3%), Centrum Semiovale (31.1%)] and significantly associated with some diabetes-specific factors (retinopathy, onset age, duration). Logistic regression identified diabetes onset age as an independent predictor of Hippocampal ($p=0.004$) and Centrum Semiovale ($p=0.01$) SPWML and the overall presence/absence of SPWML ($p=0.02$): SPWML were more frequently observed in those with later onset diabetes. Retinopathy status independently predicted Hippocampal SPWML ($p=0.03$). No significant independent associations between diabetes duration, severe hypoglycaemia exposure and SPWML were identified.

Conclusion: Subtle brain structural abnormalities are common in young adults with T1DM. These are characterised by mild brain atrophy, mild peri-ventricular white-matter abnormalities and a specific type of white-matter lesion, the Small Punctate White-Matter Lesion. Early diabetes onset appears to be the most important diabetes-specific determinant of the differences observed, predisposing to central brain atrophy yet conferring relative resistance to SPWML. Intracranial microangiopathy, as background retinopathy, may also predispose to SPWML in specific brain regions, whereas diabetes duration and severe hypoglycaemia exposure do not appear to confer obvious disadvantage to brain structure in the subjects examined by the present study.

Correlations between severity of diabetic neuropathy and impaired visual-evoked potentials at prospective evaluation in patients with long-standing type 1 diabetes

T. T. Várkonyi¹, R. Takács¹, É. Börcsök¹, C. Lengyel¹, Z. Fülöp², M. Janáky², P. Kempler³, J. Lonovics¹;

¹1st Department of Internal Medicine, University of Szeged,

²Department of Ophthalmology, University of Szeged, ³1st Department of Internal Medicine, Semmelweis University, Budapest, Hungary.

Background and Aims: Our earlier studies revealed correlations between the severity of diabetic neuropathy and central afferent dysfunctions. The aim of our present study was to characterise the progression of impaired visual-

evoked potentials, cardiovascular autonomic and peripheral sensory nerve dysfunction in patients with long-standing type 1 diabetes (DM).

Patients and Methods: 12 patients were studied (age: 46.3±3 years, duration of DM: 24.1±1.9 years; mean±SE). Every patient was tested twice, the second tests being performed 36 months after the initial ones. The five standard cardiovascular reflex tests were performed for the assessment of autonomic neuropathy (AN). Sensory nerve integrity was studied with a Neurometer (Neurotron Inc., Baltimore). The visual pathways were measured by analysis of the latencies (P100) of visual-evoked potentials.

Results: The AN score increased during the follow-up period (3.9±0.4 vs 5.7±0.5, $p<0.05$). The results of three of the five reflex tests worsened (heart rate response to breathing: 12.1±1.7 vs. 8.4±1.5 beats/min, $p<0.05$; Valsalva ratio: 1.33±0.05 vs. 1.18±0.03, $p<0.05$; orthostatic hypotension: 15±2.5 vs. 33.4±3.8 mm Hg, $p<0.01$). The severity of sensory neuropathy and the latencies of the P100 waves did not change significantly. Evaluation of the follow-up data revealed several associations between the severity of the neuropathy and the impairment of the P100 waves 3 years after the first examinations (AN score-P100 latency: $r=0.74$, $p<0.0001$; heart rate response to breathing-P100 latency: $r=-0.61$, $p<0.01$; n. peroneus: CPT at 2000 Hz-P100 latency: $r=0.48$, $p<0.05$; CPT at 250 Hz-P100 latency: $r=0.56$, $p<0.01$; CPT at 5 Hz-P100 latency: $r=0.65$, $p<0.001$).

Conclusion: Progression of parasympathetic and sympathetic autonomic neuropathy was observed during the 3-years follow-up period among patients with long-standing type 1 diabetes, while there were no significant changes in the peripheral sensory nerve function and visual-evoked potentials. The correlations between the cardiovascular autonomic and peripheral sensory neuropathy just as the impairment of the visual-evoked potentials confirmed by the follow-up data provide further evidence of an association between peripheral and central manifestations of diabetic neuropathy.

1093

Correlation between cardiac autonomic neuropathy (CAN) and left ventricular mass (LVM) in type 2 diabetes

A. Ferrière, M. Ueffing, M. Pfohl, S. Zimny;

Medical Department I, EVK Bethesda, Duisburg, Germany.

Background and Aims: Studies in diabetic patients undergoing haemodialysis suggest that mechanisms of apoptosis triggered by the vegetative nervous system might lead to a myocardial remodelling. Concerning the CAN in diabetic patients undergoing haemodialysis an association between CAN and the left ventricular mass index (LVMI) as a marker of a left ventricular hypertrophy (LVH) might exist. We studied the relationship between CAN and LVM respectively LVMI in view of the prevalence of microvascular long-term consequences in type 2 diabetes.

Materials and Methods: The indices of LVH and heart rate variability (HRV) have been analysed as well in patients with type 2 diabetes as in non-diabetic patients. Standardised wall thickness measurement has been made and diameters of the left ventricle have been determined on the basis of the ASE-convention by echocardiography. The LVM has been calculated according to the formula described by Devereux et al. The LVMI has been calculated from $LVMI = LVM / KOF$ (body surface). Additionally the relative left ventricular wall thickness (rLVWT) has been established from $rLVWT = 2 \times PWTd$ (left ventricular end-diastolic posterior wall thickness)[mm]/LVIdd (left ventricular internal end-diastolic dimension)[mm]. The parameters of the HRV (SD, SDANN5, ASDNN5, RMSSD and pNN50) have been measured using a 24-hour ECG with computer-aided analysis.

Results: 103 patients with type 2 diabetes and 107 non-diabetic patients (control group) with the same gender ratio in both groups were included. The mean age was 65±12 (mean±standard deviation) and 66±16 years respectively. In the diabetes group the mean value of HbA1c was 8.5±2.3%. In comparison to the control group the diabetic patients revealed significantly lower values of the time domain measurement of the HRV ($p=0.01$ for SD, SDANN5, ASDNN5 and RMSSD, $p=0.05$ for pNN50). The values of LVM and LVMI were significantly greater in diabetic patients compared to the control group (304.3±117.0g and 158.6±54.4g/m² versus 261.9±94.9g and 140.4±46.2g/m² ($p=0.01$)). However there was no significant correlation between the parameters of HRV, LVM and LVMI respectively.

Conclusion: The variables of the time domain measurement of HRV as indices of CAN revealed significantly lower values in type 2 diabetic patients compared to non-diabetic patients. In contrast to a previous minor study in diabetic patients undergoing haemodialysis a correlation between CAN, LVM and LVMI respectively could not be shown. We assume that CAN and LVH describe independent variables accumulating in type 2 diabetes.

1094

Cardiac autonomic neuropathy in painless post myocardial infarction patients with type 2 diabetes

T. Akhobadze¹, R. Kurashvili¹, L. Dzeladze², M. Dundua¹, E. Shelestova¹, K. Paghava¹, G. Kurashvili¹, L. Tsutskiridze¹;

¹Georgian Diabetes Center,

²Clinical Pharmacology, National Center of Therapy, Tbilisi, Georgia.

Background and Aims: Asymptomatic coronary artery disease (CAD) and painless myocardial infarction (PMI) are common in patients (pts) with diabetes mellitus and are assumed as cardiac autonomic neuropathy (CAN) manifestation. Abnormalities of left ventricular repolarisation and heart rate variabilities (HRV) – markers of autonomic dysfunction, are associated with increased mortality in type 2 diabetic (T2DM) pts. The aim of the study was to assess CAN and QTc interval dispersion (QTcd) in T2DM pts with PMI in history.

Materials and Methods: We examined 67 T2DM pts, who were divided into 3 groups (Gr): Gr.1 (22pts, mean age 56.7±7.3 yrs, 17m/5f.) who had PMI more than a month ago; Gr.2. (23pts, mean age 54.9±8.3 yrs, 16 m/7f) with typical MI in history; Gr.3 (22pts, mean age 57.4±8.1yrs, 15m/7f) without clinical signs of CAD (no changes on Holter and/or exercise ECG). Time domain HRV parameters – SDNN and triangular index (TI) were assessed on Holter

ECG. QTcd was measured on surface ECG. CAN severity was evaluated using Ewing's five standard tests (severe CAN-scores 7–10, moderate-scores 4–6, mild-scores 2–3, no CAN -scores 0–1).

Results: HRV parameters in study groups were: SDNN 89 ± 14.7 msec (Gr. 1), 93 ± 16.3 msec (Gr. 2), and 114 ± 15.6 msec (Gr. 3); TI 21 ± 7.3 (Gr. 1), 22 ± 5.1 (Gr. 2), and 35 ± 9.3 (Gr. 3). Compared to Gr. 3, HRV parameters – SDNN and TI, were statistically lower in Gr. 1 and Gr. 2 ($p=0.000$; $p=0.000$, respectively). No statistically evident difference in these parameters was observed between Gr.1 and Gr.2. QTcd was 63 ± 13.4 (Gr.1); 59 ± 11.7 (Gr.2), and 43 ± 9.7 (Gr.3). QTcd was higher in Gr.1 when compared to Gr.2, through this difference was not statistically evident; while difference in QTcd between Gr. 1/Gr. 2 and Gr. 3 was statistically significant ($p=0.000$). We revealed following CAN prevalence in the study groups: severe – 31.8% (Gr. 1), 8.7% (Gr. 2), 0% (Gr. 3); moderate 54.5% (Gr. 1), 52.2% (Gr. 2), 45.5% (Gr. 3); mild – 13.6% (Gr. 1), 30.4% (Gr. 2), 36.3% (Gr. 3), no CAN – 0% (Gr. 1), 8.7% (Gr. 2), 18.2% (Gr. 3). Severe CAN was significantly higher in Gr. 1 when compared to Gr. 2 and 3; moderate CAN was also higher in Gr. 1; only 13.6% in this group had mild CAN, while CAN absence was not found in any of the pts with PMI.

Conclusion: There was no significant difference in the HRV parameters and QTcd between typical and PMI pts. While compared to Gr. 3 there was statistically evident prolongation of QTcd in Gr. 1 and 2, and decrease in HRV. It can be explained by the dysfunction of sympathetic nervous system. In addition, disorders of parasympathetic functional tests in pts with PMI may explain the high prevalence of severe and moderate CAN in this group. All this indicates to more profound damage of vegeto-neural system in T2DM pts with PMI.

1095

Cardiac autonomic neuropathy (CAN) in T2 diabetics with or without chronic kidney disease: correlations with insulin resistance (IR), NT-proBNP and hsCRP

M. Mylonopoulou¹, N. Tentolouris², S. Antonopoulos³, S. Mikros³, P. Anastasiades³, E. Konstantellou⁴, G. Papadakis¹, A. Melidonis³, N. Katsilambros²;

¹Nephrology Dept, Tzanio General Hospital, Piraeus,

²1st Dept of Propaedeutic Medicine, University Medical School, Athens,

³Diabetes Center, Tzanio General Hospital, Piraeus,

⁴Biochemistry Dept, General Hospital, Nikaia, Greece.

Background and Aims: CAN and IR are independent risk factors for cardiac mortality in type 2 Diabetes Mellitus (T2DM) and in Chronic Kidney Disease (CKD). Heart Rate Variability (HRV) is an established non-invasive evaluation method of CAN. N-terminal pro-B-type Natriuretic Peptide (NT-proBNP) is a marker of congestive heart failure. Another biomarker for CVD is high-sensitivity C – reactive protein (hsCRP). Aim of this study was to assess CAN in T2DM patients with and without CKD, in comparison with non-diabetics with CKD and healthy controls. We measured NT-proBNP and hsCRP and we estimated IR by HOMA. We investigated their correlation and their relation with HRV parameters.

Materials and Methods: 100 patients divided into four age-matched groups (G): G1: 25 patients with T2DM and established stage 4 CKD, G2: 25 T2DM patients without CKD, G3: 25 non-diabetics with stage 4 CKD and G4: 25 healthy controls. CAN was assessed in all patients using 24-hours ECG-Holter monitoring with HRV analysis in both time and frequency domain.

Results: Marked differences in HRV were noticed between the four groups. G1 displayed significantly lower values in both time-domain maxRR, SD, SDANN, SDNN ($p<0,001$), and frequency domain parameters Total Power ($p<0,001$), VLF ($p<0,001$), LF ($p<0,001$) and LF/HF ratio ($p=0,005$) in comparison to the other 3 groups collectively. Independent comparison of G2 and G3 showed no differences. NT-proBNP and HOMA were significantly higher in G1 ($p<0,001$ and $p=0,003$) compared with the other 3 groups. There were no significant differences in NT-proBNP and HOMA between G2 and G3. hsCRP was significantly elevated in G1 compared with G2 ($p=0,02$), but not with G3. Partial correlation analysis controlling for the four groups suggests significant correlations between NT-proBNP and hsCRP ($p=0,031$) as well as between HOMA and hsCRP ($p=0,018$). Bivariate analysis within each group separately displayed significant correlations of HRV with HOMA or NT-proBNP, only in G3. In those patients, NT-proBNP was significantly correlated with time domain (PNN30 $p=0,023$, ASDNN $p=0,013$) and frequency domain parameters (Total Power $p=0,002$, LF $p=0,001$, HF $p=0,012$), while HOMA was correlated with PNN50 ($p=0,015$)

and VARINDEX ($p=0,013$). HRV displayed no correlation with hsCRP in either group.

Conclusion: Uremic T2 diabetics present significantly important CAN as well as elevated CVD markers (NT-proBNP, hsCRP and HOMA) in comparison with all other groups. No such differences were observed between uremic non-diabetics and diabetics without CKD, suggesting the synergistic role of T2DM and CKD to the development of CAN and CVD. Analysis of the four groups displays an overall correlation of hsCRP with HOMA and NT-proBNP. A significant correlation – predictive of CAN – of NT-proBNP and HOMA with time and frequency domain parameters of HRV existed only in non-diabetics with CKD. All correlations of these markers with HRV are vanished in the presence of T2DM in G1 and G2. We hypothesize that diabetes plays such a major disruptive role in CAN, irrespective of all other co-morbidities, that deprives any biochemical marker of its possible predictive value in this context.

Hospital de la Sta. Creu i S. Pau, ²Primary Care Center, Catalan Health

Institute, Olot, Girona, ³Dpt. Biochemistry, Autonomous University of

Barcelona, Hospital de la Sta. Creu i San Pau, ⁴Dept. Neurophysiology,

Catalan Health Institute, Hospital Josep Trueta, Spain,

⁵Dept. Endocrinology, ICAMED, Centro Medico Teknon, Spain.

Background and Aims: The plasma levels of the N-terminal fragment of the brain natriuretic peptide (NT-proBNP), have recently gained extreme importance as marker of myocardial dysfunction in type 2 diabetes mellitus (T2DM) patients. Interestingly, T2DM patients with cardio-vascular disease (CVD) and/or nephropathy exhibit an elevation of plasma NT-proBNP levels related to those without CVD. NT-proBNP levels are independently associated with coronary artery disease and overt nephropathy. Scarce data is available regarding the association between diabetic polyneuropathy (DPN) and NT-proBNP levels.

Materials and Methods: Hence, we set forth a cross-sectional pilot study, to assess the hypothetical relationships between NT-proBNP levels, CVD, and DPN in a group of T2DM patients (N=140; M89/F51) randomly selected from the North Catalonia Diabetes Study (NCDS). CVD and DPN (clinical and neurophysiology evaluation) prevalence were evaluated. Serum NT-proBNP was measured using an electrochemiluminescence immunoassay (Elecys[®], Roche Diagnostics, Indianapolis, Inc.).

Results: Diabetic patients age: 63.5 ± 7.6 , T2DM duration: 10.2 ± 1.2 years, HbA1c: 7.1 ± 1.6 ; DPN: 47%. Log-transformed NT-proBNP levels (logNT-proBNP) were significantly higher in T2DM patients with CVD ($P<0.0005$) and DPN ($P<0.0005$). LogNT-proBNP correlated with age ($r=0.369$; $P<0.0005$), CVD ($r=0.377$; $P<0.0005$) and DPN ($r=0.442$; $P<0.0005$) -even after correction for age and CVD ($r=0.334$; $P=0.001$)-. Log NT-proBNP was also correlated with neurothesiometer values ($r=0.406$; $P<0.0005$). No significant associations were found for gender, hypertension prevalence and micro-albuminuria

Conclusion: NT-proBNP levels display a significant association with the presence of DPN, even after correction for age and CVD.

NT-proBNP levels appear as promising molecules for T2DM micro and macro-angiopathic complications screening. Further prospective trials are warranted.

Relationship between erectile dysfunction and cardiovascular risk factors in patients with type 2 diabetes in primary care is confounded by age and medication

M. Van den Donk, F. G. W. Cleveringa, M. G. G. Meulenberg, K. J. Gorter, G. E. H. Rutten;
Julius Center for Health Sciences and General Practice,
University Medical Center Utrecht, The Netherlands.

Background and Aims: Erectile dysfunction (ED) is about 3 times more common in male patients with diabetes than in those without diabetes; its prevalence ranges between 34–89%. It is associated with both diabetes and according to most authors also with cardiovascular disease. ED prevalence is mostly based on questionnaires, which are not feasible in daily diabetes care. We measured ED prevalence when patients were asked a single question by a practice nurse during a routine diabetes control visit. Besides we assessed if routinely asking patients with diabetes mellitus type 2 (DM2) about ED identifies patients at high risk for cardiovascular disease. The aims of the study are to assess the prevalence of ED using a single question asked by a practice nurse and to assess the association between ED and cardiovascular risk factors in men with DM2 in primary care.

Materials and Methods: In a cross-sectional study, 55 general practices throughout The Netherlands participated. All patients with DM2 treated by their general practitioner were invited. During the annual check-up, the practice nurse asked male patients after an introducing sentence whether they suffered from erection problems or not. Age, duration of diabetes, ethnicity, history of cardiovascular disease (HCVD), current smoking, alcohol consumption, medication use, HbA1c, blood pressure, total cholesterol, HDL-cholesterol and BMI were also registered. The ED prevalence rate was calculated. Through univariate analysis (odds ratios (OR) and Student's T-tests), the association between the above-mentioned variables, ED and a HCVD was explored, to assess which variables were potential confounders. The association between ED and a HCVD was then corrected for confounders, in multiple logistic regression analysis. For patients without a HCVD we followed the same procedure for ED and 10 year UKPDS coronary heart disease risk estimate (ORs, Mann-Whitney tests, and multiple linear regression).

Results: The prevalence of ED in DM2 patients was 41.3%, increasing with age. After correction for confounders, there was no association between ED and a history of cardiovascular disease, OR: 0.9 (95% CI: 0.7 – 1.1), or a higher 10 year UKPDS CHD risk estimate, risk difference: 0.8% (95% CI: -1.3 – 2.9). For both associations age and medication were the most important confounders.

Conclusion: Measuring the prevalence of ED with a single question for ED asked by a practice nurse during diabetes consultation, gives an ED prevalence comparable to standardised questionnaire prevalence rates. After adjusting for confounders, the relationship between ED and cardiovascular disease could not be established. The high prevalence of ED in DM2 may be explained by a cluster of variables, among which age and medication use.

Autonomic neuropathy and hypertension in type 1 and type 2 diabetes mellitus: is there a relationship?

K. Keresztes, I. Istenes, É. Sipos, Z. Putz, P. Vargha, P. Kempler;
1st Department of Medicine, Semmelweis University, Budapest, Hungary.

Background and Aims: Cardiovascular autonomic neuropathy carries a five-fold risk for mortality in diabetic patients, but the factors leading to increased mortality have not been clarified entirely up to now. The aim of our study was to evaluate a possible connection between autonomic neuropathy (AN) and 24-hour blood pressure profile in patients with type 1 and type 2 diabetes mellitus.

Materials and Methods: The five standard cardiovascular reflex tests were used to assess the autonomic function in 102 diabetic patients who had no history of hypertension. We examined 32 patients with type 1 diabetes (mean age: 37.8 ± 12.7 years), 70 normoalbuminuric patients with type 2 diabetes (mean age: 52.3 ± 7.6 years) and 29 healthy control subjects (mean age: 51.8 ± 9.5 years). The severity of autonomic neuropathy was characterised by autonomic score. Ambulatory 24-hour blood pressure monitoring (ABPM)

was performed by MEDITECH ABPM 04 device. Among the ABPM parameters we evaluated the blood pressure load (%-time when day-time blood pressure was above 140/90 mmHg and night-time blood pressure was above 120/80 mmHg) and the hyperbaric impact values (the area under the blood pressure curve exceeding 140/90 mmHg during day-time and 120/80 mmHg during night-time).

Results: There was a significant correlation between the severity of autonomic neuropathy and the blood pressure load (systolic: $p < 0.001$; diastolic: $p < 0.01$), the hyperbaric impact values (systolic: $p < 0.01$; diastolic: $p < 0.05$) and microalbuminuria ($p < 0.001$) in type 1 diabetic patients. Autonomic neuropathy as well as microalbuminuria were independently associated with hypertension among type 1 diabetic patients. Among patients with type 2 diabetes, the severity of AN correlated positively with the 24-hour mean blood pressure, the blood pressure load (systolic: both $p < 0.0001$; diastolic: both $p < 0.01$), just as with systolic ($p < 0.001$) and diastolic ($p < 0.05$) hyperbaric impact values. Analyzing the relationship between ABPM parameters and the five cardiovascular reflex tests separately, in type 1 diabetic patients a significant negative correlation was found with two tests only – 30/15 ratio and Valsalva ratio – both tests reflect mainly parasympathetic function. Among patients with type 2 diabetes, also two predominantly parasympathetic tests – the heart rate variation during deep breathing and the Valsalva ratio – were inversely related to the ABPM parameters. The Valsalva ratio correlated negatively with the 24-hour systolic blood pressure standard deviation ($p < 0.01$). These relationships remained significant after adjustment for age, sex, body mass index and smoking.

Conclusion: Autonomic neuropathy is independently associated with elevated 24-hour ABPM parameters in patients with both type 1 and type 2 diabetes. Our data suggest that a relative sympathetic overactivity due to predominantly parasympathetic neuropathy might be responsible for the higher ABPM indices and increased blood pressure variability also in type 1 and type 2 diabetic patients. ABPM is suggested to be performed for the early assessment of hypertension in diabetic patients with autonomic neuropathy and vice versa: autonomic function should be screened as part of the cardiovascular risk assessment in diabetic patients with hypertension. Higher 24-hour-long blood pressure values just as increased blood pressure variability may contribute to the poor prognosis of cardiovascular autonomic neuropathy in diabetic patients.

⁴Department of Health and Work Ability, Finnish Institute of Occupational Health, Helsinki, Finland.

Background and Aims: Cardiac autonomic neuropathy (CAN) is a serious long-term complication of type 1 diabetes (T1D), associated with increased morbidity. Numerous studies have confirmed an association between CAN and other diabetic complications, but their temporal relationship is still unclear. Recent advances have enabled identification of early stages of CAN using spectral analysis of heart rate variability (HRV) and blood pressure variability (BPV), and assessment of spontaneous baroreflex sensitivity (BRS). Although autonomic dysfunction seems to be an early phenomenon on the path leading to diabetic micro- and macrovascular complications, the data supporting this view is limited. Thus, our aim was to study if signs of autonomic dysfunction are detectable at an early stage in a homogeneous population-based sample of uncomplicated T1D patients with short duration.

Materials and Methods: The IDEAL Study (IDentification of EARly mechanisms in the pathogenesis of diabetic Late complications), launched in 2003, is a population-based, observational follow-up study with the aim to identify early markers of late diabetic complications. At baseline we studied 116 young (age 26.3 ± 5.7 yrs) T1D patients (62 males) with short duration (8.9 ± 1.6 yrs), and 36 age- and sex-matched healthy controls. 24h ambulatory blood pressure measurement and conventional autonomic function tests were performed. Spectral analysis of HRV and BPV were obtained from a 10-minute supine recording of ECG and non-invasive, continuous blood

pressure. Spontaneous BRS was estimated from the same recording by sequence method (BRS+/+ and BRS-/-), alfa coefficient (alfa LF and alfa HF) and transfer function (BRSpc). Data are cross-sectional.

Results: Patients with T1D had higher office SBP (132 ± 13 vs. 122 ± 13 , $p<0.001$) and S-LDL cholesterol (2.4 ± 0.8 vs. 2.0 ± 0.7 , $p=0.040$), than the control subjects. There was no difference in urinary albumin excretion rate, but patients with T1D had higher estimated GFR ($p=0.01$). 24h blood pressure was higher in the T1D group (24h SBP 123 ± 7 vs. 119 ± 8 , $p<0.010$; 24h DBP 73 ± 6 vs. 70 ± 6 , $p<0.007$). Heart rate was consistently higher in the patients (24h HR 73 ± 10 vs. 69 ± 8 , $p=0.012$). The proportion of non-dippers was equal in both groups. All BRS estimates except BRS-/- were lower in T1D patients as shown in the figure.

Conclusion: In uncomplicated T1D with short duration there are already early signs of autonomic dysfunction. Collectively, these observations indicate sympathetic predominance that may predispose to future cardiovascular complications.

Stroke, whether $<$ or $>$ 4%, the mesor was 8.4 mmHg ($p<0.001$) higher in the latter group together with an unexplained DBP mesor of 7 mmHg lower.

Conclusion: 1) More than half of diabetic patients were non-dippers (a 13% higher in type 2). 2) The PP was statistically and clinically significantly higher in diabetic patients with cardiac autonomic dysfunction. 3) This higher value seems related to a higher CHD risk at 10-year.

Circadian blood pressure variability: cardiovascular autonomic dysfunction and cardiovascular risk as influential factors in diabetes mellitus

J. Cabezas-Cerrato^{1,2}, R. C. Hermida^{3,4}, D. E. Ayala⁵,
J. M. Cabezas-Agricola², C. Calvo⁶;

¹Medicine, University Hospital of Santiago, Santiago de Compostela,

²Medicine (Servicio de Endocrinología y Nutrición), University Hospital of Santiago, Santiago de Compostela, ³Bioengineering, University of Vigo, Santiago de Compostela, ⁴Unidad de Hipertensión, University Hospital of Santiago, Santiago de Compostela, ⁵Bioengineering, University Hospital of Santiago, Santiago de Compostela, ⁶Medicine (Unidad de Hipertensión), University Hospital of Santiago, Santiago de Compostela,

Background and Aims: The relationship between diabetes mellitus (DM) and circadian blood pressure variability (CBPV) is yet controversial. This research was designed to study the influential factors in CBPV in diabetes. We report the first 61 consecutive diabetic patients (61% type 2 DM) studied for two of this possible factors: cardiovascular autonomic function (CAF) and cardiovascular risk (CVR) estimated for 10-year.

Materials and Methods: BP was measured at 20-min intervals from 0.7:00 to 23:00h and at 30-min intervals at night for 48h. Physical activity was simultaneously monitored every minute by wrist actigraphy to accurately calculate the diurnal and nocturnal means of BP on a pair subject basis. CAF was evaluated for the three main standard tests: HRDB, VM and Standing-up by a computer aided system. Subjects were classified according to the number of abnormal parameters into two groups: with no-abnormal autonomic parameters (GAP, 0) and with 1 or more abnormal autonomic parameter (GAP, 1). CVR for coronary heart disease (CHD) and Stroke for 10-year was stimulated by the UKPDS Risk Engine v.2.

Results: 33 (54%) diabetic patients were non-dippers (rate of 46% of 24 type 1, and 59% of 37 type 2). Pulse pressure in mmHg (PP) was higher in GAP, 1 than in GAP, 0 both during the day (55.6 ± 1.5 vs. 42.9 ± 2.2 , $p<0.001$) and during the night (53 ± 1.5 vs. 45 ± 1.4 , $p<0.001$). When patients were divided according to their CVB for CHD whether $<$ or $>$ 10%, the mean value of the 24h data-adjusted SBP curve (mesor) was 6 mmHg higher ($p<0.001$) in the group of CVR $>$ 10%. When patients were divided according the CVR for

Possible involvement of AGE and MMP-2 in podocyte detachment and loss

K. Fukami¹, Y. Takamiya¹, S. Ueda¹, S.-I. Yamagishi², T. Fujimura¹, A. Hayashida¹, K. Koike¹, Y. Matsumoto¹, M. Takeuchi³, S. Okuda¹;
¹Department of Medicine, Division of Nephrology, Kurume University School of Medicine, Fukuoka, ²Department of Internal Medicine, Division of Cardiovascular Medicine, Kurume University School of Medicine, Fukuoka, ³Department of Biochemistry, Hokuriku University, Kanazawa, Japan.

Background and Aims: Podocyte effacement is considered to be an important phenomenon for the progression of proteinuria in diabetic nephropathy (DN). Recently, loss of slit membrane protein, nephrin is involved in the detachment of podocytes from glomerular basement membrane (GBM) in DN. Metalloproteinases-2 (MMP-2) is decreased in glomeruli in advanced diabetic kidneys, and thereby, plays a central role in the pathogenesis of diabetic glomerulosclerosis. However, the role of MMP-2 in podocyte detachments in early diabetic nephropathy remains to be elucidated. Further, there is a growing body of evidence that AGE could participate in the progressive alteration in renal architecture and loss of renal function in diabetes as well. Therefore, we first examined here whether MMP-2 expression and activity were increased in early phase of diabetic nephropathy in rats. We next studied the pathological involvement of AGE and MMP-2 on podocyte detachment and loss *in vitro*.

Materials and Methods: Diabetes was induced by streptozotocin (50mg/kg) in Sprague Dawley (SD) rats. After 8 or 16 weeks, MMP-2 expression and activity were measured by immunohistochemistry and zymography, respectively. Nephrin gene expression was evaluated by real-time RT-PCR. AGE were prepared by incubating BSA with glyceraldehyde for 7 days. DNA fragmentation and caspase-3 levels in murine immortalized podocytes were examined by comet assay and western blots, respectively.

Results: Plasma level of glucose, HbA1c and kidney to total body weight ratio were increased by about 2-3-folds in 8- and 16-week diabetic rats, compared with non-diabetic control rats (plasma glucose; 589±38 mg/dl, HbA1c; 8.8±0.3 in 16-week diabetic rats). MMP-2 expression and activity were increased to about 4-5-folds in the cortex of whole kidney, isolated glomeruli and the urine in 8- and 16-week diabetic animals (p<0.05). Compared with control rats, albumin excretion rate was increased by 4-folds in 16-week diabetic rats, while nephrin gene expression was decreased to about 50 % (p<0.01). *In vitro*, 100 µg/ml AGE significantly increased MMP-2 and caspase-3 expression to about 1.5-2-folds and subsequently induced apoptotic cell death in cultured immortalized podocytes (p<0.05). Human recombinant MMP-2 at 1 nM and 100 µg/ml AGE were also found to cause podocyte detachment from basement membrane produced by endothelial cells.

Conclusion: The present study demonstrated for the first time that MMP-2 expression and activity are increased rather than decreased in early phase of experimental diabetic nephropathy. AGE may play a role in podocyte detachment and loss via MMP-2 activation *in vitro*.

1102

Regulation of VEGF by pentosidine and glycated serum

G. L. Viviani, A. Puddu, A. Durante, D. Storace, R. Sanguineti, P. Odetti; DIMI, Università di Genova, Italy.

Background and Aims: Proliferative retinopathy, one of the major long term complications of diabetes, is characterized by increased neovascularization in the retina. Relative hypoxia in retina, resulting in the induction of vascular endothelial growth factors (VEGFs) and other vascular mediators that stimulate proliferation of retinal endothelial cells, has been suggested as one of multiple mechanisms. VEGF-A is constitutively produced by retinal pigmented epithelium (RPE) cells. Exposure to high glucose and advanced glycation end-products (AGEs), a common situation found in diabetes, increases VEGF A secretion. Up-regulation of VEGF A gene expression is mediated by the transcription factor HIF-1. Moreover VEGF A has been reported to increase secretion of VEGF C, another angiogenic factor, and to

act synergistically with it to promote neovascularization. The aim of this study was to investigate whether pentosidine (PENT), a well characterized AGE, and glycated serum (GS) are able to modulate the secretion of VEGF-A and VEGF-C in the human RPE cells ARPE-19.

Materials and Methods: PENT was synthesized from N-alpha-t-Boc-lysine, N-alpha-t-Boc-arginine and D-ribose, and purified by HPLC. GS was obtained by incubation of FBS with 50 mol/l ribose at 37 °C for 7 days. ARPE-19 cells were incubated in DMEM/F12 medium supplemented with 10% FBS, containing 0.25 pM of PENT, a comparable concentration to plasma levels in diabetes, or in DMEM/F12 1:1 medium supplemented with 10% GS. A set of cells was lysed after 4h for evaluation of HIF-1α expression by immunoblot. Another set was cultured for 24h and then supernatants were collected for VEGF analysis. Levels of secreted VEGF-A and VEGF-C were evaluated by ELISA and normalized to protein content of the corresponding lysate.

Results: GS, but not pentosidine, was able to increase HIF-1α expression and VEGF-A secretion (respectively 212.6 ± 15.83 p<0.05; 157.2 ± 10.01 p<0.05). VEGF-C secretion was increased in both conditions, but the increment was more marked in presence of GS (PENT 155.7 ± 5.364 p<0.001; GS: 220.4 ± 3.037 p<0.0001).

Conclusion: Our results demonstrate that: a) PENT, independently from VEGF-A and HIF-1α, is able to increase VEGF-C in ARPE-19 cells; b) increment of VEGF-A by GS is associated to HIF-1α increase; c) VEGF-A, elevated in GS condition, further increases VEGF-C secretion. Therefore, both GS and PENT, by increasing VEGF secretion, may play a detrimental role in stimulating angiogenesis.

Interaction between the receptor for advanced glycation end products (RAGE) and estrone (E1) in the development of type 2 diabetic nephropathy

B. E. Harcourt¹, A. Mibus¹, A. Gasser¹, S. Andikopoulos², M. Thomas¹, M. T. Coughlan¹, K. Sourris¹, G. Rice³, A. Bierhaus⁴, M. E. Cooper¹, J. M. Forbes¹;

¹Diabetes Complications, Baker Heart Research Institute, Melbourne, Australia, ²Department of Medicine, University of Melbourne, Australia, ³Proteomics, Baker Heart Research Institute, Melbourne, Australia, ⁴Department of Medicine, University of Heidelberg, Germany.

Background and Aims: Some 25–40% of persons with Type 2 diabetes, of which obesity is a major risk factor, will develop nephropathy. We hypothesize that estrone (E1) secreted from white adipose tissue (WAT), worsens the progression of nephropathy via up-regulation of the receptor for advanced glycation end products (RAGE) through the estrogen receptor β (ERβ).

Materials and Methods: Healthy RAGE deficient (RAGE^{-/-}) and C57Bl/6 (WT, wild type) mice (N=10), fed diets either low in AGEs (LAGE) or High in AGEs and saturated fat (HFF) were studied for 16 weeks. A separate WT group was given the HFF diet in conjunction with the AGE cross-link breaker alagebrium (ALA, 1mg/kg/day).

Results: Healthy RAGE deficient (RAGE^{-/-}) and C57Bl/6 (WT, wild type) mice (N=10), fed diets either low in AGEs (LAGE) or High in AGEs and saturated fat (HFF) were studied for 16 weeks. A separate WT group was given the HFF diet in conjunction with the AGE cross-link breaker alagebrium (ALA, 1mg/kg/day). WT mice fed a HFF diet had significantly increased WAT at the peri-renal and visceral fat depots when compared to LAGE fed WT mice (Peri-renal; 73±27 vs 179±28mg, p<0.0001). Although visceral WAT accumulation was increased in both HFF fed RAGE^{-/-} mice (743±114mg) and WT mice (698±175mg), there was no increase in peri-renal fat seen in HFF fed RAGE^{-/-} mice (91±40mg) as compared to HFF WT mice (179±28, p<0.01 vs LAGE WT; p<0.01 vs HFF RAGE^{-/-}). Visceral fat accumulation was however decreased in ALA treated HFF fed mice (462±107mg, p<0.05 vs HFF WT). The visceral WAT gene expression of ERβ was lower in all RAGE^{-/-} mice when compared to WT LAGE mice (RAGE^{-/-} p<0.01; RAGE^{-/-} HFF p<0.05). HFF WT had increased visceral WAT gene expression of ERβ (p<0.05 vs WT LAGE), which as ameliorated with ALA therapy (p<0.01 vs HFF WT mice).

Conclusion: This data suggests a link between estrone and RAGE in renal disease in HFF mice.

Fibrin gel porosity relates to glycosylated haemoglobin in patients with type 1 diabetes mellitus

A. M. Antovic, N. H. Wallen, A.-C. Salomonsson, P.-E. Lins, U. Adamson, G. Jörneskog;

Dept of Clinical Sciences, Danderyd Hospital, Karolinska Institute, Stockholm, Sweden.

Background and Aims: We have previously demonstrated tight and less permeable fibrin clot structure in patients with type 1 diabetes, which may contribute to increased atherothrombotic risk in these patients. However, the mechanisms behind these alterations are unclear and therefore the present study was aimed to investigate the relation between the fibrin clot structure and glycaemic control in patients with type 1 diabetes.

Materials and Methods: Fifty-five patients (age: 38±11; diabetes duration 17±12 years) and 15 controls (age: 40±8) were investigated. Fibrin clot properties were analysed in recalcified plasma samples after addition of thrombin *in vitro*, using liquid permeation technique, and permeability coefficient (Ks) and fiber mass-length ratio (γ) were calculated.

Results: Glycaemic control, measured by glycosylated haemoglobin level (HbA_{1c} %) was significantly elevated in patients compared to healthy control subjects ($p<0.001$). Ks was decreased in diabetic patients ($7.4\pm 2.4\text{ cm}^2$; $p<0.01$) as compared to healthy subjects ($10.0\pm 3.4\text{ cm}^2$) while γ was not significantly altered. Plasma fibrinogen levels in patients were similar to those in healthy controls. An inverse correlation was found between permeability coefficient (Ks) and HbA_{1c} ($r=0.32$; $p=0.006$), whereas no correlation was found between fiber mass-length ratio (γ) and HbA_{1c}.

Conclusion: Fibrin clots created in plasma samples from patients with diabetes type 1 are tighter, less porous than those from healthy individuals and these unfavourable changes in fibrin clot structure are significantly related to the glycaemic control of the investigated subjects. Despite normal plasma fibrinogen levels, the patients with poor glycaemic control (higher HbA_{1c} levels) have less porous fibrin network structure (lower Ks values), indicating that the changes in fibrin network permeability may be the result of the modified fibrinogen clotting property involving glycosylation of the fibrinogen molecule.

1105

Pigment epithelium-derived factor protects against AGE- or diabetes-induced retinal derangement through its anti-oxidative properties expressionY. Yoshida^{1,2}, S.-I. Yamagishi¹, T. Matsui¹, R. Yamakawa², T. Imaizumi¹;¹Department of Internal Medicine, ²Department of Ophthalmology, Kurume University School of Medicine, Japan.

Background and Aims: Pigment epithelium-derived factor (PEDF) is the most potent inhibitor of angiogenesis, suggesting that loss of PEDF contributes to proliferative diabetic retinopathy. However, the role of PEDF against retinal leukostasis and vascular hyperpermeability, the characteristic features of early diabetic retinopathy, remains to be elucidated. Since AGE, the senescent macroprotein derivatives formed at an accelerated rate under diabetes, are involved in the pathogenesis of diabetic retinopathy, we investigated here whether and how PEDF could inhibit the AGE- or diabetes-induced retinal leukostasis and vascular hyperpermeability in rats.

Materials and Methods: AGE were prepared by incubating BSA with D-glyceraldehyde for 7 days. Adherent leukocytes to retinal vasculatures were imaged with FITC-coupled concanavalin A lectin. Gene expression was analyzed by RT-PCR. Retinal vascular permeability was evaluated by leakage of FITC-conjugated dextran from retinal vasculature.

Results: Retinal levels of an oxidative stress marker, 8-hydroxydeoxyguanosine (8-OHdG), ICAM-1 gene expression and leukostasis were increased to about 1.5-folds in streptozotocin-induced diabetic rats ($p<0.01$). Intravenous administration of PEDF or pyridoxal phosphate, an AGE inhibitor, completely inhibited the increase in 8-OHdG levels and subsequently suppressed ICAM-1 gene expression and retinal leukostasis in diabetic rats ($p<0.01$). The amplitudes of a- and b-waves in the electroretinogram, one of the most sensitive markers for early diabetic retinopathy, were significantly reduced to about 70 % of control rats, which were completely prevented by the treatment of PEDF. Further, intravenous injection of 1 mg AGE to normal rats increased

retinal levels of 8-OHdG, gene expression levels of p22phox and gp91phox, two membrane components of NADPH oxidase ($p<0.05$) and ICAM-1, retinal leukostasis and vascular permeability to about 1.5-folds ($p<0.01$), all of which were also completely blocked by simultaneous treatment of PEDF ($p<0.05$). In addition, AGE injection to normal rats decreased retinal PEDF levels to about 70 % of those in control rats.

Conclusion: These results suggest that PEDF may protect against early diabetic retinopathy by suppressing the deleterious signaling of AGE via its anti-oxidative properties. Substitution of PEDF may offer a promising strategy for halting the development of early diabetic retinopathy.

Hypertension increases pro-oxidant generation and decreases antioxidant defense in the kidney in the early stage of experimental diabetes

S. K. Biswas, E. B. M. Peixoto, D. S. Souza, J. B. Lopes de Faria;

Division of Nephrology, Faculty of Medical Sciences, State University of Campinas, Brazil.

Background and Aims: Oxidative stress contributes to the pathogenesis of nephropathy resulting from both diabetes mellitus and hypertension. Diabetes and hypertension frequently coexist in humans, and individually both of them can induce oxidative stress in the kidney. Previously, we demonstrated that the combination of hypertension and diabetes exaggerates renal oxidative stress. The aim of the present study was to assess pro-oxidant and antioxidant mechanisms for the induction of oxidative stress in the kidney in presence of hypertension and diabetes mellitus.

Materials and Methods: Diabetes was induced in spontaneously hypertensive rats (SHR) and their genetically normotensive control Wistar Kyoto (WKY) rats by streptozotocin at 12 weeks of age. After 10 days, rats were sacrificed and kidneys were collected. Renal cortical nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity was assessed by lucigenin-enhanced chemiluminescence, and the expressions of gp91phox, Nox4, nitrotyrosine, extracellular-superoxide dismutase (EC-SOD), heme-oxygenase-2 (HO-2) and receptor for advanced glycation end products (RAGE) were evaluated by Western blot analysis. Renal cortical 8-hydroxy-2'-deoxyguanosine (8-OHdG) was assessed by immunohistochemistry, and the reduced form of glutathione (GSH) was measured by colorimetry.

Results: Systolic blood pressure was higher ($p<0.001$, $n=15$) in control (C) and diabetic (D) SHR than the WKY groups. Plasma glucose levels were similar in WKY-D and SHR-D groups. NADPH-dependent superoxide generation in the renal cortex was significantly elevated in WKY-D and SHR-D groups compared to the respective control groups ($p<0.01$, $n=5$). Superoxide generation was further elevated in SHR-D group compared to WKY-D group ($p=0.024$). The expression of gp91phox subunit of NADPH oxidase was significantly elevated in SHR-D group ($p<0.05$), but not in WKY-D group, compared to the respective control groups. However, RAGE and Nox4 levels were found similar between control and diabetic groups of both WKY and SHR strains. Renal cortical EC-SOD level was found markedly decreased in SHR compared to WKY groups. However, EC-SOD level was non-significantly increased in WKY-D group and decreased in SHR-D group compared to respective control groups. Non-enzymatic antioxidant GSH level was slightly increased in WKY-D than WKY-C, but it was significantly decreased ($p=0.033$, $n=10$) in SHR-D than SHR-C. However, antioxidant HO-2 levels did not differ among the groups. Finally, nitrotyrosine and 8-OHdG, markers of oxidative stress, were found similar in the kidney in WKY-C and WKY-D, but they were found elevated in SHR-D compared to SHR-C.

Conclusion: Pro-oxidant generation increases in the kidney in the early stage of diabetes, which further increases in presence of hypertension. On the other hand, antioxidant system remains unaltered in early diabetes, but the presence of hypertension depletes antioxidant protection in the kidney in early diabetes. Consequently, oxidative stress appears in the kidney in early diabetes in hypertensive animals but not in normotensive animals. We therefore conclude that hypertension increases pro-oxidant generation and decreases antioxidant defense in the kidney in the early stage of experimental diabetes.

Increased skin autofluorescence: a more pronounced marker of mortality in haemodialysis patients than diabetes mellitus?

E. G. Gerrits^{1,2}, H. L. Lutgers³, G. H. W. Smeets¹, A. J. Smit³, H. J. G. Bilo^{2,3},
¹Department of Medicine, Isala Clinics, Zwolle,

²Diabetes Center, Isala Clinics, Zwolle, ³Department of Medicine, University Medical Center Groningen, The Netherlands.

Background and Aims: Advanced glycation endproducts (AGEs), measured in tissue, represent cumulative glycemic and oxidative stress. In addition to diabetes mellitus (DM), accelerated formation and tissue accumulation of AGEs occurs in patients with renal failure and dialysis which progresses during time. Skin autofluorescence (AF) non-invasively measures tissue accumulation of AGEs and is suitable for clinical application. Recent studies have already demonstrated its predictive value in overall and cardiovascular mortality in type 2 diabetic patients and hemodialysis patients. We investigated whether skin AF has an additional predictive value concerning mortality in diabetic hemodialysis versus non-diabetic hemodialysis patients.

Materials and Methods: Patients were recruited from our hemodialysis center and baseline skin AF was assessed at the lower (non-shunt) arm of the included patients. Skin AF measurement is based on the fluorescence characteristics of certain AGEs and is expressed in arbitrary units (AU). After a follow up period of 3.2 years we assessed mortality in relation to the presence or absence of DM, and to the level of baseline skin AF.

Results: Baseline skin AF was obtained in 106 hemodialysis patients, mean age of 65 years, 68% male and a mean renal replacement therapy duration of 3.6 years. There were 83 non-diabetic patients and 23 type 2 diabetic patients (mean diabetes duration 16.1 years; mean HbA1c 6.8%). At the end of follow up 38 patients had died: 12 diabetic patients (52%) and 26 non-diabetic patients (31%), which was borderline non-significant, $p = 0.065$ (χ^2). Baseline skin AF was higher in the deceased independent of the presence or absence of DM. In the diabetes group baseline skin AF was increased, but t test showed no significance in the non-survivors compared to the survivors (table).

Table. Skin autofluorescence – mean \pm SD (AU)

Hemodialysis group	Survivors	Non-survivors	p (non-survivors versus survivors)	Total
Non-diabetic	2.94 \pm 0.91 (n=57)	3.56 \pm 0.67(n=26)	0.002	3.14 \pm 0.88 (n=83)
Diabetic	3.00 \pm 0.81 (n=11)	3.43 \pm 0.89 (n=12)	0.24	3.22 \pm 0.86 (n=23)
Total	2.95 \pm 0.89 (n=68)	3.52 \pm 0.74(n=38)	0.001	3.15 \pm 0.88 (n=106)

Conclusion: Our study confirms a higher mortality rate in diabetic hemodialysis patients compared to non-diabetic hemodialysis patients. Mortality was increased in hemodialysis patients with a higher baseline skin AF, independent of the presence or absence of DM. This might implicate that skin AF is a better predictor for mortality in hemodialysis patients than the presence or absence of DM.

1108

Experimental diabetes treated with stobadine: effects on kidney oxidative/nitrosative stress parameters

A. Cumaoglu¹, C. Cevik¹, M. Kavutcu¹, N. Ari², U. Bagriacik³, L. Rackova⁴, C. Karasu⁵;

¹Biochemistry, Gazi University, Ankara, Turkey, ²Pharmacology, Ankara University, Ankara, Turkey, ³Immunology, Gazi University, Ankara, Turkey, ⁴Experimental Pharmacology, Slovak Academy of Sciences, Bratislava, Slovakia, ⁵Medical Pharmacology, Gazi University, Ankara, Turkey.

Background and Aims: Glycation, generation of advanced oxidation/nitration protein products and formation of protein carbonyl groups play important roles in diabetes, its secondary complications, and renal failure. Stobadine, a synthetic pyrroindole anti-oxidant, has the ability to reduce tissue injury induced by mechanisms involving reactive oxygen species in different oxidative stress models. Stobadine has been shown to reduce renal proteinuria, albuminuria and enzymuria, and decreases conjugated diene

level and histochemical changes in kidney of diabetic animals. In addition, stobadine is able to antagonize the negative effects of diabetes on renal Na,K-ATPase, catalase and glutathione peroxidase. Stobadine has also been shown to have hypoglycemic, antihyperlipidemic and lipid peroxidation lowering effects on experimental diabetic animals. The aim of the present study was to investigate the effect of dietary supplementation with stobadine on renal markers of oxidative/nitrosative stress and antioxidant capacity of diabetic rats.

Materials and Methods: Wistar rats were made diabetic by streptozotocin (55 mg/kg, i.p.). Some of them (D) and control (C) rats were treated orally for 4 months with stobadine (STB; 24.7 mg/kg/day) starting at 1st week of diabetes induction (CSTB and DSTB prevention study). The levels of advanced oxidation protein products (AOPP) (by a spectrophotometric method), protein carbonyl content (PCC), 3-nitrotyrosine (3-NT) – a marker specific for protein modification by nitric oxide derived oxidants-, and antioxidant potential (AOP) in kidney homogenates (by ELISA) were studied.

Results: STB treatment associated with decreased blood glucose levels seen in D rats. AOPP, 3-NT, PCC and AOP were found to be significantly higher in D group. Administration of STB was accompanied by a decrease of the all parameters studied in kidney of diabetic animals as shown in the table (Data \pm SEM; ANOVA, * $p < 0.05$ vs. C).

Conclusion: The ability of STB as an antioxidant and a factor reducing protein nitrosylation and oxidative modification, and a protecting antioxidant tissue defense may account, at least partly, for its previously observed histological protection of diabetic kidney.

	C	CSTB	D	DSTB
AOPP (nmol/mg protein)	6.23 \pm 0.43 n=10	5.37 \pm 0.47 n=7	9.31 \pm 0.17* n=8	7.63 \pm 0.32* n=9

Atorvastatin not only decreases serum levels of AGE in diabetic patients, but also inhibits the AGE-induced C-reactive protein expression in hepatoma cells

Y. Jinnouchi¹, S.-I. Yamagishi¹, M. Takeuchi², T. Imaizumi¹;

¹Internal Medicine, Kurume University School of Medicine, Japan,

²Department of Pathophysiological Science, Hokuriku University, Kanazawa, Japan.

Background and Aims: Lipid-lowering agents, statins, have been recently shown to reduce the risk for cardiovascular events in diabetic patients. Indeed, a multicentre randomized placebo-controlled trial revealed that atorvastatin prevented first cardiovascular events including stroke, in patients with type 2 diabetes without high LDL-cholesterol levels. In addition, statin treatment is associated with less risk of cardiovascular events than placebo treatment even in overlap groups where patients exhibited equivalent LDL-cholesterol levels. These observations support the concept that beyond lipid-lowering effects of statin could contribute at least in part to cardiovascular event reduction in diabetes. In this study, we examined whether atorvastatin treatment decreased serum AGE levels in diabetic patients. We also investigated whether atorvastatin could inhibit the AGE-induced CRP expression in Hep3B cells, a human hepatoma cell.

Materials and Methods: Sixteen hypercholesterolemic type 2 diabetic patients (mean age of 63.6 \pm 2.1 years, 8 males and 8 females) without any cardiovascular disease who were previously untreated with statins, were enrolled for the present study. The patients were treated with 10 mg atorvastatin once daily for 4 weeks. Age- and sex-matched 9 hypercholesterolemic diabetic patients who were treated with diet therapy only for 4 weeks served as control subjects. Serum levels of AGE were measured with ELISA before and after the treatment of atorvastatin. In vitro, AGE were prepared by incubating BSA with 0.1 mol/l D-glyceraldehyde for 7 days. Reactive oxygen species (ROS) generation was measured by using the fluorescent probe CM-H2DCFDA.

Gene expression was analyzed by quantitative real-time RT-PCR. CRP levels in the medium were measured with an ELISA.

Results: There were no significant differences of fasting glucose and HbA1c levels between before and after atorvastatin treatment. However, serum levels of AGE were significantly decreased after 4-week treatment with atorvastatin, whereas those of control subjects remained unchanged; AGE levels before and after atorvastatin treatment were 15.0 ± 0.5 and 13.6 ± 0.1 U/ml, respectively ($p < 0.05$). Although atorvastatin treatment significantly decreased total cholesterol, LDL-cholesterol and triglycerides levels in our patients, there were no significant correlations between changes of AGE and those of lipid parameters. In vitro, AGE significantly increased the ROS generation in Hep3B cells by about 1.3-fold ($p < 0.05$). Atorvastatin dose-dependently inhibited the AGE-induced increase in ROS generation ($p < 0.05$). In addition, AGE increased CRP mRNA levels in Hep3B cells to about 6-folds ($p < 0.01$), which was significantly blocked by atorvastatin or an anti-oxidant, N-acetylcysteine ($p < 0.05$). Atorvastatin inhibited the AGE-induced CRP secretion by Hep3B cells in a dose-dependent manner as well.

Conclusion: Atorvastatin not only decreased serum AGE levels in patients with type 2 diabetes in a cholesterol-lowering independent manner, but also blocked the AGE-signaling to CRP expression through its anti-oxidative property in vitro. Our present study suggests that atorvastatin may have pleiotropic effects against atherosclerosis by blocking both AGE formation and its downstream signaling to inflammation.

Longitudinal association of glucose metabolism with neuropathy and peripheral arterial disease: the AusDiab study

R. Tapp^{1,2}, P. Zimmet², A. Tonkin¹, J. Shaw²;

¹Department of Epidemiology and Preventive Medicine, Monash University,

²Epidemiology Department, International Diabetes Institute, Melbourne, Australia.

Aims: We determined the incidence of peripheral neuropathy and peripheral arterial disease (PAD) across categories of glucose metabolism in an Australian population and assessed risk factors for these outcomes.

Materials and Methods: The Australian Diabetes Obesity and Lifestyle study (AusDiab), is a national, longitudinal study of adults aged ≥ 25 years from 42 randomly selected areas of Australia. Neuropathy and PAD were assessed in 1999–2000 and 2004–2005 in participants identified as having diabetes (based on self report and oral glucose tolerance test), impaired glucose metabolism (IGM) and in a random sample with normal glucose tolerance (NGT). Complications data from both 1999–2000 and 2004–2005 were available for 1294 participants.

Results: The five year incidence of peripheral neuropathy was 16.5% in those with known diabetes at baseline (KDM), 7.7% in those with newly diagnosed diabetes (NDM), 7.3% in those with IGM and 5% in those with NGT. The five year incidence of PAD was 7.3% in those with KDM, 3.2% in those with NDM, 3.1% in those with IGM and 1.6% in those with NGT. At baseline 19.6% of those with diabetes were at risk of foot ulceration and at follow-up 27.6% were at risk of foot ulceration. Those with KDM at baseline were four times more likely to develop PAD compared to those with NGT after adjustment for age, sex, systolic BP, cholesterol and smoking (3.90 [1.15–13.26]). Independent risk factors for peripheral neuropathy were height (1.74 [1.05–2.88] per 10 cm), age (2.16 [1.53–3.05] per 10 years) and HbA1c (1.24 [1.01–1.53] per 1%).

Conclusion: This is one of the first national, longitudinal population-based studies of neuropathy and one of the very few in which diabetes was defined by an oral glucose tolerance test. The present study identified a substantial proportion of the diabetic population at high risk of foot ulceration.

Randomised controlled trial of education in the prevention of foot ulcer recurrence in diabetes

W. Jeffcoate¹, K. Radford¹, P. Ince¹, M. Smith¹, F. Game¹, N. Lincoln²;

¹Diabetes and Endocrinology, Foot Ulcer Trials Unit, Nottingham,

²Institute of Work, Health and Organisations, University of Nottingham, United Kingdom.

Background and Aims: Although the importance of education in the prevention of foot ulcers is accepted, there are few data to substantiate its effectiveness. Nevertheless, a single previous randomised trial has suggested that a one-hour educational intervention may be associated with a significant reduction in incidence of both new ulcers and of amputation in the group at highest risk: those with previous ulcers (Malone et al, 1989). We have sought to confirm these findings by undertaking an observer-blind, randomised controlled trial of targeted education in such a population.

Materials and Methods: Patients with ulcers which were newly epithelialised, and which remained healed at 28 days, were randomised to receive either usual care or a single hour-long, semi-structured but personalised, educational interview in their own home with a specialist health care professional. The interview was based on standard educational material, refined following discussion with a focus group of ulcer-sufferers and supplemented by illustrations of different types of foot problems. An educational leaflet was given to reinforce the principles of good foot care behaviour. The interview was followed after one month by a telephone interview in which issues raised earlier were revisited. The control group received the educational leaflet only. Ulcer recurrence and Hospital Anxiety and Depression (HAD) scale scores were documented at 6 and 12 months, and foot care behaviour (Nottingham

Assessment of Functional Footcare) at 12 months. New ulceration at 12 months was the primary endpoint and was determined by questionnaire sent to both GP and patient, and examination of hospital records by an observer blind to randomisation. In order to detect a reduction in the 12 month incidence of new ulceration from 35% to 15% (two-sided, 80% power, $p < 0.05$), 69 patients were required in each group.

Results: Of 259 patients attending one of three specialist multidisciplinary foot clinics between April 2003 and September 2005, who fulfilled the inclusion criteria, 87 were excluded (52 – withheld consent; 11 – serious medical problems; 5 – non-self caring; 19 – other reasons). 172 patients were randomised: 87 to the intervention group with 85 controls. Reported foot care behaviour was significantly better in the intervention group at 12 months ($t=2.09$, $p=0.04$). There were slight discrepancies in the number of new ulcers reported by patients and those documented by hospital records, and every effort was made to establish which was correct. There were, however, no significant differences between the intervention and control groups in either case (12 months: patient report – 33% versus 41%, respectively (OR 1.38, CI 0.69–2.796); medical records – 41% versus 41% (OR 1.01, CI 0.55–1.85). There were similarly no differences between the groups in the number of amputations (minor – intervention 8, control 8; major – intervention 1, control 1). There were no significant differences in HAD (Anxiety, Depression) scores.

Conclusion: We conclude that although the educational programme was associated with an apparent improvement in protective footcare behaviour, there was no evidence of any effect on either ulcer incidence or amputation. Further work is needed to establish the role of formal education programmes in this group.

1112

Ethnic differences in risk of foot diseases in persons with diabetes on dialysis

A. Ndip¹, J. Williams², H. LaFontaine³, L. A. Lavery², A. J. M. Boulton¹; ¹Diabetes and Medicine, Manchester Diabetes Centre, Manchester, United Kingdom, ²Surgery, Texas A&M University Health Sciences Centre, Georgetown, United States, ³Health Sciences Centre, University of Texas, San Antonio, United States.

Background and Aims: Hispanics with diabetes in the USA are known to be at increased risk of foot ulceration and amputation compared to non-Hispanics, whilst in the UK, Indo-Asians and Afro-Caribbeans have lower rates of ulceration. Whether these differences persist when these patients reach end-stage renal disease (ESRD) is unknown. We therefore sought to examine ethnic differences in diabetic foot ulceration in persons on dialysis.

Materials and Methods: We examined foot problems according to ethnic origin in diabetic patients on dialysis in centers in the UK and USA. A consecutive sample of all persons with diabetes on dialysis in Texas (US) and Manchester (UK) were assessed for foot problems including neuropathy, peripheral arterial disease, past and present foot ulcers, Charcot foot, and amputation. Risk for foot diseases was assessed based on the international diabetic foot risk classification. Chi-squared test was used for comparing categorical data.

Results: A total of 208 diabetic patients were included (UK 92, USA 116), 53% males, predominantly with type 2 diabetes (82%) and mean age of 59.8 (range 26–86) years. Peripheral neuropathy was present in 67% of patients, peripheral vascular disease in 48%, while 32.4% had a history of previous foot ulcers and 15.9% were already amputees. Among the UK patients, 4 were bilateral amputees whilst 20.5% of those with at least one limb had active ulcers including 22.6% Caucasians and 22.2% Indo-Asians ($P > 0.05$). Seven percent had had a diagnosis of Charcot foot. Further, no significant differences were observed in any of the 4 risk categories between Indo-Asians and Caucasians. In the US cohort, Hispanics were at significantly higher risk in all categories compared to non-Hispanics (19.6%, 7.8%, 43.2%, 29.4% vs. 17.5%, 27.5%, 17.5% and 37.5% respectively) ($p = 0.016$).

Conclusion: Thus, the high risk of diabetic foot diseases within ethnic minorities in the US appears to persist when they enter ESRD whereas in the UK, ethnic minorities known to be at low risk of diabetic foot diseases appear to lose this protection when in ESRD. The very high levels of foot pathology in all diabetic patients in ESRD emphasize the need for a comprehensive foot care program for these patients.

1113

Reduced incidence of lower-limb amputations in the diabetic population of a German city, 1990–2005

C. Trautner^{1,2}, B. Haastert³, P. Mauckner⁴, L.-M. Gaetcke³, G. Giani³; ¹Medicine Science Consulting, Berlin, ²Department of Public Health, University of Applied Sciences, Wolfsburg, ³Institute of Biometrics and Epidemiology, German Diabetes Center, Duesseldorf, ⁴Department of Internal Medicine, Remigius Hospital, Leverkusen, Germany.

Background and Aims: A reduction of diabetes-related amputations by at least one-half within 5 years was declared a primary objective for Europe (St. Vincent Declaration, 1989). We collected data in one German city (Leverkusen, approximately 160 000 inhabitants) to ascertain a potential change in incidence rates of amputations. This goal had not been achieved until the end of 1998. In this study, we evaluated whether the incidence of amputations in Leverkusen had decreased until the end of 2005.

Materials and Methods: From all three hospitals in Leverkusen, we obtained complete lists of lower-limb amputations of the years 1990/1991 and 1994–2005. Only the first observed amputation was counted for the analysis. Only non-traumatic amputations in residents of Leverkusen were considered. We estimated incidence rates of amputations in the entire population, the diabetic population, and the nondiabetic population. Data about the population structure, separately for each year of the observation period, were received from the city administration and the Federal Office of Statistics. To test for time trend, we fitted Poisson regression models, adjusting for age and sex.

Results: 692 patients met the inclusion criteria. Of all subjects, 58% were male, and 72% were known to have diabetes. Mean age was 71.7 years. Incidence rates in the diabetic population (standardised to the estimated German diabetic population, per 100 000 person-years) varied considerably between years and were as follows: 1990: 549; 1991: 356; 1994: 544; 1995: 386; 1996: 426; 1997: 433; 1998: 463; 1999: 474; 2000: 415; 2001: 304; 2002: 335; 2003: 360; 2004: 281; 2005: 428.

The Poisson models showed that in the diabetic population, the estimated relative risk (RR) per year was 0.976 ($p=0.0164$). The same trend was observed when only amputations above the ankle ($n=352$; RR=0.970; $p=0.0318$) were considered. Over 15 years, an estimated reduction of major amputations by 36.7% results. The Poisson models showed no significant change of incident amputations over time in the nondiabetic population. (RR=1.022; $p=0.1981$).

Conclusion: Although possible sources of bias cannot be excluded with certainty, the data indicate a reduction of the incidence of amputations. This finding is likely to be due to improved management of the diabetic foot syndrome (e. g. wound treatment and metabolic control) after a network of specialised physicians (a foot clinic and two physicians' offices specialised in diabetes) and defined clinical pathways for patients with diabetes were introduced.

1114

Predictors of amputation in diabetic foot disease

L. Prompers; on behalf of the Eurodiale Group, Internal Medicine, University Hospital Maastricht, The Netherlands.

Aims: Amputation is a serious outcome of diabetic foot ulcers. Data on the determinants of major (=lower leg) and minor amputation are scarce. In the multi-center Eurodiale study performed by 14 European centers, prospective data were collected on clinical outcome and its determinants, including data on determinants of major and minor amputation.

Methods: Data were obtained on 1232 consecutive patients with diabetes and a new foot ulcer. Patients were categorized in 4 stages: A;(PAD- / infection-), B;(PAD- / infection+), C;(PAD+ / infection-), D;(PAD+ / infection+). Patients were followed until final outcome (healing, major amputation or death) or up to one year. Predictors of major and minor amputation were determined by means of multiple logistic regression analyses (manual stepwise backward procedure).

Results: Major amputation was performed in 5% of the total population; ranging from 2 to 10% in stage A to stage D ($p < 0.001$). Minor amputation was performed in 18%; ranging from 8 to 31% ($p < 0.001$) respectively. In group D 34% underwent a major or minor amputation. Independent predictors of a major amputation were ulcer size (OR=7.71), PAD (OR=4.12),

visual impairment (OR=2.32), PAD (OR=4.12), gender (F vs. M-OR=0.39), and a neurological disorder (OR=0.18). Independent predictors of a minor amputation were depth (OR=6.22), PAD (OR=1.98) and infection (OR=1.78). In both models an interaction is present between PAD and infection ($p<0.001$). Analyzing PAD+ and PAD- patients separately, showed that gender, ulcer size and infection were predictors of major amputation in PAD+ and age and gender in PAD-. Predictors of minor amputation in PAD+ were depth and infection, and in PAD- heart failure, depth and PNP.

Discussion: Although the major amputation rate is relatively favorable, minor amputation is a frequent outcome of a diabetic foot ulcer. Patients with both PAD and infection are significantly more likely to undergo a major or minor amputation. When analyzing the determinants of amputation a clear interaction is present between the presence of PAD and infection. More insight into this relation and data on the optimal treatment for patients with both PAD and infection are urgently needed.

1115

Evaluation of the impact of chiropodist care in the secondary prevention of foot ulcerations in diabetic subjects over a period of 6 years

G. Köhler¹, W. Haas¹, I. Rakovac², M. Schintler³, G. Bock¹, S. Korsatko¹, J. Plank¹, T. R. Pieber¹;

¹Department of Internal Medicine, Diabetes and Metabolism, Medical University Graz, ²Institute of Medical Technologies and Health Management, Joanneum Research, ³Department of Plastic Surgery, Medical University Graz, Austria.

Background and Aims: Diabetic foot ulcers after healing are associated with a high risk for recurrence of ulcers and amputations. Prevention of foot related complications is a major challenge in diabetes care. We have recently demonstrated in a randomised controlled trial with duration of 1 year that chiropodist care can reduce recurrence rate of foot ulcers within one year. The aim of this follow up study was to investigate the impact of chiropodist care in the original study population after 6 years.

Materials and Methods: After healing of a diabetic foot ulcer, 91 patients [female (n=40), diabetes type 1 (n=6) and type 2 (n=85), age [mean ($\bar{A}\pm$ SD)] $65\bar{A}\pm 11$ years, BMI $28.5\bar{A}\pm 4.4$, diabetes duration $16\bar{A}\pm 11$ years, HbA1c $8.4\bar{A}\pm 1.6\%$] were initially randomized to regular chiropodist care, which was free of charge for patients, or a control group for the period of one year. The whole study cohort was invited to participate in a follow up evaluation 5 years after end of the randomised control trial. Outcome was analysed to assess the impact of self-paid chiropodist care (at least once every 8 weeks) and the recurrence rate of ulcers, amputation, and death.

Results: 89 out of 91 patients (2 lost to follow up) could be analysed after 6 years. 40 underwent regular chiropodist care. 26 in the chiropodist care group vs. 38 patients in the control group developed a new ulcer within the six years [HR 0.60 (95%CI 0.36–0.97), p 0.04] (Fig.1), 4 vs. 10 amputations [HR 0.39 (95%CI 0.14–1.16), p 0.09] were recorded, 11 vs. 21 patients died [HR 0.59 (95%CI 0.30–1.21), p 0.15] in the chiropodist vs. the control group, respectively. Analyses for the aggregated endpoint (ulceration, amputation, death) showed a reduction in favour of the chiropodist care group vs. the control group (29 vs. 46 events [HR 0.54 (95%CI 0.33–0.83), $p<0.01$]).

Conclusion: Our follow up investigation confirms the high rate of adverse outcome in patients with a diabetic foot syndrome. More than every second patient developed a new ulcer or amputation within the six years of follow up. Furthermore, our data suggests that regular chiropodist care may reduce the recurrence of ulcers and amputations.

1116

CDUK: a UK-wide, web-based survey of the management of the acute Charcot foot of diabetes

F. Game¹, R. Catlow², W. Jeffcoate¹, E. Jude³, M. Edmonds⁴, N. Baker⁵, G. Jones⁶;

¹Diabetes and Endocrinology, Foot Ulcer Trials Unit, Nottingham,

²Diabetes, CDUK Management Committee, Blackburn,

³CDUK Management Committee, Tameside, ⁴CDUK Management

Committee, London, ⁵CDUK Management Committee, Ipswich,

⁶CDUK Management Committee, Blackburn, United Kingdom.

Background and Aims: The acute Charcot foot is a rare, but serious, complication of diabetic neuropathy – which may lead to progressive deformity of the affected foot, and often to limb loss. Pathogenesis is uncertain and current therapy is mainly reliant on reduced weight bearing until the active phase of the disease remits. It is recommended that this is achieved by the use of non-removable below knee casts or walkers. There are few data available on the median time to disease remission and whether outcome is affected by other treatments, such as bisphosphonates. For this reason we set up a web-based survey of active cases of Charcot disease in the UK (CDUK), in order to define baseline characteristics, precipitating factors, management details and outcome, in as large a cohort as possible.

Materials and Methods: Participating clinicians were invited to register anonymised details of patients with active disease being managed between 1st June 2005 and 31st December 2006, and further details were requested at 3-monthly intervals for 12 months.

Results: A total of 279 (73% male) cases were registered to January 2007; mean age 57 years (range 21–90); 72% Type 2 diabetes. Outcome data are available for 200 patients at 3 months post registration, 142 patients at 6 months and 61 patients at 12 months. 61.6% were registered as having had a likely precipitating event within the 6 months prior to onset (accident 36%, previous ulcer 35%, surgery to affected foot 12%, osteomyelitis 7%). Initial management included offloading specified as non-removable below knee 34.1%, removable below knee 45.5%, non-removable foot 1.4%, removable foot 2.9% and other (eg. bed rest, crutches) 8.9%. 40.1% had a non-removable below knee offloading device at some stage during the follow up period. 25.4% of patients received treatment with intravenous bisphosphonates, 19.4% with oral bisphosphonates, some in combination. 5.3% had more than one treatment with intravenous bisphosphonates. 131 patients went into remission from their acute Charcot during follow up in a median of 10 (range 2–40) months. Those who had a non-removable offloading device at some stage in their management had a median time to resolution of 8.5 months compared to 12 months in those who had a removable offloading device (Mann Whitney U 1543, $p=0.006$). Those who were treated with any bisphosphonates had a median time to resolution of 12 months compared to 9 months in those who had none (Mann Whitney U 1598, $p=0.013$).

Conclusion: Whilst the possibility of confounders cannot be excluded these data support the use of non-removable offloading devices in the management of the acute Charcot foot of diabetes. The role of bisphosphonates requires further investigation in placebo controlled trials.

Impact of the basal activity in the renin angiotensin system (RAS) on NT-proBNP during hypoglycaemia and hypoxaemia in normal subjects

R. Due-Andersen¹, U. Pedersen-Bjergaard¹, C. E. Larroude², J. K. Kanters², C. Kistorp³, J. Faber³, N. V. Olsen⁴, B. Thorsteinnsson¹;

¹Endocrinology Section, Department of Internal Medicine, Hillerød Sygehus, ²Biomedical sciences, University of Copenhagen, ³Department of Cardiology and Endocrinology, Frederiksberg University Hospital, Copenhagen, ⁴Department of Neuroanaesthesia, Copenhagen University Hospital, Denmark.

Background and Aims: There is a slightly increased risk of sudden death among young patients with insulin treated diabetes compared to healthy young subjects. Malignant cardiac arrhythmias originating due to hypoglycaemia induced QT prolongation could be responsible for some of these deaths. Brain type natriuretic peptide (BNP) is thought to be a cardioprotective peptide. The peptide is released (together with the inactive N-terminal part of the prohormone, NT-proBNP) from the cardiac myocytes in response to different kinds of myocardial stress. BNP antagonise many of the classic effects of angiotensin II and a significant interplay exists between BNP and the RAS. The aims of this study were to explore if myocardial stress induced by hypoglycaemia and hypoxaemia affected NT-proBNP levels and if basal RAS activity had impact on changes in NT-proBNP levels during the stimuli. Additionally we wanted to investigate if the cardiac repolarisation (measured as the QTc) was correlated to the NT-proBNP levels.

Materials and Methods: From a cohort of 303 healthy young men, 8 subjects with high RAS activity and 9 subjects with low RAS activity (age 26 ± 4 years) were studied on three different occasions separated by at least three weeks: 1) hypoglycaemia (mean plasma-glucose 2.7 ± 0.5 mmol/l), 2) hypoxaemia (mean pO_2 5.8 ± 0.5 kPa), and 3) normoglycaemic normoxia (control day). NT-proBNP was measured at baseline, during the stimuli and in the recovery phase.

Results: Hypoglycaemia did not affect the NT-proBNP level. Hypoxaemia was significantly associated with an increase in NT-proBNP: baseline 2.2 (± 1.5) pmol/l – hypoxaemia 2.4 (± 1.5) pmol/l, $p = 0.001$ during the stimulus but not in the recovery phase. RAS activity had no impact on the NT-proBNP level neither at baseline, nor during hypoglycaemia nor hypoxaemia. Hypoglycaemia and hypoxia induced QTc prolongation compared with Qtc on the control day ($p < 0.001$, both stimuli). The QTc prolongation did not correlate with the NT-proBNP level during either of the stimuli.

Conclusion: Hypoxaemia but not hypoglycaemia caused small increases in NT-proBNP. The basal activity in RAS had no impact on NT-proBNP levels at any point. The QTc prolongation during both hypoglycaemia and hypoxaemia was not correlated to the NT-proBNP level.

Time course of the antiproteinuric and the antihypertensive effect of aliskiren in patients with type 2 diabetes and albuminuria

F. Persson¹, P. Rossing¹, K. J. Schjødt¹, T. R. Juhl¹, L. Tarnow¹, C. D. A. Stehouwer², C. Schalkwijk², F. Boomsma³, E. Frandsen⁴, H.-H. Parving⁵;

¹Steno Diabetes Center, Gentofte, Denmark, ²Department of Medicine, University Hospital, Maastricht, The Netherlands, ³Department of Internal Medicine, Section Vascular Medicine, Erasmus MC, Rotterdam, The Netherlands, ⁴Department of Clinical Physiology and Nuclear Medicine, Glostrup University Hospital, Denmark, ⁵Department of Medical Endocrinology, University Hospital of Copenhagen, Denmark.

Background and Aims: The renin inhibitor aliskiren lowers blood pressure in both non-diabetic and diabetic hypertensive subjects, but it is not known whether this treatment can decrease albuminuria and if so, if this is done independently of its blood pressure lowering capability. We evaluated the time course of the antihypertensive and antialbuminuric effect of renin inhibition. We also evaluated the effect on both variables after 4 weeks of cessation of treatment.

Materials and Methods: Fifteen patients with type 2 diabetes and albuminuria were included. After a 4-week washout period, patients received aliskiren 300 mg once daily for 28 days. Early morning urine samples were collected for daily determination of UACR during 56 days. Mean of three consecutive days were analysed. Twenty-four hour blood pressure was measured at baseline and after 3,7,14 and 28 days of treatment and 3,7,14 and 28 days after cessation of treatment. Estimated GFR (revised MDRD) was calculated at baseline, during treatment and during washout.

Results: Baseline UACR was 173 (39–1725) mg/g (median and range) and mean ambulatory blood pressure (BP) was 142/75 mmHg (SD13/10), eGFR was 76 ml/min/1.73m². UACR was significantly reduced after 5–7 days of treatment by 29% (14–41) (95% CI) with further reduction to 44% (32–54) during the 28 day treatment period ($p=0.001$ vs. baseline). 24-hour mean systolic BP was significantly lowered by 6 mmHg after 7 days ($p=0.037$ vs. baseline) with no further reduction after 28 days. BP returned towards baseline levels 7 days after cessation of treatment, whereas UACR was still 22 (2–37) % reduced after 4 weeks of withdrawal. There was no association between individual decline in UACR and BP at the end of the treatment period. No significant change in eGFR.

Conclusion: Renin inhibition with aliskiren 300 mg once daily reduces UACR and arterial blood pressure in patients with type 2 diabetes and micro- and macroalbuminuria. The study demonstrates a significant effect on both variables already after one week. In addition, a further reduction in UACR was seen after 4 weeks, which was in part sustained after 4 weeks of wash-out and was independent of the reduction in blood pressure. This suggests that the reduction in UACR by aliskiren is explained both by haemodynamic and non-haemodynamic factors.

Optimal dose of lisinopril for renoprotection in type 1 diabetic patients with diabetic nephropathy

K. J. Schjøedt¹, A. Astrup¹, F. Persson¹, L. Tarnow¹, P. Rossing¹, H.-H. Parving^{2,3};

¹Steno Diabetes Center, Gentofte,

²Department of Medical Endocrinology, Rigshospitalet, Copenhagen,

³Faculty of health science, University of Aarhus, Denmark.

Background and Aims: ACE inhibitors are first-line therapy for renoprotection in type 1 diabetic patients with diabetic nephropathy. The optimal dose for renoprotection of the ACE-inhibitor lisinopril has not been established. The purpose of this study was to evaluate the optimal renoprotective effect, as reflected by short-term changes in urinary albumin excretion rate (UAER), of ultrahigh doses of lisinopril in type 1 diabetic patients with diabetic nephropathy.

Materials and Methods: A total of 56 type 1 diabetic patients with diabetic nephropathy were included in this double-masked randomized crossover trial consisting of three treatment periods. At inclusion, ongoing antihypertensive treatment was discontinued and replaced with slow-release furosemide in individual but fixed doses [median (range)] 60 (0–360) mg daily, for the entire studyperiod. After this 2 months wash-out period (baseline), patients were treated in random order with lisinopril 20, 40, and 60 mg once daily, each dose for 2 months. UAER (three 24-hour urine collections), 24-hour ambulatory blood pressure (ABP) and estimated GFR (MDRD) were determined after the wash-out period and after each treatment period. GFR was measured as ⁵¹Cr-EDTA clearance at baseline.

Results: Forty-nine of 56 randomized patients completed the study. Two patients (who were on lisinopril 60 mg and 20 mg resp.) were excluded due to dizziness combined with an (reversible) increase in plasma creatinine (39% and 31% resp.). One patient on lisinopril 60 mg was excluded due to high blood pressure (180/90 mm Hg), unchanged plasma creatinine and potassium. Four patients with unchanged plasma creatinine and potassium withdrew consent due to mild dizziness (lisinopril 60 and 40 mg resp.), mild diarrhoea (40 mg) and restless legs (20 mg). Baseline values were: 24-hour UAER [geometric mean (95% CI)] 362 (240 to 545) mg/24 hours, ambulatory blood pressure [mean (SD)] 142(14)/74 (8) mm Hg, and GFR 81 (30) mL/min/1.73 m². All doses of lisinopril significantly reduced UAER, ambulatory blood pressure, and eGFR from baseline. Reductions in UAER from baseline were 63% (55% to 69%), 71% (66% to 76%), and 70% (64% to 75%) with increasing doses of lisinopril ($P < 0.001$). Compared to lisinopril 20 mg there was a significant further reduction in UAER with lisinopril 40 mg of 23% (8

to 35) and 60 mg 19% (3 to 31) $p < 0.05$. After adjustment for changes in 24-hour ABP, the difference in UAER between 20 and 40 mg was not significant ($P = 0.14$). There was no difference in UAER between lisinopril 40 and 60 mg. With increasing doses of lisinopril, systolic ABP was reduced from baseline by 10 (6 to 15), 13 (9 to 19), and 12 (8 to 17) mm Hg, and diastolic ABP by 6 (4 to 8), 8 (6 to 10), and 7 (5 to 10) mm Hg ($P < 0.05$ for diastolic ABP 20 vs. 40 mg, otherwise NS between doses). There was a positive correlation between changes in blood pressure and changes in UAER on lisinopril 20 mg compared to lisinopril 40 mg ($\Delta 24$ -h diastolic BP vs. Δ UAER 20–40 mg, $R = 0.54$, $P < 0.001$).

Conclusion: High dosing of lisinopril (40 mg once daily) is generally safe and offers additional renoprotection as reflected by short-term changes in UAER in comparison to the currently recommended dose of 20 mg. In contrast ultrahigh doses of lisinopril (60 mg once daily) does not provide further renoprotection as compared to lisinopril 40 mg once daily.

1120

Irbesartan reduces urinary albumin excretion in hypertensive- and non-hypertensive Chinese patients with type 2 diabetes

S. Shang¹, C. Pan²;

¹Sanofi-Aventis China, Shanghai,

²Endocrinology, Military General Hospital, Beijing, China.

Background and Aims: Albuminuria is an early sign of damage to both the kidney and the heart. As data from China (MAPS study) shows a high prevalence of MAU and albuminuria (around 40% and 17% respectively), preventing or delaying the progression of diabetic nephropathy is therefore an essential management goal. Two large studies (IRbesartan MicroAlbuminuria type 2 diabetes mellitus in hypertensive patients [IRMA 2] and the Irbesartan Diabetic Nephropathy Trial [IDNT]) showed irbesartan exerting a renoprotective effect (slowing the progression of renal disease) in hypertensive patients with type 2 diabetes at both, early and later stages of diabetic nephropathy. The current study was aiming to evaluate the efficacy and safety of irbesartan in Chinese hypertensive- and non-hypertensive patients with type 2 diabetes.

Materials and Methods: Three hundred thirty patients, aged 30–70 years with type 2 diabetes and albuminuria (UAER between 20 and 500 μ g/min), with ($n = 241$) or without ($n = 89$) hypertension, were randomly assigned to 300 mg/d irbesartan or placebo for 24 weeks. Adjunctive antihypertensive therapies (excluding ACE inhibitors and angiotensin II receptor antagonists) could be added in order to achieve appropriate blood pressure reduction. The primary end point was the change in urinary albumin excretion rate (UAER) from baseline to 24 weeks.

Results: In hypertensive type 2 diabetes patients, irbesartan significantly reduced albuminuria (mean change of UAER (log transformed) 0.14 versus 0.000 in placebo groups ($p < 0.05$). The reductions in SBP and DBP observed in the irbesartan group were greater than in the placebo group (7.0/4.1 mmHg for irbesartan, 1.5/1.9 mmHg for placebo, $p < 0.05$). In normotensive Type 2 diabetes patients, irbesartan also significantly reduce albuminuria (mean change of UAER (log transformed) 0.18 versus 0.000 in placebo groups, $p < 0.05$). Covariance analysis by ANCOVA showed significant UAER reduction independent of BP reduction. Overall adverse event-rate was similar between irbesartan (44.26%) and placebo group (51.69%). Drug related adverse events were also similar in both groups (placebo 9.64%; irbesartan 13.66%).

Conclusions: Irbesartan 300mg is effective in reducing urinary albumin excretion rate in Chinese hypertensive- or normotensive patients with type 2 diabetes. The observed effects on albuminuria occurred partially BP-independent. Irbesartan showed a comparable safety profile as placebo.

Prevalence of ACE inhibition escape phenomenon in patients with type 2 diabetes and diabetic nephropathy

N. Trubutsyna, L. Nikankina, G. Katsya, A. Ilin, M. Shamkalova, A. Deev, S. Kuharenko, A. Aleksandrov, N. Goncharov, M. Shestakova; Nephropathy, Endocrinology research center, Moscow, Russian Federation.

Background and Aims: We evaluated the prevalence of the ACE inhibition escape phenomenon during long-term ACE inhibitors (ACEI) treatment in patients with type 2 diabetes and diabetic nephropathy (DN).

Materials and Methods: A total of 62 patients (37 men, 25 women) with type 2 diabetes and DN who received ACEI were studied. Escape of ACE inhibition was defined as an increase in plasma angiotensin II (AII) more than 50,6 pg/ml. Upper limit of normal range was calculated (mean \pm 1SD) from values of control subjects, who involved age-matched normotensive subjects without diabetes. Dietary salt intake was controlled.

Results: Duration of ACEI treatment was 6.6 \pm 3.4 years. Plasma AII level in the control group was 34.5 \pm 16.1 pg/ml. Patients were divided into two groups according to their levels of AII: more than 50,6 pg/ml – escape group (EG), less than 50,6 pg/ml – non-escape group (NEG). ACE inhibition escape occurred in 24 patients (39%). There were no significant differences between the groups in age, duration of diabetes, albuminuria, lipid levels, 24-h blood pressure, duration of ACEI treatment, diabetes control, hypertension management, 24-h urinary sodium. Patients in EG had a significantly higher cardiac interventricular septum thickness ($p = 0.02$), more often had hypo- and akinetic segments of myocardium ($p = 0.03$). Also they showed lower 24-h urinary potassium excretion ($p = 0.03$), higher level of plasma endothelin, serum creatinin and glomerular filtration rate (not statistically significant). Plasma renin concentration was higher in the EG ($p = 0.004$). AII did not correlate with aldosterone levels in both groups.

Conclusion: A relatively large percentage of type 2 diabetics with DN is affected by ACE inhibition escape. It may explain the lack of reno- and cardioprotective effect of renin-angiotensin-aldosterone system blockade.

Glucose fluctuations and activation of oxidative stress in type 1 diabetes patients

I. M. E. Wentholt¹, W. Kulik², R. P. J. Michels¹, J. B. L. Hoekstra¹, J. H. DeVries¹;

¹Internal Medicine, Academic Medical Center, Amsterdam,

²Laboratory for Genetic Metabolic Diseases, Academic Medical Center, Amsterdam, The Netherlands.

Background and Aims: Hyperglycemia is a major risk factor for microvascular complications and accelerated atherosclerosis in diabetes. Hyperglycemia-induced oxidative stress is seen as a key pathophysiological factor in these processes. In contrast to HbA1c, short-term glucose fluctuations showed a strong correlation ($r = 0.86$) with oxidative stress in 21 type 2 diabetes patients (Monnier, JAMA 2006), and may have predictive value for development of diabetic complications. We evaluated the relation between glucose fluctuations and oxidative stress in type 1 diabetes patients.

Materials and Methods: Continuous glucose monitors (CGMS gold) were inserted subcutaneously in 25 patients with a mean (SD) HbA1c of 8.1 (0.9) % for a period of 48 hrs. During the measurement, patients collected two subsequent 24-h urine samples, while 24 age- and sex-matched healthy controls collected one 24-h urine for determination of 15(S)-8-iso-PGF₂ α using HPLC MS/MS. Mean Of the Daily Differences (MODD), Mean Amplitude of Glycemic Excursions (MAGE) and Continuous Overlapping Net Glycemic Action (CONGA) over 1 h were calculated as markers for inter-day, intra-day and rapid glucose variability, and correlation with 15(S)-8-iso-PGF₂ α excretion was sought.

Results: Median (IQR) urinary excretion of 15(S)-8-iso-PGF₂ α was significantly higher in the patients than in the healthy controls: 159 (137 – 216) pg/mg of creatinine versus 118 (101 – 146) pg/mg of creatinine ($P = 0.001$). Data on glucose variability were: median (IQR) MODD 3.7 (3.2 – 5.0) mmol/L, MAGE 7.6 (6.4 – 9.0) mmol/L, CONGA-1 2.3 (2.1 – 2.8) mmol/L. Univariate regression did not reveal an association for any marker of glucose variability with 15(S)-8-iso-PGF₂ α excretion, (maximum $r^2 = 0.01$, 0.08 and 0.07 for inter, intra-day and rapid glucose variability, respectively),

neither did analysis after correction for HbA1c, age, gender and smoking in a multivariate model. Spearman's rho correlation coefficients between 15(S)-8-*iso*-PGF2 α excretion and MODD, MAGE and CONGA-1 were -0.148, -0.399 and -0.207, respectively, all non-significant.

Conclusion: We report no relationship between inter-, intra-day and rapid glucose variability and urinary 15(S)-8-*iso*-PGF2 α , determined with a highly specific method of HPLC MS/MS. Our data confirm that patients with type 1 diabetes have higher levels of urinary 15(S)-8-*iso*-PGF2 α than age and sex matched healthy controls, suggesting the existence of an oxidative stress favouring factor, other than glucose variability. We did not see a relation between high glucose variability and elevated levels of oxidative stress in patients with type 1 diabetes.

1123

The therapeutic efficacy of prostglandin E1 in diabetic patients with nephropathy

L. Liao¹, J. Dong², S. C. Liew³, K. O. Lee⁴, J. Zhao¹;

¹Endocrinology, Shandong Provincial Hospital, Jinan, China,

²Endocrinology, Qilu Hospital, Jinan, China, ³Endocrinology, The National University Hospital, Singapore, ⁴Endocrinology, The National University Hospital, Singapore.

Background and Aims: To investigate the efficacy of prostglandin E1 (PGE1) in diabetic patients with diabetic nephropathy (DN).

Materials and Methods: 120 patients, 60 with microalbuminuria (30 to 300 mg/24 hrs) and 60 with clinical nephropathy (>300mg/24 hrs) were studied. The patients had a mean (SD) age of 58 \pm 10.6 yrs (Range:28–78 yrs), mean duration of diabetes of 10.5 \pm 5.0 yrs (Range:2–24 yrs) and all had acceptable BP<130/80mm Hg. The 60 patients with microalbuminuria were randomly assigned to two treatment groups, microalbuminuria – ACEI group, treated with ACEI (benazpril, Lotensin) 10mg qd for 12 months, and microalbuminuria – PGE1 group who were treated with benazpril 10mg qd for 12 months AND had intravenous lipo-prostaglandin E1 (alprostadil injection) daily for 15 days. Similarly, the 60 patients with clinical nephropathy were also randomly assigned to nephropathy- ACEI group and nephropathy – PGE1 group.

Results: Urine albuminuria was significantly decreased in all the patients at the end of the one year study period (P<0.01). The decrease in the PGE1 – treated groups was more significant compared with the benazpril alone groups (P<0.01). Urine albuminuria in some patients decreased to normal range (<30 mg/day) immediately after 15 days' PGE1 treatment. At the end of 12 mths, all the patients who had received PGE1 treatment had significantly less proteinuria compared to benazpril alone patients (Tab.1).

Conclusion: PGE1 is effective and rapid in decreasing albuminuria, and is significantly more effective than therapy of benazpril alone.

PS 113 Diabetic foot: skin and bone

1124

Patients with type 1 diabetes and recurrent Charcot osteoarthropathy have reduced bone mass in the calcaneum and osteopaenia of the femoral neck and need supplementation with vitamin D therapy

M. E. Edmonds¹, M. Buxton-Thomas², C. Moniz³, N. L. Petrova¹;

¹Diabetic Foot Clinic, ²Nuclear Medicine Department, ³Department of Clinical Biochemistry, King's College Hospital, London, United Kingdom.

Background and Aims: We have noted a group of young diabetic patients with type 1 diabetes who presented with Charcot osteoarthropathy and continued to have recurrent Charcot osteoarthropathy at different sites associated with fracture. The aim of this study was to perform a bone evaluation in this group of patients by measuring calcaneal bone mass, bone mineral density (BMD) of the femoral neck and lumbar spine and biochemical parameters of bone health.

Materials and Methods: There were 8 patients with type 1 diabetes (7 females and 1 male). Mean age was 40 \pm 7.7 years (mean \pm SD) and mean duration of diabetes was 25 \pm 5.5 years. After their initial presentation, 7 patients developed fractures in the contralateral foot leading to Charcot osteoarthropathy and 2 of these also developed fractures of the tibial condyle leading to Charcot knee. One further patient sustained a pelvic fracture. Bone mineral density was measured in the lumbar spine and femoral neck by using DEXA scan. Bone mineral mass of the calcaneum was assessed by quantitative ultrasound. Bone mineral mass and density were expressed as a T-score. Serum vitamin D, parathyroid hormone (PTH), calcium and creatinine were also measured. Estimated glomerular filtration rate (eGFR) was calculated.

Results: Although BMD was within normal range in the spine (T-score: –0.8 \pm 0.4 SD), there was osteopaenia in the femoral neck (T-score:-1.7 \pm 0.8 SD) and T-score in the calcaneum was –2.7 \pm 0.4 SD, which was very low. There was evidence of vitamin D insufficiency with a mean level of 14 \pm 6.8 ug/L (reference range: 10–42 ug/L). Corrected calcium level was 2.26 \pm 0.1 mMol/L at the lower limit of the reference range (2.20–2.60 mMol/L). Serum PTH was 56 \pm 38.6 ng/L and was at the upper limit of the reference range (13–75 ng/L). Serum creatinine was raised at 131 \pm 26.8 uMol/L (reference range: 45–120 uMol/L). Estimated GFR was 41 \pm 15 ml/min (moderate impairment of renal function <60 ml/min).

Conclusion: These patients with type 1 diabetes and recurrent Charcot osteoarthropathy had reduced calcaneal bone mass, osteopaenia of the femoral neck and normal BMD in the lumbar spine. They also had vitamin D insufficiency associated with a compensatory rise in PTH and moderate impairment of renal function. This indicates that bone health in patients with type 1 diabetes and recurrent Charcot osteoarthropathy should be investigated and optimised with vitamin D supplementation. Possible osteoporosis prevention therapies should also be considered.

1125

Biochemical markers of bone turnover in patients with type 2 diabetes and their correlations with HbA_{1c} levelsB. Ozkan¹, A. Ozkan², I. Capoglu^{1c}, Z. Umudum², Y. Sahin², H. Alp²;¹Pediatric Endocrinology and Metabolism, ²Clinical Biochemistry,³Endocrinology and Metabolism, Ataturk University Faculty of Medicine, Erzurum, Turkey.

Background and Aims: In this study, the probable effects of metabolic control on bone turnover markers in patients with type 2 diabetes mellitus (Type 2 DM) were prospectively carried out.

Materials and Methods: Thirty-five cases with type 2 DM aged between 37 and 66 years (18 female, 17 male) were included in this study. All cases were evaluated with particular respect to diabetic ages, current ages, follow-up periods, body mass indexes, treatment protocols, complications and bone turnover markers (bone specific alkaline phosphatase (B-ALP), osteocalcin (OC), urine deoxypyridinoline (DPyr), urine n-telopeptid (NTx) both at the beginning and end of the study (mean 4.9±1.2 months).

Results: Mean HbA_{1c} (%) concentration of the cases was 10.6±1.6 %, and this rate decreased to the level of 7.7±1.0 % nearly 5 months follow-up period ($p=0.000$). In parallel with decrease of HbA_{1c} level, the bone turnover markers also were reduced significantly at the same period. While mean concentration of urinary DPyr (nmolDPyr/mmolCr), which is one of the markers of bone resorption, was 28.6±11.6 in the beginning of the study, it decreased to the level of 17.9±7.1 at the end of the follow-up period ($p=0.000$). Similarly, mean urinary NTx (nmolBCE/mmolCr) concentration, that is also marker of bone resorption, showed significantly decrease from the level of 93±13.7 to 67.1±12.8 at the same period ($p=0.000$). On the other hand, the reduce of bone formation parameters was also found in parallel with HbA_{1c} level in posted time-interval. While mean serum B-ALP levels were 129.5 ±37.3 U/l in the beginning of the study, it was reduced to the level of 94.8±35.1U/l at the end of the study. Similarly, serum OC (ng/ml) concentration decreased from 94.6±16.8 ng/ml to 66.3± 17.3 ng/ml and significantly was correlated with the HbA_{1c} levels during study period.

Conclusion: We concluded that effective management of the metabolic disorder in cases with type 2 diabetes is the one of the most important contributors for improvement of the bone turnover.

1126

RANKL plays an important role as activator of osteoclastic bone resorption in acute Charcot osteoarthropathyN. L. Petrova¹, G. Mabilieu², M. E. Edmonds¹, A. Sabokbar²;¹Diabetic Foot Clinic, King's College Hospital, London,²Botnar Research Centre, Nuffield Department of Orthopaedic Surgery, University of Oxford, United Kingdom.

Background and Aims: Charcot osteoarthropathy is characterised by increased bone resorption, but the cellular mechanisms are not fully understood. It is possible that receptor activator of nuclear factor κ B ligand (RANKL), a recently described essential cytokine for the formation and activation of osteoclasts, may play an important role as an activator of osteoclastic bone resorption in acute Charcot osteoarthropathy.

The aim of this study was to investigate the involvement of RANKL in the pathogenesis of Charcot osteoarthropathy by determining and comparing the extent of osteoclast formation and their bone-resorbing activity in patients with Charcot osteoarthropathy and age/sex-matched controls.

Materials and Methods: We studied 8 male subjects, mean age of 59 ± 5 years (mean ± SD). These included 3 patients presenting with acute Charcot osteoarthropathy, and 5 control patients (3 with diabetes and 2 without diabetes). We used a technique to generate functional human osteoclasts *in vitro* from peripheral blood monocytes. It is known that in the presence of macrophage-colony stimulating factor (M-CSF), RANKL induces osteoclast formation from a subpopulation of monocyte cells, which are capable of differentiation into osteoclasts. Peripheral blood monocytes isolated from the EDTA-treated whole blood taken on the same day from all patient and control subjects, were cultured on dentine slices and glass coverslips in the presence of M-CSF and soluble RANKL. Osteoclasts were evident after 10–14 days on coverslips as multinucleated cells which stained positive for tartrate resistant acid phosphatase (TRAcP); one of the osteoclast-specific markers. The number of osteoclasts formed on glass coverslips was compared between

the patients with Charcot osteoarthropathy and controls. Functional evidence of osteoclastic resorption was determined on dentine slices after 21 days in culture and the extent of lacunar resorption was expressed as the percentage of eroded surface by the number of formed TRAcP-positive osteoclasts.

Results: Although the mean number of newly-formed osteoclasts *in vitro* in the presence of M-CSF and sRANKL in the patients with Charcot osteoarthropathy was similar with that of controls (31 ± 25.9 vs. 44 ± 41.2, $p=0.654$), the osteoclasts in the Charcot patients were more aggressive and demonstrated significant increased resorbing activity. The extent of lacunar resorption in the patients with Charcot osteoarthropathy and the percentage of eroded surface by osteoclasts was significantly greater compared with controls (11.52 ± 6.2% vs. 4.05 ± 1.3%; $p=0.036$).

Conclusion: Using this technique we were able to generate osteoclasts from circulating osteoclast precursors *in vitro*, by the addition of sRANKL in the presence of M-CSF in both Charcot patients and controls. Although the number of osteoclasts in the patients with Charcot osteoarthropathy was similar to that in the control subjects, the osteoclasts which were formed from the patients with Charcot osteoarthropathy were functionally more aggressive, exhibiting a significant increase in the extent of resorbing activity.

This is the first scientific evidence that RANKL plays an important role as an activator of osteoclastic bone resorption in acute Charcot osteoarthropathy. Supported by EFSD/AstraZeneca Clinical Travel Fellowship and Diabetes UK

Impaired reaction to hypoxia as a mechanism for development of diabetic foot ulcersS.-B. Catrina^{1,2}, I. Botusan^{1,2}, V. Sunkari¹, O. Savu^{1,3}, J. Grünler¹, K. Brismar¹;¹Molecular Medicine and Surgery, Karolinska Institute, Stockholm,²Endocrinology, University of Medicine and Pharmacy "CarolDavila", Bucharest, Romania, ³Diabetes, N.C. Paulescu Institute, Bucharest, Romania.

Background: Diabetic foot ulcers represent major therapeutic concern, where chronic hyperglycemia and hypoxia are suggested to play essential roles. Hypoxia-inducible factor 1 (HIF-1) is a transcription factor expressed in response to physiologically relevant levels of hypoxia by stabilization of its alpha subunit. It induces more than 70 genes, which adapt the cell to low oxygen tension. We have proposed that hyperglycemia induce a deficient reaction of the cells to hypoxia and this deficit is a central mechanism in the development of diabetic foot ulcers.

Material and Methods: The effects of hyperglycemia on HIF-1alpha stability and function were performed in primary dermal fibroblasts and primary dermal endothelial cells from humans and mice. Protein expression was evaluated by Western blot while function and translocation by transient transfection with GFP tagged constructs or by luciferase assay. Evaluation of the expression of target genes was done by quantitative RT-PCR. The animal experiments were based on a full thickness wound model in db/db mice. HIF 1 alpha was induced locally by chemical inhibition of its degradation or by adenoviral transfer and the healing process was followed by taking pictures, histology, immunohistochemistry, qRT-PCR.

Results: We have demonstrated that hyperglycemia is able to interfere with the hypoxia-dependent stabilization of HIF-1 α protein at the degradation level. High glucose levels decrease as well the transcription activation potency of HIF-1 α , as assessed by transient hypoxia-inducible reporter gene assays and RT-PCR of its target genes. The interference of hyperglycemia with hypoxia-dependent stabilization of HIF α protein levels was confirmed *in vivo* where only very low levels of HIF 1 α protein could be detected diabetic wounds, as compared to chronic venous ulcers. As a proof of concept we were able to show that induction of HIF-1 α by a chemical approach or by viral transfer in experimental wounds in db/db mice is able to normalize the healing rate.

Conclusion: In conclusion, we demonstrate that hyperglycemia, impairs hypoxia-dependent protection of HIF-1 α against proteosomal degradation and we were able to show that by correcting this defect the wound healing can be normalized in a well established diabetic wound model.

Autologous tissue repair cells in the treatment of critical limb ischaemia (CLI) induced chronic foot ulcer on diabetic foot patients without option of revascularisation: a new therapeutic approach?

S. Kirana¹, B. Stratmann¹, D. Lammers¹, T. Quast¹, P. Minartz¹, M. Negrean¹, A. Stirban¹, S. Petrule¹, M. H. Gastens², H. Körperich³, C. Götting², W. Prohaska², C. Prante², K. Kleesiek², D. Tschöpe¹;

¹Heart and Diabetes Center NRW, ²Institute for Laboratory and Transfusion Medicine, Heart and Diabetes Center NRW, ³Institute for Radiology, Nuclear Medicine and Molecular Imaging, Heart and Diabetes Center NRW, Bad Oeynhausen, Germany.

Background and Aims: Diabetic Foot Syndrome (DFS) appears as a concomitant illness of diabetes mellitus. Diabetes is one of the main causes of non-traumatic amputation in Germany due to severe peripheral arterial occlusive disease with chronic critical limb ischemia being the most abundant problems. Ulceration results as a failure of the microcirculation and occlusive disease of larger blood vessels exacerbating pre-existing microvascular abnormalities.

The aim of this study is to assess the improvement of blood perfusion induced by expanded bone marrow stem cells for wound healing.

Materials and Methods: Eleven DFS patients with CLI and without option of surgical or interventional revascularisation were recruited and randomized to either the transplant group or the control group. About 40 ml of bone marrow was harvested from the iliac crest, followed by preparation and culture of mononuclear cells. Application sites of the enriched mesenchymal bone marrow cells (BM) or expanded autologous stem cells – tissue repair cells (TRC) are intramuscular (i.m.) into the M. gastrocnemius or intraarterial (i.a.) into the A. femoralis communis. Three patients were excluded (due to hypoplastic bone marrow, withdrawal of patient's consent and amputation of affected lower limb).

Results:

Pt No.	Group	Before		20 wks		52 wks		Complete wound healing (wks)
		LD	BOLD	LD	BOLD	LD	BOLD

8	BM i.m	2.82	4.3	1.30	1.6	***	***	48

LD: Laser Doppler; BOLD: Blood Oxygen Level Dependency, measurement using magnetic resonance tomography technique; * Pat refused the diagnostic; ** Analysis will be performed in June 2007; *** Analysis will be performed in April 2007; 1) No wound healing because of osteomyelitis

Independent from application methods, all patients treated with BM or TRC show tendential improvements of microcirculation (reactive hyperemia) of the affected foot as well as complete primary wound healing. No serious adverse event related to the treatment was noted. No calcification of soft tissue has been observed.

Conclusions: The transplantation of expanded autologous bone marrow stem cells as well as mesenchymal bone marrow cells in diabetic patients with critical limb ischemia induced chronic tissue ulcers proved to be safe and shows tendential improvement of microcirculation and complete wound healing.

Non-viral EGF (Epidermal Growth Factor) gene therapy accelerated cutaneous wound healing in streptozotocin diabetic C57BL/6J mice

J. Park¹, H. Chung¹, C. Yoon¹, M. Kwon¹, S. Lee¹, M. Kim²;

¹Division of Endocrinology and Metabolism, Department of Internal Medicine, Paik Memorial Institute for Clinical Research, Pusan Paik Hospital, Inje University, Busan, ²Division of Endocrinology and Metabolism, Department of Internal Medicine, Maryknoll General Hospital, Busan, Republic of Korea.

Background and Aims: EGF (Epidermal Growth Factor) is one the important growth factors involved in the healing of wounds. Topical peptide EGF has been used for the treatment of diabetic foot ulcer in several countries, but its high cost and the inconvenience of daily application due to its short half life have limited its wide spread clinical usage. EGF gene therapy might have potential to overcome these limitations. Continuous production of EGF at the transfected tissue at the margin just beneath the cutaneous wound might bypass the hostile degradation of EGF by over expressed proteinases at the wound bed, and the long term gene expression could enable so-called "one dose for cure". In addition the direct and indirect cross talking among various growth factors involved in wound healing might facilitate the sound healing.

Materials and Methods: We cloned novel mini-circle plasmid DNA containing one of the isoform of human EGF EGF⁸²⁸ driven by the chicken β -actin promoter with furin recognition sequence to enhance the release from the Golgi apparatus. The biologic competence of this novel plasmid was verified using cultured HEK293 and A549 cells via the increased phosphorylation of PI3K and GSK3 β . Ultrasound micro-bubble destruction method with SonoVue(SF₆) as a bubbling agent was used for non-viral gene delivery. Streptozotocin was injected intraperitoneally to induce diabetes mellitus into total 20 C57BL/6J mice, and the another 20 mice were served as control group. Expressed EGF tissue concentrations were measured via ELISA and semi-quantitative RT-PCR. VEGF, KGF and TGF- β expressions were also traced via Western blot, ELISA and RT-PCR. The degrees of neoangiogenesis were assessed by qualitative laser Doppler flowmetry (Periscan, PIM).

Results: Wound healing in diabetic animals was markedly enhanced after EGF gene therapy. The level of EGF and the degree of EGF mRNA expression were markedly increased in the gene therapy group. The level of EGF gradually decreased 10 days after gene injection. VEGF, KGF and TGF- β concentrations were also changed after EGF gene therapy. The histologic analysis revealed that the healing process was characterized by increased neovascularization and epithelization at the wound. No side effects were noticed during this experiment.

Conclusion: In conclusion, non-viral EGF gene therapy could accelerate cutaneous wound healing in streptozotocin diabetic mice without any significant side effects. This strategy could be used in actual human trial not only due to its superior efficacy but also appreciable safety.

Different expression of Connexin 43 during wound healing in an ex-vivo skin organ culture model transplanted with diabetic and non-diabetic keratinocytes

R. Lobmann¹, S. Zacheja¹, P. Houdeck², J. Brandner²;

¹Endocrinology and Metabolism, University of Magdeburg,

²Dept. of Dermatology, University Hamburg-Eppendorf, Germany.

Background and Aims: Wound healing is known to require a well organized balance of numerous cytokines, growthfactors, as well as proteases (MMP's) and their inhibitors (TIMP's). Moreover, direct cell-cell communication via gap junctions plays an important role in the dynamics of keratinocytes during reepithelialization. Disruption of these biological processes may lead to the formation of chronic wounds, such as diabetic foot ulcers.

Materials and Methods: To assess the differences in mRNA expression of connexin (Cx) 43, an important gap junctional protein of the epidermis, during wound healing of diabetic and non-diabetic patients, an 8 mm punch biopsy was taken from 14 diabetic and 11 non-diabetic intact lateral thighs. Keratinocytes were cultured and transplanted into a skin organ culture model. mRNA-expression of Cx43 was analyzed after 0 hrs, 7 hrs and 18 hrs/24 hrs of wound healing by using quantitative real-time PCR (TaqMan).

Results: We demonstrate significant different dynamics of Cx expression during the wound healing process whereas in our previous studies no statistical relevant differences of mRNA-expression of MMP's, TIMP's, and cytokines (TNF α , IL-1 β) were shown between diabetic and non-diabetic patients at the various points of time. RT-PCR indicated a delayed decrease of Cx43 ($p=0.001$) during wound healing of diabetic keratinocytes in contrast to non-diabetics who showed an early loss of Cx43 ($p=0.009$) after 7 hours.

Conclusion: Our results suggest the importance of a well-regulated balance of Cx such as an early downregulation of Cx43 to initiate the migration of keratinocytes. A delayed decrease of Cx43 may lead to chronification of diabetic wounds.

Assessment of the activity of Pédimed® cream on bacterial flora and skin hydration in diabetic feet

C. Roques¹, S. Trentin¹, C. Panizzutti¹, C. Saint Martory², C. Dupont³, E. Garrigue³, A. Degouy²;

¹Microbiology and Virology, Fonderephar, Toulouse, ²European Research Center on the Skin, Pierre Fabre Research Institute, Toulouse,

³Pierre Fabre Santé, Pierre Fabre Laboratories, Castres, France.

Background and Aims: Diabetes is a common disease which generates various complications. Among these, feet lesions which may become serious if left untreated and therefore call for amputation. The objective of this study was to assess the activity of Pédimed® cream on bacterial flora and skin hydration in diabetic feet.

Materials and Methods: Randomized open label comparative monocentric study among 30 diabetic patients (20 women and 10 men, mean age : 60.4 \pm 10.7 years).

Treatment: Randomized application of Pédimed® cream (ruscus aculeatus, tocopheryl nicotinate, olamine piroctone, urea, lactamid, petrolatum jelly and glycerin) to one foot twice daily over a 3 weeks period.

Protocol : Comparative evaluation between treated side (TS) and non-treated side (NTS) at D0 and D21 of the activity on bacterial flora by microbiological testing as well as the hydrating effect by cutaneous clinical score, hydration index (corneometry) and squame samples analysis (D-Squame test).

Results: At D0, there was no significant difference between the 2 application sites as regards the bacterial flora and skin hydration.

At D21, a significant reduction in total aerobic (-1.75 log ; $p < 0.001$) and anaerobic flora (-1.60 log ; $p < 0.001$) was observed for TS, with no significant evolution for NTS. Inter-group analysis revealed significant differences between TS and NTS, in favor of TS.

The clinical hydration score was significantly improved for TS (-52.8 % ; $p < 0.001$) whereas it decreased for NTS ($+10.5$ % ; $p = 0.03$), confirming the significant inter-group difference ($p < 0.001$). The hydration index was significantly increased for TS ($+66.0$ % ; $p < 0.001$) and NTS ($+21.6$ % ; $p = 0.003$), with a more significantly marked improvement for TS ($p < 0.001$). Finally, desquamation was significantly reduced for TS ($p < 0.001$), with no significant disease progression for NTS, and a significant inter-group difference ($p < 0.002$).

Conclusion: During the study period, Pédimed® cream demonstrated an antimicrobial activity, expressed by a reduction in the bacterial flora, as well as a clinical improvement in skin dryness, an emollient effect and a regulation or reduction of desquamation.

PS 114 Complications: new markers and inflammation

Effect of natriuretic peptide clearance receptor exon 8 A/G polymorphism on urinary albumin excretion and blood pressure responses to dietary salt reduction

S. Hadjadj;

Endocrinology-Diabetology, Poitiers University Hospital, France.

Introduction: There is a familial clustering for the renal complications associated with type 2 diabetes. The natriuretic peptide clearance receptor (NPCR) was shown to be a risk factor for diabetic nephropathy in longitudinal epidemiological studies. The functional rule and clinical relevance of this polymorphism are currently unknown.

Setting: Secondary tertiary diabetic clinic.

Objective of the Study: to analyse the response on urinary albumin expression (UAE) and blood pressure (BP) to the reduction in sodium intake, in type 2 diabetic micro macro albuminuric patients.

Patients and Methods: Type 2 diabetic men with micro macro albuminuria and diuretic treatment were matched for age, RAS blocking medication (ACE inhibitor or ARB) and NPCR polymorphism. They were studied twice in usual dietary sodium intake and after 50% reduction of sodium intake. The dietary salt reduction lasted 10 days. In the 3 consecutive days preceding the clinical visit, patients collected urines for 24-hour determination of sodium, creatinine and albumin.

Results: 8 AA versus 7 non AA patients were studied. Their clinical characteristics did not differ at baseline (table 1). The dietary sodium reduction was similar in the two groups and resulted in a significant decrease in UAE ($p=0.009$) and systolic BP ($p=0.0063$). However, only those patients with the AA genotype yielded a significant response to dietary salt reduction on UAE ($p=0.0117$) and SBP ($p=0.0057$).

	AA patients (n=8)	non-AA patients (n=7)	p
Baseline data			
Âge (years)	61 +/- 10	66 +/- 6	0.2363
SBP (mmHg)	143 +/- 14	137 +/- 7	0.3982
DBP (mmHg)	79 +/- 6	73 +/- 6	0.0807
estimated GFR (ml/min)	88 +/- 36	72 +/- 24	0.3596
Weight (kg)	89.2 +/- 11.5	89.7 +/- 15.7	0.9456
Natriuresis (mmol/24h)	231 +/- 69	231 +/- 104	0.9994
UAE (mg/24h)	231 (134–526)	282 (60–465)	0.7285
Change between the 2 visits			
Natriuresis Reduction (mmol/24 h)	107 +/- 62	111 +/- 69	0.9105
SBP Reduction (mmHg)	18 +/- 13	3 +/- 9	0.0262
UAE Reduction (mg/24 h)	93 (48; 250)	20 (45; -8)	0.0372

Conclusion: The short-term response to dietary sodium reduction is related to the NPCR exon 8 A/G polymorphism. This could lead to potential modification of therapeutic strategies.

The endothelial thrombomodulin – protein C system modulates diabetic nephropathy: protective effect of the prothrombotic factor V Leiden mutation

B. Isermann, I. Vinnikov, B. Hummel, T. Madhusudhan, M. Kashif, S. Herzog, A. Bierhaus, P. P. Nawroth;

Department of Internal Medicine I and Clinical Chemistry, University of Heidelberg, Germany.

Background and Aims: Activation of the coagulation system in diabetes mellitus has been established. Recently we have been able to show that the

endothelial thrombomodulin (TM) protein C (PC) system, which mediates antiinflammatory and antiapoptotic effects in addition to anticoagulation, protects against diabetic nephropathy in mice. These data established a crucial role of endothelial dysfunction and associated loss of the TM-PC system for diabetic nephropathy (manuscript in revision). The factor V Leiden (FVL) mutation, the most frequent prothrombotic risk factor in Caucasians, disrupts the anticoagulant function of the TM-PC system at the substrate level, while other, receptor dependent effects of the TM-PC system (such as inhibition of inflammation and apoptosis) remain functional. We have previously shown that the FVL mutation is associated with increased levels of activated PC and improved survival in severe inflammation in mice and men (Kerlin, Blood, 2003). Since diabetes is associated with inflammation we addressed experimentally the question whether the FVL mutation (1) results in higher levels of PC activation in diabetic mice *in vivo* and (2) protects against diabetic nephropathy.

Materials and Methods: Persistent hyperglycemia was induced using streptozotocin in wild-type (WT), heterozygous (FVL^{wt/q}) and homozygous (FVL^{q/q}) FVL mice. Blood coagulation (TAT, D-Dimer), inflammation (IL-1b, IL-6), apoptosis (TUNEL, p53, Bax, Bcl-2) and nephropathy (albuminuria, histology) were analyzed after 6 months of persistent hyperglycemia.

Results: In diabetic WT mice markers of diabetic nephropathy, including albuminuria, kidney weight, glomerular size, and extracellular matrix deposition (PAS-staining), were significantly increased in comparison to non-diabetic WT mice. Conversely, diabetic FVL^{q/q} mice were partial and FVL^{wt/q} mice were significantly protected against diabetic nephropathy. The protection against diabetic nephropathy in FVL-positive (FVL^{wt/q} or FVL^{q/q}) mice was associated with a normalized Bax/Bcl-2 ratio. Hyperglycemia induced a significant pro-coagulant response (TAT, D-Dimer) in diabetic FVL-positive mice. The increased thrombin generation was associated with an enhanced PC-activation in diabetic FVL positive mice. These data imply that increased thrombin generation in diabetic FVL-mice results in increased activation of PC. Together with our previous data showing that activated PC protects against diabetic nephropathy through inhibition of glomerular apoptosis these data show that the FVL mutation inhibits apoptosis and diabetic nephropathy through modulation of activated PC dependent signalling via PARs (protease activated receptor).

Conclusion: These results establish that the coagulation system modulates diabetic complications. The cytoprotective effects of the endothelial TM-PC system protect against diabetic nephropathy *in vivo*. These results show that endothelial dysfunction crucially modulates diabetic nephropathy. Further experiments extending these *in vivo* findings to humans have been initiated. Supported by DFG IS 67/2-2

Proton NMR metabonomics of type 1 diabetes reveals multivariate biochemical characteristics of diabetic complications

V.-P. Mäkinen^{1,2}, P. Soininen³, C. Forsblom^{1,4}, M. Parkkonen^{1,4}, P. Ingman⁵, K. Kaski², M. Ala-Korpela², P.-H. Groop^{1,4};

¹Folkhälsan Research Center, Folkhälsan Institute of Genetics, Helsinki, Finland, ²Laboratory of Computational Engineering, Helsinki University of Technology, Espoo, Finland, ³Department of Chemistry, University of Kuopio, Kuopio, Finland, ⁴Division of Nephrology, Helsinki University Central Hospital, Helsinki, Finland, ⁵Department of Chemistry, University of Turku, Helsinki, Finland.

Background and Aims: Macrovascular disease in connection to diabetic nephropathy accounts for most of the premature deaths in type 1 diabetic patients. Metabolic syndrome is common in the subset that develop these serious complications, which suggests that the risk factors are similar to those in the general population. The definitions of risk criteria, however, may not be well suited for type 1 diabetes nor be accurate enough to detect subtle metabolic changes. For this reason, we have measured proton nuclear magnetic resonance (NMR) spectra of serum for a subset of type 1 diabetic patients from the Finnish Diabetic Nephropathy (FinnDiane) study. Our goal is to determine the multi-variate metabolic characteristics of type 1 diabetes that will serve as the baseline for the prospective phase of FinnDiane, and to evaluate the role of proton NMR as an analytical tool in this effort.

Materials and Methods: Proton NMR spectra of serum for 613 type 1 diabetic patients was measured on a Bruker AVANCE 500Mhz spectrometer. Age- and sex-matched patients were selected from the FinnDiane cohort based on nephropathy status. Proton NMR data was obtained from two molecular windows: a standard spectrum with wide lipoprotein lipid and albumin signals and a T2-filtered spectrum that better reveals the smaller metabolites with lower molecular weights. A double-tube system for reference substance was used to enable absolute quantification of metabolites. The complex spectral data was analysed by constructing a self-organising map, an unsupervised neural network analysis method.

Results: The self-organising map of the spectra identified multi-variate spectral profiles that are linked to clinical criteria such as nephropathy, retinopathy, metabolic syndrome and macrovascular complications. It also revealed specific connections between the diagnoses (e.g. nephropathy) and the corresponding serum biochemistry. The observations were validated by non-spectroscopic data from the FinnDiane database and interpreted with the help of statistical map colourings (figure).

Conclusion: A single proton NMR analysis of serum for type 1 diabetic patients gave enough information for a multi-metabolite characterisation of diabetic complications that is likely to be of great value in the sub-clinical screening of metabolically vulnerable patients. (Fig. 1)

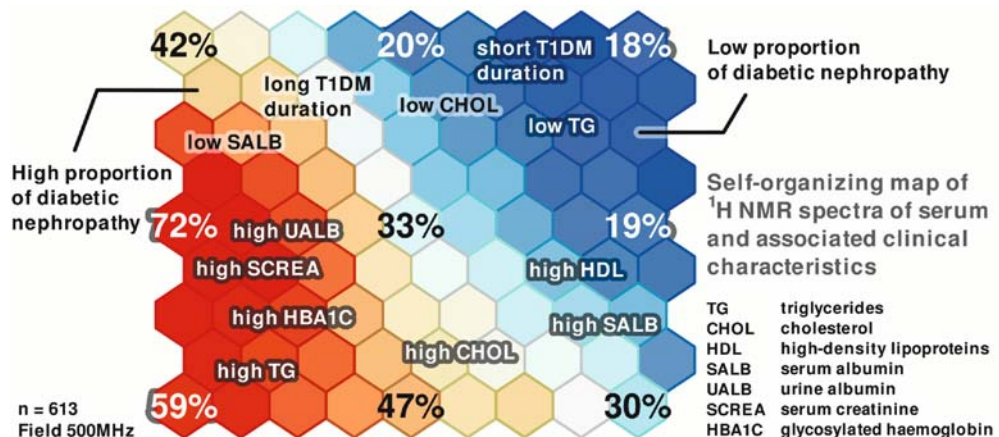

Fig. 1

New protein biomarkers for diabetic nephropathy

J. McGuire, M. Lajer, L. Tarnow, P. Rossing, F. Pociot; Steno Diabetes Center, Gentofte, Denmark.

Background and Aims: If early signs of diabetic nephropathy are identified and treatment is initiated early and aggressively it is possible to prevent or at least postpone its development. We applied proteomics to discover new and better protein biomarkers from serum for several aspects of diabetic nephropathy using a significant cohort of type 1 diabetes (T1D) patient samples.

Materials and Methods: The sample cohort contained 168 patient samples split into four groups (normal, micro- and macroalbuminuria plus non-diabetic controls; $n = 42$ each) and was used for discovery of serum-based protein biomarkers for the early detection of diabetic nephropathy. Some of the patients were on anti-hypertensive medication at the time of sampling and are expected to be a representative diabetic sample set. Aliquots (50 μ L) of serum were processed using parallel, filter plate-based anion exchange fractionation. Four of the six fractions were analyzed in a top-down proteomics approach on CM10, H50 and IMAC30 arrays in a SELDI-TOF-MS system. Reference human serum samples were run alongside the patient samples to ascertain intra-assay reproducibility. All steps were performed on a liquid handling robot. Univariate statistical methods were chosen for feature reduction: student's t-test for comparison of normo- and macroalbuminuria groups and ANOVA of a linear regression model of normo-, micro- and macroalbuminuria groups. Peaks showing highly significant P values (≤ 0.001) in either test were carried forward for further analysis. Peak quality was checked manually to ensure robustness.

Results: We have analysed a large set of diabetic nephropathy serum samples using a top-down proteomics approach based on SELDI-TOF-MS that produced about 7000 mass spectra. The study has to date identified approximately 200 protein peaks in the mass range 2 – 100 kDa with significant P values using an ANOVA test among three albuminuria groups (normo-, micro- and macroalbuminuria; $n = 42$ for each group) and among the proteins that are already identified, beta-2-microglobulin is significantly increased ($P = 0.002$) in the macroalbuminuria group (> 300 mg albumin/24 h) versus the normoalbuminuria group (< 30 mg albumin/24 h) and this is in agreement with what has previously been reported in the literature. Transferrin, an 80 kDa protein, is an important circulating source of iron in the body and was found to be significantly decreased ($P = 0.0002$) in the macroalbuminuria versus the micro- and normoalbuminuria groups. The identities of the other candidate biomarkers are still under investigation.

Conclusion: With the help of proteomics we have identified over 200 protein peaks that show highly significant differences between normo- and macroalbuminuria groups or ANOVA P values among the three diabetic groups (normo-, micro- and macroalbuminuria). Two of the proteins have already been identified as beta-2-microglobulin and transferrin. Further markers and a model for prediction of diabetic nephropathy using a panel of serum proteins will be presented.

Increased urinary excretion of proinflammatory cytokines is associated with renal structural changes in type 1 diabetic patients

V. V. Klimontov¹, I. A. Bondar¹, A. P. Nadeev²;

¹Department of Endocrinology, ²Department of Pathology, Novosibirsk State Medical University, Novosibirsk, Russian Federation.

Background and Aims: Inflammatory mechanisms are believed to be involved in the pathogenesis of diabetic nephropathy. Recent experimental studies have shown that cytokines synthesized by resident renal cells and migrating inflammatory cells, such as monocytes/macrophages, contribute to progression of glomerular and interstitial sclerosis in diabetes. The aim of our study was to assess the relation between urinary excretion of proinflammatory cytokines and diabetic nephropathy in type 1 diabetic patients.

Materials and Methods: 57 patients with type 1 diabetes were examined, including 22 normoalbuminuric (group DN0), 23 microalbuminuric (group DN1) and 12 macroalbuminuric ones (group DN2). Urinary excretion of interleukin-1beta (IL-1beta), monocyte chemoattractant protein-1 (MCP-1) and chemokine regulated upon activation, normal T-cell expressed and

secreted (RANTES) was determined by ELISA and compared to control (10 healthy subjects, group C). A kidney biopsy was performed in 8 normoalbuminuric and 10 microalbuminuric patients. Mesangial fractional volume [Vv(mes/glom)], the width of glomerular and tubular basement membrane (GBM and TBM) was estimated by morphometric analysis. The presence of CD-68-positive cells (macrophages) in glomeruli and interstitium was studied immunohistochemically.

Results: (median, percentile 25–75). IL-1beta excretion was increased significantly in patients with micro- and macroalbuminuria as compared to control (DN0: 0.38, 0.24–0.57, $p=0.23$; DN1: 0.64, 0.31–0.98, $p=0.02$; DN2: 1.37, 0.97–1.58, $p=0.00008$; C: 0.25, 0.19–0.48 pg/ μ mol creatinine). MCP-1 excretion exceeded control in all diabetic groups (DN0: 14.7, 5.9–21.6, $p=0.04$; DN1: 14, 5.2–37.9, $p=0.03$; DN2: 64.3, 42.4–109.3, $p=0.0006$; C: 5.1, 1.4–16.8 pg/ μ mol creatinine). RANTES excretion was increased significantly in patients with macroalbuminuria, but not in normo- and microalbuminuric patients (DN0: 0, 0–0.1, $p=0.84$; DN1: 0.02, 0–0.13, $p=0.21$; DN2: 0.32, 0.22–0.44, $p=0.0005$; C: 0, 0–0.06 pg/ μ mol creatinine). IL-1beta and MCP-1 correlated negatively with glomerular filtration rate ($r=-0.42$, $p=0.002$ and $r=-0.38$, $p=0.006$ respectively). In normoalbuminuric and microalbuminuric patients excretion of cytokines correlated with the width of GBM (IL-1beta: $r=0.69$, $p=0.002$; RANTES: $r=0.43$, $p=0.07$) and TBM (IL-1beta: $r=0.73$, $p=0.002$; MCP-1: $r=0.47$, $p=0.05$; RANTES: $r=0.53$, $p=0.04$). Correlations between cytokines and Vv(mes/glom) were weak and non-significant (all $p \geq 0.05$). CD-68-positive macrophages were revealed in the renal interstitium (but not in glomeruli) in one normoalbuminuric patient and in six patients with microalbuminuria.

Conclusion: In type 1 diabetic patients increased urinary excretion of proinflammatory cytokines (IL-1beta, MCP-1 and RANTES) is associated with albuminuria, basement membrane width and macrophage appearance in the renal interstitium. This supports the hypothesis that inflammation is involved in pathogenesis of diabetic nephropathy.

1137

Inflammatory markers predict all cause mortality in type 1 diabetic patients with diabetic nephropathy in a 10-year follow-up study

A. S. Astrup¹, L. Tarnow¹, L. Pietraszek¹, C. G. Schalkwijk²,

C. D. A. Stehouwer², P. Rossing¹, H.-H. Parving^{3,4};

¹Steno Diabetes Center, Gentofte, Denmark, ²Dept of Internal Medicine, Academic Hospital Maastricht, The Netherlands, ³Dept of Medical Endocrinology, Rigshospitalet, Copenhagen, Denmark, ⁴Faculty of Health, Aarhus University, Denmark.

Background and Aims: To evaluate the significance of cardiovascular biomarkers on mortality in type 1 diabetic patients with and without diabetic nephropathy.

Material and Methods: We prospectively followed 199 type 1 diabetic patients with diabetic nephropathy and 192 patients with persistent normoalbuminuria for 10 years. Biomarkers were measured at baseline in 1993. The endpoint was all-cause mortality. In order to combine the biomarkers we constructed two combined z-scores, one for inflammation and one for endothelial dysfunction. The inflammatory Z-score combined C-reactive protein (hsCRP), interleukin-6 (IL-6), soluble intercellular adhesion molecule-1s-(sICAM-1), and secreted phospholipase A(2) (sPLA2). The Z-score for endothelial dysfunction combined vascular cell adhesion molecule 1 (sVCAM-1), plasminogen activator inhibitor-1 (PAI-1), and sICAM-1, since sICAM-1 is both an inflammatory marker and a marker of endothelial dysfunction. For each individual, the values of each marker were expressed as a Z-score: (value in the individual minus the mean value in the study population) / standard deviation; a value that thus ranged from approximately -2.5 to +2.5. Thus the inflammatory Z-score was calculated as (Z-score of hsCRP + Z-score of IL-6 + Z-score of sICAM-1 + Z-score of sPLA2)/4 and the Z-score for endothelial dysfunction (Z-score of PAI-1 + Z-score of sVCAM-1 + Z-score of sICAM-1)/3.

Results: During follow-up 60 patients (30%) with nephropathy died versus 16 (8%) of normoalbuminuric patients, log rank test $p < 0.0001$. In unadjusted Cox regression analysis the Z-score for inflammation was significantly predictive of death in patients with diabetic nephropathy (Hazard Ratio (HR) 1.9 (95% CI 1.3–2.8; $p=0.001$) but not in patients with persistent normoalbuminuria HR 0.5 (0.2–1.2; $p=0.11$). After adjusting for traditional cardiovascular risk factors (age, sex, systolic blood pressure, smoking, cholesterol, HbA1c, urinary albumin excretion, heart rate variation) the Z-score was still significantly

predictive of death in patients with diabetic nephropathy: HR 1.7(1.1–2.6; $p=0.025$). In unadjusted analysis endothelial dysfunction was associated with death in patients with diabetic nephropathy, HR 1.6 (1.0–2.3; $p=0.031$) but not in patients with persistent normoalbuminuria; HR 0.9 (0.4–2.3; $p=0.9$). After adjusting for traditional risk factors the association was no longer significant in patients with diabetic nephropathy; HR 1.2 (0.8–1.8; $p=0.4$).

Conclusions: Our 10-year follow-up study in type 1 diabetic patients with and without diabetic nephropathy indicates inflammatory biomarkers are significantly predictive of all-cause mortality in patients with diabetic nephropathy.

1138

Plasma concentration of asymmetrical dimethylarginine (ADMA) predicts cardiovascular morbidity and mortality in type 1 diabetic patients with diabetic nephropathy

M. Lajer¹, L. Tarnow¹, A. Jorsal¹, T. Teerlink², H.-H. Parving^{3,4}, P. Rossing¹; ¹Steno Diabetes Center, Gentofte, Denmark, ²VU, University Medical Center, Amsterdam, The Netherlands, ³Department of Medical Endocrinology, Rigshospitalet, University Hospital of Copenhagen, Denmark, ⁴Faculty of Health Science, University of Aarhus, Denmark.

Background and Aims: Asymmetrical dimethylarginine (ADMA) is an endogenous nitric oxide synthase inhibitor elevated in conditions associated with endothelial dysfunction and atherosclerosis as well as in patients with diabetic nephropathy. ADMA levels have been shown to be predictive of cardiovascular events (CVD) and total mortality in non-diabetic kidney disease, and of coronary artery disease.

Therefore, the aim of this study was to investigate whether circulating ADMA levels are predictive of cardiovascular events, decline in glomerular filtration rate (dGFR), end-stage renal disease (ESRD), and all-cause mortality in type 1 diabetic patients.

Materials and Methods: This study was a prospective observational follow-up study; including 397 type 1 diabetic patients with overt diabetic nephropathy (247 men; age 42.1 ± 10.5 years (mean \pm SD); duration of diabetes 28.3 ± 8.8 years; GFR 76 ± 33.5 ml/min/1.73 m²) and a control group of 175 patients with longstanding type 1 diabetes and persistent normoalbuminuria (106 men; age 42.6 ± 9.7 years; duration of diabetes 27.6 ± 8.2 years. Patients were followed for 11.0 (0.0–12.9) years (median (range)) with yearly measurements of GFR (51Cr-EDTA plasma clearance)

Results: Among patients with diabetic nephropathy, plasma ADMA levels above the median predicted fatal and non-fatal CVD ($p < 0.001$) during follow-up, persisting after adjusting for conventional CVD covariates including baseline GFR (adjusted hazard ratio (HR) of 2.05 (1.31–3.20), $p = 0.002$). Furthermore, elevated ADMA levels predicted increased rate of decline in GFR, development of ESRD, and overall mortality ($p < 0.001$, $p = 0.004$, and $p < 0.001$, respectively). However, only dGFR and ESRD tended to be significant after adjustment for well known progression promoters including baseline GFR (adjusted HR of -0.1 (-1.70; 0.10); $p = 0.082$ and adjusted HR of 1.77 (0.95–3.33); $p = 0.075$ for dGFR and ESRD, respectively).

Among the 175 patients with persisting normoalbuminuria 6 patients with ADMA levels below the median for this group of patients compared to 14 (16%) patients with the highest ADMA levels died during the follow-up period ($p = 0.050$) and an unadjusted hazard ratio of 2.52 (0.97–6.56), ($p = 0.058$). ADMA levels were not associated with fatal or non-fatal CVD in this low risk population (NS).

Conclusion: Plasma ADMA levels predicts fatal and non-fatal cardiovascular events in patients with type 1 diabetic nephropathy. Furthermore, increased ADMA levels tended to be predictive of increased risk of progressive diabetic kidney disease. In patients with persisting normoalbuminuria elevated ADMA levels predicted an increased overall mortality rate.

1139

Asymmetric dimethylarginine (ADMA) and microvascular complications in type 2 diabetes patients: the Hoorn Study

A. M. van Sijl^{1,2}, A. M. W. Spijkerman¹, J. M. Dekker¹, C. D. A. Stehouwer³, R. J. Heine^{1,4}, T. Teerlink⁵;

¹EMGO-Institute, VU University Medical Center, Amsterdam, ²Department of General Practice, VU University Medical Center, Amsterdam, ³Department of Internal Medicine, Academic Hospital Maastricht, Maastricht, ⁴Department of Endocrinology/Diabetes Center, VU University Medical Center, Amsterdam, ⁵Department of Clinical Chemistry, VU University Medical Center, Amsterdam, The Netherlands.

Background and Aims: High levels of asymmetric dimethylarginine (ADMA), an endogenous inhibitor of nitric oxide synthase, have been recognized as an important marker of cardiovascular disease and diabetes. Inhibition of nitric oxide synthase results in less nitric oxide production, precipitating vasoconstriction and oxidative stress, which may induce microvascular complications in diabetes. The aim of the present study was to investigate the associations of ADMA and ADMA-to-arginine ratio with microvascular complications.

Materials and Methods: The population consisted of 544 elderly participants with and without type 2 diabetes. ADMA and arginine were determined with high performance liquid chromatography. Peripheral neuropathy was assessed with the vibration perception threshold and with the temperature discrimination threshold. Microalbuminuria was measured by the albumin-to-creatinine ratio and retinopathy with ophthalmoscopy and fundus photography. Linear and logistic regression analyses were performed.

Results: ADMA and ADMA-to-arginine ratio were not statistically significantly associated with microalbuminuria and retinopathy. High levels of ADMA (3rd tertile) were statistically significantly associated with high temperature discrimination threshold in patients with diabetes, regression coefficient (95% confidence interval): RC (CI), 0.52 (0.003 to 1.03). A moderate ADMA-to-arginine ratio (2nd tertile) was statistically significantly associated with low vibratory perception threshold in participants with diabetes: RC (CI), -10.51 (-21.01 to -0.01).

Conclusion: Overall, there was no consistent evidence that ADMA or ADMA-to-arginine ratio were associated with microvascular complications. In patients with diabetes, high levels of ADMA were significantly associated with high temperature discrimination threshold. These equivocal results warrant prospective studies to investigate the associations of ADMA with microvascular complications.

1140

Plasma asymmetric dimethylarginine (ADMA) is associated with retinopathy in type 2 diabetes mellitus

M. T. Malecki¹, A. Undas², K. Cyganeck¹, B. Mirkiewicz-Sieradzka¹, P. Wolkow³, G. Osmenda³, M. Walus-Miarka¹, T. J. Guzik³, J. Sieradzki¹; ¹Department of Metabolic Diseases, ²Institute of Cardiology, ³Department of Pharmacology, Jagiellonian University, Medical College, Krakow, Poland.

Background and Aims: Asymmetric dimethylarginine (ADMA), an endogenous inhibitor of nitric oxide synthase, has been reported to be associated with coronary artery disease, hypertension in non-diabetic populations and also nephropathy in type 1 diabetes mellitus. It is not known whether there is any association of ADMA with diabetic retinopathy (DR). The objective of the study was to evaluate the relationship between plasma ADMA and the occurrence of DR in type 2 diabetes mellitus (T2DM).

Materials and Methods: We studied 111 T2DM patients without DR (NDR) and 71 T2DM subjects with DR (mean age 55.7 ± 6.2 and 57.1 ± 7.0 years, respectively). The control group consisted of 52 apparently healthy individuals matched for age and gender. Plasma ADMA, SDMA, and arginine levels were measured by high-performance liquid chromatography. The diagnosis of DR was based on ophthalmic examination. Potentially important clinical covariables were also measured. Determinants of DR were identified via stepwise multivariable logistic regression analysis.

Results: The ADMA level was highest in T2DM patients with DR (0.60 ± 0.06 $\mu\text{mol/L}$), intermediate in the subjects with T2DM and NDR (0.51 ± 0.06 $\mu\text{mol/L}$), and lowest among controls (0.45 ± 0.05 $\mu\text{mol/L}$) ($p < 0.001$ for all intergroup comparisons). In stepwise multivariable logistic regression, plasma ADMA levels remained an independent predictor of the presence of DR ($p < 0.0001$,

OR = 1.65, 95%CI: 1.39 – 1.97) in T2DM patients. DR was also independently associated with age at examination ($p < 0.0001$, OR = 0.79, 95%CI: 0.70 – 0.88) and duration of T2DM ($p = 0.032$, OR = 1.1, 95%CI: 1.008 – 1.2). DR was not associated with smoking status, creatinine levels, glycated hemoglobin or lipids in our study.

Conclusion: Our findings suggest that elevated ADMA level is an independent predictor of DR in T2DM.

PS 115 Neuropathy: symptoms and treatment

1141

Painful neuropathy is associated with greater autonomic dysfunction compared to painless neuropathy in diabetes mellitus

J. L. B. Marques, R. A. Gandhi, G. L. Ferrari, C. J. Emery, S. Tesfaye; Diabetes Research Unit, Royal Hallamshire Hospital, Sheffield, United Kingdom.

Background: Although a clear relationship between peripheral diabetic neuropathy (DPN) and cardiac autonomic neuropathy (CAN) is recognised, the relationship of CAN with sub-types of DPN is less clear.

Aims: The aim of this study was to investigate the relationship of CAN to painless and painful neuropathy.

Methods: Seventy-six subjects (20 healthy volunteers (HV), 20 no DPN, 18 painful DPN, 18 painless DPN) underwent detailed neurophysiological investigations and spectral analysis of short-term heart rate variability (HRV). HRV is a highly sensitive measure of autonomic function and was calculated according to the frequency-domain method (total power (TP), low frequency (LF) and high frequency (HF) for assessment of sympathovagal modulation of heart rate) and results logarithmically transformed to correct for skewness.

Results: There were no significant differences in subjects with no DPN compared to HV in HF (4.6 ± 1.6 (mean \pm SD) vs. 5.4 ± 0.9), LF (5.1 ± 1.5 vs. 5.5 ± 1.0) or TP (6.6 ± 1.2 vs. 7.1 ± 0.8), $p > 0.1$. Subjects with painless DPN had a reduction in all 3 measures (compared to HV); 3.8 ± 1.0 (HF), 4.2 ± 1.5 (LF), and 5.9 ± 1.1 (TP), $p < 0.05$. There was a further reduction in subjects with painful DPN; 2.4 ± 1.2 (HF), 3.0 ± 1.3 (LF), and 4.8 ± 1.1 (TP), $p < 0.05$. After correcting for age and drug therapy, there were no longer any significant differences between HV, and subjects with no DPN and painless DPN. The painful DPN group, however, continued to have significantly lower levels in all 3 parameters.

Conclusion: This study shows that subjects with painful DPN have significantly greater autonomic dysfunction than subjects with painless DPN. It suggests there are differing profiles of nerve fibre involvement in different types of diabetic neuropathy. The greater autonomic dysfunction seen in painful DPN may be reflecting more predominant small fibre involvement. The role that autonomic dysfunction may play in the pathogenesis of painful DPN also needs consideration.

1142

Upper abdominal symptoms in patients with type 1 diabetes are not related to impaired gastric emptying caused by autonomic neuropathy

J. Punkkinen¹, M. Färkkilä¹, S. Mätzke², T. Korppi-Tommola², T. Sane³, P. Piirila⁴, J. Koskenpato¹;

¹Department of Gastroenterology,

²Laboratory of Nuclear Medicine, ³Department of Endocrinology,

⁴Laboratory of Clinical Physiology, Helsinki University Hospital, Finland.

Background and Aims: Diabetic gastroparesis is a common condition occurring in about 30–50% of diabetic patients with a long disease history. Studies examining the relation of autonomic neuropathy and diabetic gastroparesis have been contradictory whereas acute changes in plasma glucose concentrations affect gastric emptying more clearly. The objective was to examine the causal relation of upper abdominal symptoms to gastric emptying and autonomic nerve function in patients with type 1 diabetes.

Materials and Methods: Gastric emptying of solids and liquids were measured with standardized scintigraphy in type 1 diabetic patients (age 42±8 and diabetes duration 29±11 years, HbA_{1c} 8.4±1.4 %) with upper abdominal symptoms for at least 3 months (upper abdominal pain, fullness, early satiation, nausea or vomiting) but with no findings in gastroscopy or abdominal ultrasound. Helicobacter pylori infection was excluded by negative findings in the gastroscopy biopsies. Autonomic nerve function was examined by standardized cardiovascular tests (heart rate variation during controlled and deep breathing and Valsalva manoeuvre, diastolic blood pressure rise during isometric handgrip exercise, and blood pressure and pulse reactions during active orthostatic test with measurement of maximum/minimum ratio of heart rate variation). Glucose concentrations were measured during scintigraphy. Severity of abdominal symptoms and quality of life were examined by validated questionnaires (SF-36).

Results: 7/27 (26%) of patients with upper abdominal symptoms had delayed gastric emptying of solids and 3/27 (11%) of liquids. Gastric emptying rate of solids correlated positively with the autonomic neuropathy score ($r=0.56$, $P<0.01$), but not to abdominal symptom score or actual plasma glucose concentrations during scintigraphy. Using the Cox regression model for an increment of one in the autonomic neuropathy score, the gastric emptying rate of solids emptying was 31% smaller (10–47 95% CI; $P = 0.006$). Considering emptying rate of liquids, for an increment of one in the autonomic neuropathy score, the gastric emptying rate of liquids rate was 20% smaller (–1–37 95% CI; $P = 0.06$). Neither gastric emptying rate of solids nor liquids correlated with age, duration of diabetes, glucose concentrations during scintigraphy, HbA_{1c} or abdominal symptoms. All of eight aspects of quality of life in diabetic patients with abdominal symptoms were significantly lower than in the normal population.

Conclusion: Impaired gastric emptying of solids in patients with type 1 diabetes is related to autonomic neuropathy but not to actual glycemic control during scintigraphy. However, upper abdominal symptoms observed in these patients can not be explained by impaired gastric emptying.

1143

High prevalence of urinary incontinence in diabetic women is independent of age; preliminary results of a case-control study

P. Topsever¹, M. T. Filiz¹, C. Uludag², N. Dede Cinar²;

¹Department of Family Medicine, Kocaeli University, Istanbul,

²Department of Nursing, Sakarya University, Sakarya, Turkey.

Background and Aims: Urinary incontinence (UI) is an important health problem with psychological, social and hygienic effects on women. UI can also have considerable impact on quality of life of the affected individual and has been reported to be associated with the presence of some chronic diseases. The aim of the present study was to explore the association between Diabetes Mellitus (DM) and urinary incontinence in a sample of adult women.

Materials and Methods: In total, 954 women (mean age 38.4±13.0 years, BMI 26.0±5.1 kg/m², prevalence of gravidity 85.5%, prevalence of parity 82.2%) composed of 344 diabetic cases (fasting plasma glucose 145.3±36.2 mg/dL, systolic blood pressure 129.3±13.9 mmHg diastolic blood pressure 76.4±8.5 mmHg, DM complications 12.4%, insulin therapy 17.0%, oral antidiabetic therapy 83.0%) and 610 non-diabetic controls (chronic diseases 15.2%) attending six Primary Health Care Centers and one State Hospital diabetes

outpatient clinic were enrolled in this study. After giving their informed consent, all participants filled in a questionnaire inquiring “any kind of urinary leakage”, related symptomatology and personal medical history. Reproductive and medical history was verified from patient records. The subjects were dichotomized into cases and controls according to presence of DM. Except for descriptives (median/range and mean±SD, %), Independent Samples t-test and Chi-Square test were used; binary logistic regression analysis with the presence of UI as dependent and variables of interest as covariates was performed producing odds ratios (OR); areas under the curve (AUC) were calculated with a sensitivity of ≥90%, a statistical significance of <0.05 and a confidence interval (CI) of 95%.

Results: When diabetic cases were compared with non-diabetic controls, they were older (49.3±10.3 years vs. 32.3±10.1 years), more overweight (BMI 27.9±4.9 kg/m² vs. 24.9±4.8 kg/m²), had experienced more pregnancies (mean number of pregnancies 3.1±1.0 vs. 2.0±1.3) and more deliveries (mean number of deliveries 2.8±1.1 vs. 1.8±1.3) and displayed a higher prevalence of UI (41.9% vs. 13.5%) with $p<0.001$ for all. After adjustment for plausible confounders (age, reproductive history like number of deliveries and medical history like presence of chronic comorbidities, diabetic complications), logistic regression revealed the presence of DM (OR 2.9, 95%CI 2.1 to 4.0, $p<0.001$), BMI over 22.5 kg/m² (sensitivity ≥90%, AUC 0.67, 95%CI 0.63 to 0.71, $p<0.001$, OR 1.1, 95%CI 1.0 to 1.1, $p=0.002$), and history of more than one pregnancy (sensitivity ≥90% AUC 0.72, 95%CI 0.68 to 0.75, $p<0.001$, OR 1.6, 95%CI 1.4 to 1.9, $p<0.001$) as independent determinants of urinary incontinence in adult females.

Conclusion: Even after adjustment for plausible confounders like age, UI was more prevalent in adult diabetic women. The fact that determinants of UI identified in the present sample were modifiable, is important in terms of its prevention. Relationship of UI with diabetes related parameters like metabolic and hemodynamic parameters and disease related quality of life need to be elucidated further.

1144

Anxiety, depression and neuropathic pain in diabetes

E. V. Salgami¹, L. Vileikyte¹, J. S. Gonzalez², C. Waterman¹, K. Breislin¹, A. J. M. Boulton¹, M. Peyrot²;

¹Diabetes, University of Manchester, United Kingdom,

²Psychology, Harvard Medical School, Boston, United States,

³Sociology, Loyola College, Baltimore, United States.

Background and Aims: As new medications for diabetic neuropathic pain are potent mood modulators, exhibiting either anxiolytic or anti-depressant properties, it is important when prescribing therapies, to determine whether the patient with neuropathic pain is predominantly anxious or depressed. Theoretical and empirical research suggests that whether a person is anxious or depressed is a function of duration of the medical disorder.

Materials and Methods: We therefore studied 46 patients (mean age 61 years; 73% male) with diabetes (71% type 2) and chronic neuropathic pain (>6 months duration, mean =47months), and examined the association between two indices of pain severity (pain intensity and duration) and negative affect. Neuropathy was diagnosed using Neuropathy Disability Score (mean 6.7) and Vibration Perception Threshold (mean 26.7 volts). Pain severity was assessed with the Visual Analog Graphic Rating Scale, VAS (>3mm; mean= 8.7).

Results: Consistent with the tripartite model of mood, negative affect was measured with four scales from the Mood and Anxiety Symptom Questionnaire, MASQ, two of which assessed symptoms of generalized distress that are non-specific, i.e., common to both anxiety (11 items; $\alpha = 0.81$) and depression (12 items; $\alpha = 0.93$); while the other two scales measured symptoms unique to anxiety (anxious arousal: 17 items, $\alpha = 0.88$) and depression (anhedonic depression: 22 items; $\alpha = 0.95$). Of demographic and disease variables, only age significantly correlated with MASQ scales at the bivariate level and was therefore retained in subsequent regression analyses. Pain duration was not significantly associated with MASQ scales, whereas pain severity was a significant independent predictor of specific measures of anxiety and depression symptoms (anxious arousal: $\beta = 0.41$; $p=0.018$; anhedonic depression: $\beta = 0.45$ $p = 0.007$).

Conclusion: These findings suggest that anxiety and depression are both associated with chronic painful neuropathy, and that pain intensity and not duration is associated with negative affect. This highlights the importance

of measuring symptoms that are unique to anxiety and depression when examining the association between neuropathic pain and negative affect.

1145

Depression is a major confounder of outcomes in clinical intervention trials of therapeutic compounds in painful diabetic neuropathy

S. Tesfaye¹, R. A. Gandhi¹, C. J. Emery¹, H. Bowler², D. Selvarajah¹;

¹Diabetes Research Unit, University of Sheffield,

²Department of Pharmacy, Clinical Trial Unit, Sheffield, United Kingdom.

Background and Aims: Painful diabetic neuropathy causes great distress and disability to sufferers and affects quality of life immensely. Drug treatments are often ineffective and complicated by side effects. Some recent clinical drug trials comparing the efficacy of new therapeutic interventions with placebo have been complicated by a large placebo response. We conducted a post hoc analysis to assess the effects of depression on outcomes in a randomised placebo control trial evaluating the efficacy of sativex (a cannabis based medicinal product) in painful diabetic neuropathy.

Materials and Methods: Following a 1 week screening phase, 28 diabetic subjects with painful diabetic neuropathy were randomised to receive either sativex or matching placebo. Doses of study medication were titrated up over a two week titration phase until either a maximum tolerated dose was achieved or adequate pain relief obtained. During the screening phase, baseline level of depression was assessed by using the Hospital Anxiety and Depression Score (HADS) and daily pain assessed by completion of a pain diary. Following the two week titration phase, subjects proceeded to a ten week maintenance phase which terminated on a final visit. Primary outcome measure was change in total pain scores from baseline between the two treatment arms. For the post hoc analysis we divided the subjects into two groups based on the HADS [no depression (HADS<10) and depression (HADS>10)]. Using univariate analysis of covariance we compared outcomes between depressed and non depressed subjects after adjusting for study medication received.

Results: There was no significant difference in primary outcome measures between the active and placebo arms of the study ($p=0.74$). Mean (SD) HADS for the depression ($n=10$) and no depression ($n=18$) groups were 13.4 (3.5) and 5.94 (2.2) respectively. Subjects with depression had higher baseline total pain scores compared to those without depression [186.8(66.3) vs 130.3(72.8); $p=0.050$]. Subjects with depression had a significant improvement in the primary outcome measure compared to those without depression, after adjusting for allocation to the active or placebo arm of the study [mean change in total pain scores (standard error of the mean) $-94.7(23.4)$ vs $-30.9(17.5)$; $p=0.039$].

Conclusion: Depression may be a major confounder of outcomes in clinical trials assessing the efficacy of therapeutic interventions in painful diabetic neuropathy. Subjects with even moderate levels of depression are more likely to have higher baseline pain scores and respond favourably to any intervention, whether in the placebo or active arm of a study.

Effects of pregabalin on pain and nerve conduction in patients with painful diabetic peripheral neuropathy (DPN): a 13-week randomized controlled trial and 6-month open-label safety extension

J. Arezzo¹, J. Rosenstock², L. LaMoreaux³, L. Pauer³, U. Sharma⁴;

¹Neuroscience and Neurology Dept., Albert Einstein College of Medicine, Bronx, ²Diabetes and Endocrinology Dept., Dallas Diabetes and Endocrine Center, Dallas, ³Pfizer Inc, Ann Arbor, ⁴Consultant, Pfizer Inc, Canton, United States.

Background and Aims: This 13-week randomized clinical trial evaluated pregabalin 600 mg/d (BID) as treatment of painful DPN.

Materials and Methods: Primary efficacy measure was endpoint (EP) mean pain score (MPS) on an 11-point numeric rating scale (NRS) derived from patients' daily pain diaries. Secondary efficacy measures included weekly MPS and EP and weekly sleep-interference scores (on an 11-point NRS). Primary safety endpoints were amplitude and conduction velocity for 4 nerves (median-motor, median-sensory, ulnar-sensory, and peroneal-motor) assessed at baseline (BL), EP, and 2-week follow-up.

Results: 82 patients were randomized to pregabalin, 85 to placebo (PBO). After 1-week dose escalation, pregabalin patients received 600 mg/d for 12 weeks. EP MPS was significantly lower in pregabalin-treated patients than in PBO-treated patients (mean difference, -1.28 ; $P=0.0003$). Significant pain improvement among pregabalin patients was evident at Week 1 and every weekly timepoint thereafter. Pregabalin was statistically significantly superior to PBO for reducing pain-related sleep-interference score at every weekly timepoint (except Weeks 9, 10) and at EP (mean difference, -1.08 ; $P=0.0019$). No statistically significant differences in amplitude or velocity were observed for any of the 4 nerves tested. In an open-label (OL) extension of this trial, patients received 150–600 mg/d pregabalin (BID), adjusted to optimize efficacy and tolerability, for up to 6 months. 97% of patients received dosages of ≥ 300 mg/d. Pregabalin was generally well tolerated, with 70/104 patients completing 24 weeks of treatment. 15 patients (14%) withdrew from OL treatment because of AEs. Peripheral edema, dizziness, and somnolence were the most common AEs associated with treatment.

Conclusion: Pregabalin 600 mg/d (BID) showed robust and sustained efficacy in pain improvement with no meaningful effect on nerve conduction during 13 weeks of double-blind treatment. Pregabalin was generally well tolerated during both 13-week double-blind and 6-month OL treatment.

Effect of gabapentin on impaired brain GABA transmission associated with type 1 diabetes

I. Shymanskyi, T. Kuchmerovska, V. Kopelevich, A. Klimenko;

Coenzymes, O.V. Palladin Institute of Biochemistry, Kyiv, Ukraine.

Background and Aims: The anticonvulsant drug gabapentin (an amino acid chemically related to gamma-aminobutyric acid, GABA) has been shown recently to exhibit antinociceptive, anxiolytic and neuroprotective activity. Several animal and clinical studies have investigated the use of the drug as the management of neuropathic pain associated with diabetes. Although the binding site for gabapentin in the nervous system has been identified as the alpha-2-delta subunit of voltage-gated calcium channels, it is not yet clear how this finding relates to the modulatory action of gabapentin on various neurotransmitter systems in the brain. In view of the data showing GABA-mimetic properties of gabapentin, we have now evaluated the role of GABAergic system in the mechanism of its action in diabetic brain.

Materials and Methods: All studies were carried out after 5 weeks of STZ-induced diabetes (60 mg/kg, i.p.) in rats treated for 14 days with or without gabapentin (50 mg/kg, i.p.). GABA content was assayed in brain by cation exchange chromatography. The uptake and the release of [U - ^{14}C]GABA were determined in purified brain synaptosomes. Reactive oxygen species (ROS) production was measured quantitatively in synaptosomes using cell permeable dye 2',7'-dichlorofluorescein diacetate (DCF-DA).

Results: It was shown that diabetes lowered the brain level of GABA to 1.79 ± 0.09 from 2.36 ± 1.24 $\mu\text{mol/g}$ tissue in control ($p < 0.05$). This may account for $53.4 \pm 4.9\%$, probably compensatory, elevation of GABA uptake by diabetic synaptosomes vs control. To evaluate the possibility of diabetes-induced influence on quantal mode of the neurotransmitter secretion we examined the effect of the depletion of cytosolic GABA pool by 1 mM nipecotic acid (competitive inhibitor of the GABA transporter) on neurosecretion evoked by KCl (30 mM) depolarization. Diabetic synaptosomes pretreated with nipecotic acid exhibited significant, more than two-fold, increase in unstimulated GABA release, whereas K^+ -evoked Ca^{2+} -dependent neurotransmitter release was much lower as compared to control suggesting diabetes-induced inhibition of GABA exocytosis from synaptic vesicles, $p < 0.05$. Following gabapentin administration, the content of brain GABA was almost completely restored with simultaneous $33.5 \pm 3.7\%$ decrease in GABA uptake by synaptosomes, $p < 0.01$. It was found that drug treatment diminished synaptosomal response to nipecotic acid but augmented GABA secretion evoked by high KCl, $p < 0.05$. As oxidative stress could be implicated in the diabetes-associated impairment of GABA transmission, gabapentin efficacy to counteract ROS generation in synaptosomes was assessed. Indeed, administration of the drug attenuated increased DCF-DA-sensitive cellular ROS production in diabetic rats. At the same time, gabapentin had no lowering effect on blood glucose and brain sorbitol levels.

Conclusion: The data suggest that diabetes may cause physiologically drastic failure in realization of GABA-mediated inhibitory effects in CNS. The decrease in GABA uptake by gabapentin as well as its facilitatory action

on GABA exocytosis may result in elevation of GABA concentration in the synaptic cleft leading to better synaptic inhibition and thereby contributing to its neuroprotective effects. This, together with the antioxidant action of gabapentin might deserve further investigation for evaluating the link between the observed findings at the level of GABAergic transmission and the clinical effects of the drug.

N¹-methylnicotinamide in prevention of diabetes-associated brain disorders

T. Kuchmerovska, I. Shymanskyi, S. Stepanenko, A. Klimenko; Coenzymes, O.V. Palladin Institute of Biochemistry, Kyiv, Ukraine.

Background and Aims: It was previously revealed that vitamin PP exerts strong neuroprotective action and can be efficient in brain abnormalities induced by type 1 diabetes. More evidences have been emerged indicating that besides being essential for energy transduction, the intermediates of vitamin PP metabolism have a variety of significant regulatory roles, some of which are involved in fundamental cellular processes. The potential function of N¹-methylnicotinamide (MNM), the end product of niacin metabolism, in regulatory events has not yet attracted considerable attention. The aim of the study was to evaluate the potential benefits from N¹-methylnicotinamide treatment on brain disorders associated with diabetes.

Materials and Methods: The studies were carried out after 6 weeks of STZ-induced diabetes (60 mg/kg, i.p.) in rats treated for 5 weeks with or without MNM dissolved in drinking water (100 mg/kg of body weight) after 1 week of diabetes induction. The uptake and the release of [2-¹⁴C]serotonin (5HT) were determined in purified synaptosomes. The synaptosomal plasma membrane potential was measured by accumulation of ³H-labelled tetraphenylphosphonium bromide ion.

Results: In diabetes, the hepatic vitamin PP content was shown to be significantly lower (540±37 vs 795±52 nmol/g tissue in control, *p*< 0.05). Diabetes caused 34.8±2.4 % decrease in the activity of Na⁺,K⁺-ATPase that indicates lowered efficacy of Na⁺,K⁺-pump, *p*< 0.01. To further support the role of Na⁺,K⁺-ATPase in neuropathophysiology of diabetic complications, we examined the possibility of alterations in transmembrane plasmatic potential of rat brain synaptosomes related to impaired ion transportation via synaptic membranes. It was shown more than two-fold decrease in the membrane potential of synaptic endings in diabetes vs control. Compared to control, diabetes led to 45.3±3.2 % elevation of the spontaneous release and 37.0±2.8 % decrease in the uptake of 5HT in isolated synaptic endings, *p*< 0.05. In addition, these changes were associated with 1.62-fold elevation of brain sorbitol concentration compared with control rats. NAD⁺ contents and free cytosolic NAD⁺/NADH ratios were approximately to the same extent reduced in brain and liver in diabetes vs. control. MNM supplementation to diabetic rats elicited slight lowering effect on blood glucose level. The content of vitamin PP in liver was completely restored in MNM-treated rats. Following the MNM treatment the activity of Na⁺,K⁺-ATPase was 13.5±1.2 % increased vs diabetes, *p*< 0.05. The membrane potential of rat brain synaptosomes was reversed to initial level in MNM-supplemented diabetic rats. It is most likely that attenuation of synaptosomal membrane potential after MNM administration contributed to slight currently established improvement of 5HT uptake and spontaneous release. These changes correlated with 33.1±2.9 % reduction in brain sorbitol content, *p*< 0.05. MNM treatment partially normalized brain and liver NAD⁺ levels and exhibited strong normalizing effect on redox state of free cytosolic NAD⁺/NADH-couples only in rat liver.

Conclusion: MNM treatment can be used as a strategy to improve brain cell function in diabetes. The mechanisms of MNM-related neuroprotection involve glucose lowering action, extra-brain metabolic effects and do not exclude direct MNM modulatory action on synaptic membrane properties. MNM ability to attenuate brain abnormalities related to diabetes deserves prospective study.

1149

Benfotiamine and alpha-lipoic acid in the treatment of type 1 diabetic patients with autonomic gastroenteropathy

A. A. Serhiyenko, V. A. Serhiyenko, L. M. Serhiyenko; Endocrinology, Medical University of Lviv, Lviv, Ukraine.

Background and Aims: The perspective direction in the treatment of diabetic autonomic gastroenteropathy (DAGP) is the use of antioxidant and 'neurotrophic' B-group vitamins, in particular, benfotiamine (BET) – liposoluble vitamin B₁ form. The aim of this study was to assess the effects of BET, alpha-lipoic acid (ALA) and their combinations on clinical peculiarities, dynamics of instrumental and biochemical parameters in Type 1 diabetic patients with DAGP.

Materials and Methods: 64 patients with Type 1 DM and moderate/severe DAGP (23,6±2,9 years), BMI 17,2±1,79 kg/m², DM duration 5,2±1,3 years, HbA1c 8,5±1,6 % were allocated to three groups. Patients of group A received BET 150 mg in dragee three times; B – ALA 600 mg in tab. tid; C – BET 150 mg in dragee three times plus ALA 600 mg in tab. tid. The duration of the study was 2 months. Gastric electrical activity was evaluated by cutaneous electrogastrography (EGG) spectral analysis by distribution of the 3 spectra of gastric slow-wave frequency: bradygastria, normo-, and tachygastria; function of autonomous nervous system – by short-term spectral analysis of heart rate variability (HRV); contraction activity of the gallbladder by real-time ultrasonography. We investigated also the activities of superoxide dismutase (SOD), glutathion peroxidase (GPO), glutathione (GSH), malonedialdehyde (MDA), conjugated dienes (CD). contents in the RBC's. Parameters were observed at baseline state and at the end of 2 month period. Statistics: ANOVA.

Results: Progressing of DAGP is accompanied by increase in percentage of tachygastria (25,9±12,8 % vs 17,3± 7,6 %, *p*<0,01), reduction in percentage of normogastria (60,2 ±9,7 % vs 72,3± 10,1 %, *p*<0,01), bradygastria (3,5±0,9% vs 5,7±0,7% *p*<0,05). This disturbances, can testify about vagal damage. DAGP is accompanied by decrease in gallbladder ejection fraction at 30, 40 and 60 min after egg yolk; depression of SOD (*p*<0,001), GPO (*p*<0,01) activities, GSH content (*p*<0,01) with simultaneous increase MDA (*p*<0,001), CD concentration (*p*<0,05). Results between treatment group at 2th month were the following: the HbA1c did not changed during the trial in investigated groups (*p*>0,05). More expressed positive dynamics of investigated parameters, including, increase in gallbladder ejection fraction, improve of HRV parameters were observed in group C (table).

Mean % change from baseline at 3 months	BET (n=23)	ALA (n=21)	BET/ALA (n=20)
Bradygastria	+49,7*	+12,3	+74,2**
Normogastria	+32,9	+14,7	+69,4**
Tachygastria	-31,2	-18,4	-64,8**
SOD	+30,1	+49,2*	+67,3**
GPO	+11,3	+54,3*	+72,3**
GSH	+21,4	+42,3*	+62,7**
MDA	-29,2	-52,7*	-79,4**
CD	-32,4	-49,8*	-71,8**
Postprandial fullness	-64,3*	-23,9	-87,3**
Weight	+18,4	+16,9	+49,3*
Dyspepsia	-39,8*	-18,4	-74,3**
Dysphagia	-42,4*	-26,2	-84,3**
Expressive of abdominal pain	-57,9*	-42,6*	-93,8*
Night diarrhoea	-60,3*	-39,5*	-92,1**
Constipation and obstipation	-58,3**	-12,6	-82,7**

Treatment difference presented with 95% CI. **p*<0,01, ***p*<0,001

Conclusion: Thus, the combined treatment sick of BET and ALA during two months is accompanied by more expressed improvement of clinical current of DAGP, instrumental and biochemical parameters. The received results allow to assume, that efficiency of treatment by BET and ALA has no connections with improvement of compensation of DM, and cause direct influence of the last on the function of autonomous nervous system. So, combination of BET and ALA might be clinically useful for treatment, prevention from the progression of DAGP.

PS 116 New mechanisms in diabetic retinopathy

1150

Small populations of progenitor cells present in adult rodent retina are modified by diabetes and hypertension

J. M. Lopes de Faria, T. C. Cavalcanti, K. C. Silva, P. A. Boer, J. B. Lopes de Faria;
Faculty of Medical Sciences, University of Campinas, Brazil.

Background and Aims: The mature mammalian retina displays regenerative capacity. Stem/progenitor cells involved in this process may have important clinical applications in degenerative retinal disease as diabetic retinopathy (DR), retinitis pigmentosa and glaucoma. These observations prompt us to search for retinal cell replication in vivo in a model that combines diabetes and hypertension, a well-recognized factor associated with exacerbation of DR. Additionally, we characterized the nature of these replicating cells, assessed the retinal expression of a cell-cycle inhibitor (p27kip1) and search for earlier markers of DR.

Materials and Methods: Spontaneously hypertensive rats (SHR) and their normotensive control Wistar Kyoto (WKY) rats were rendered diabetic by streptozotocin injection and after 15 days the rats were sacrificed and the retinas collected.

Results: Although a rare phenomenon, positively stained BrdU cells attesting their proliferative nature were present in the retina. The number of BrdU positive cells in the retina was higher in SHR than in WKY ($p=0.01$) and after 15 days of DM, there was a marked reduction in cell replication only in diabetic SHR rats ($p=0.007$). The BrdU positive cells were also colabeled for neuron or glial or vascular progenitor cell markers as demonstrated by the presence of nestin, GFAP and Flk-1 antigens. The abundance of p27Kip1 was higher in ganglion cell layer in both diabetic groups ($p=0.05$) and also in inner nuclear layer only in diabetic SHR ($p=0.02$). There was a marked increment of VEGF expression in diabetic SHR ($p=0.02$) accompanied by blood-retinal barrier breakdown ($p=0.01$). **Conclusion:** We observed a small number of progenitor cells in the retina that are affected by both diabetes and hypertension. The concomitance of these two conditions markedly reduce the number of these progenitor cells. These findings may launch a new understanding of diabetic retinal neurodegeneration raising the possibility of regenerative therapy.

Changes of different types of endothelial progenitor cells in relation to stages of diabetic retinopathy in type 1 diabetic patients

G. H. Scherthaner¹, S. Brunner², F. Zeiler², S. Binder², G. Scherthaner³;

¹Internal Medicine II – Angiology, Medical University of Vienna,

²Ophthalmology, Rudolfstiftung Hospital,

³Medicine I, Rudolfstiftung Hospital, Vienna, Austria.

Background and Aims: Bone marrow-derived endothelial progenitor cells (EPC) have been suggested to be involved in vascular repair following ischemia and tumour neo-angiogenesis. It is tempting to speculate that EPC might also be involved in advanced diabetic retinopathy (DR) by directly going to the site of ischemia to differentiate and induce new vessel formation. In type 1 diabetic (T1D) patients only an in vitro augmented clonogenic potential of progenitor cells has been demonstrated so far. Thus, an in vivo study of circulating progenitor cells (CPC), EPC, and activated EPC (actEPC) was performed in T1D patients.

Materials and Methods: Ninety patients were studied and staged for DR according to the Early Treatment Diabetic Retinopathy Study (ETDRS) Group classification: no retinopathy (NoDR; $n=30$), mild non-proliferative DR (mNPDR; $n=30$), moderate-severe NPDR (msNPDR; $n=10$), mild-moderate proliferative diabetic retinopathy (mPDR; $n=10$) and severe PDR (sPDR; $n=10$). CPC, EPC and actEPC were defined by a direct 4-colour immunofluorescence staining (CPC being CD34+/CD133+, EPC being CD34+/CD133+/CD309+ and actEPC being CD34+/CD133+/CD309+/CD31+) and enumerated by flow cytometry.

Results: Baseline characteristics (mean±STD) of the study population were an age of 41±12 years, diabetes duration of 21±2 years and an HbA1c of

7.8±1.5 rel%. EPC were significantly lower in mNPDR (114±66; $p<0.001$) and msNPDR (77±40; $p=0.042$) vs No-DR (244±115). In contrast, EPC were unchanged in mPDR (248±155) vs No-DR. In contrast, EPC were significantly augmented in sPDR (389±124) vs all other stages. Numbers of undifferentiated progenitor cells (CPC) did not differ between No-DR, mPDR and sPDR. The most impressive finding was the 3-fold augmentation of actEPC in sPDR (325±118; $p<0.001$) vs No-DR (100±49), but also in comparison with mNPDR, msNPDR and mPDR (158±119; $p=0.006$).

Conclusion: EPC show a stage-related regulation in type 1 diabetic patients with or without DR. Advancing stages of non-proliferative retinopathy were associated with a significant reduction of EPC vs. patients without retinopathy. In contrast, proliferative retinopathy showed a strong increase in EPC and actEPC numbers. In summary, EPC and actEPC, but not CPC are associated with proliferative diabetic retinopathy. Prospective studies are needed to define whether these findings have diagnostic or even therapeutic impact in diabetic retinopathy.

High glucose-conditioned extracellular matrix enhances apoptosis of human retinal pericytes

E. Berrone¹, E. Beltramo¹, K. Nizheradze², S. Tarallo¹, M. Porta¹;

¹Dept. Internal Medicine, University of Turin, Italy, ²Laboratory of

Biomarkers, Institute of Colloid and Water Chemistry, Kiev, Ukraine.

Background and Aims: Thickening of the basement membrane and selective loss of pericytes are among the first events in the onset of diabetic retinopathy. We reported reduced adhesion of bovine retinal pericytes (BRP) cultured on extracellular matrix (ECM) produced by endothelial cells (HUVEC) in high hexose concentrations, probably due to glycation of matrix proteins, but no changes in their apoptosis. Some observations suggest, however, that human and bovine pericytes may behave differently in experimental conditions mimicking the diabetic milieu. The aim of this study was to verify human retinal pericytes (HRP) behaviour, when cultured on altered ECMs.

Materials and Methods: Conditioned ECMs were obtained by growing HUVEC for 7 days in culture media containing normal (5.6 mmol/l) or high (28 mmol/l) D-glucose. Cells were then lysed and ECM fixed by NH₄OH. HRP were cultured in normal or high glucose on these conditioned ECMs or plastic alone. Pericyte adhesion was evaluated after 12–18 hours. After 7 days of culture, cell proliferation was assessed by cell counts and BrdU incorporation. DNA fragmentation was evaluated by ELISA, as a marker of early apoptosis. The expression of three genes involved in apoptosis, *p53*, *Bax* and *Bcl-2*, was determined by RT-PCR and their concentration in cell lysate by ELISA.

Results: HRP adhered less on high glucose-conditioned ECM and plastic than on normal glucose-conditioned ECM, while there were no significant differences, after 7 days, in their number, nor in DNA synthesis, when grown in physiological glucose. In contrast, DNA synthesis was impaired in HRP cultured in high glucose, in comparison with HRP cultured in normal glucose on the three different matrixes. Apoptosis was greatly enhanced by high glucose-conditioned matrix, both in HRP grown in normal and high glucose and this was confirmed by *p53*, *Bcl-2* and *Bax* mRNA expression and protein concentration.

Conclusion: Human pericyte apoptosis seems to be strongly affected by matrix produced in high glucose and this could play a major role in the development of diabetic retinopathy. Moreover, this behaviour is different from that observed with bovine pericytes, underlining the importance of establishing a cell model for diabetic retinopathy as similar as possible to the human diabetic eye.

1153

Crosstalk between *tnf-alpha*, *nadph oxidase*, *pkcbeta1/2*, and *core 2 transferase* in diabetic leukocytes

R. Chibber, B. M. Ben-Mahmud, E. M. Kohner;

Cardiovascular Division, King's College London, United Kingdom.

Background and Aims: Increasing evidence suggests that chronic, sub-clinical inflammation plays an important role in diabetic retinopathy.

We have recently reported that a glycosylating enzyme, core 2 β -1, 6-N-acetylglucosaminyltransferase (core 2 GlcNAc-T), is implicated in increased leukocyte-endothelial cell adhesion in retinopathy via an up-regulation mechanism controlled by tumour necrosis factor- α (TNF- α) (Ben-Mahmud et al., 2006). The aim of the present study was to elucidate the potential role of NADPH oxidase signalling pathway in the raised activity of core 2 GlcNAc-T in diabetic leukocytes. NADPH oxidase is the most important source of cellular reactive oxygen species (ROS) in leukocytes and blood vessels.

Materials and Methods: Human leukocytes (U937 cells) and a lymphoblastoid cell-line deficient in p47phox were cultured in RPMI medium containing norml (5.6 mM glucose). The cells were exposed to TNF- α (8 pg/ml) for 24 h in the presence and absence of (i) NADPH oxidase inhibitors, 30 μ M apocynin and 1 μ M of scrambled and unscrambled gp91ds-tat (ii) 50 nM LY379196, a specific PKC β 1/2 inhibitor and (iii) antioxidants, 15 mM N-acetyl cysteine (NAC, 15 mM) and 5 mM Tiron. NADPH oxidase activity was measured using cytochrome c reduction assay. PKC β 1/2 activity was measured using TruLight™ PKC- β 1/2 assay kit (Calbiochem, UK).

Results: Compared to control medium, exposure to TNF- α (8pg/ml; 24h) raised core 2 GlcNAc-T activity in human leukocytes [1722 \pm 255.3 (n = 10) vs. 374 \pm 80.3 (n = 10), P<0.0001] that was significantly reversed with apocynin and LY379196. These findings were further supported with (i) significant reversal of TNF- α -induced core 2 GlcNAc-T activity with unscrambled and not scrambled gp91ds-tat, a specific NADPH oxidase inhibitor, (ii) use of a lymphoblastoid cell-line deficient in p47phox, a major subunit of NADPH oxidase, and (iii) reversal with NAC and Tiron.

Conclusion: Our results demonstrate a novel signaling crosstalk between TNF- α , core 2 GlcNAc-T, NADPH oxidase and PKC β 1/2 in diabetic leukocytes.

Pro-Angiogenic Growth Factors, including VEGF, inhibit expression of the Anti-Angiogenic Protein PEDF: implications for new vessel formation in diabetes

R. Donnelly¹, P. Atherton², G. Manning¹, B. Wang¹;

¹Vascular Division,

²Clinical Physiology, Nottingham University, Derby, United Kingdom.

Background and Aims: New vessel formation is a key component of diabetes-related complications, and is influenced by the local inter-play between pro- and anti-angiogenic factors. Vascular Endothelial Growth Factor (VEGF), basic Fibroblast Growth Factor (bFGF) and Tumour Necrosis Factor- α (TNF- α) are important pro-angiogenic growth factors, while Pigment Epithelium Derived Factor (PEDF) is a powerful inhibitor of angiogenesis associated inversely with retinopathy severity; PEDF replacement has been explored as a therapeutic option in ocular neovascularisation. This study explored the regulatory interactions between these cytokines, in particular the effects on PEDF expression.

Materials and Methods: Human umbilical smooth muscle cells were cultured to confluence, starved and quiesced in a low-serum medium for 24 hours. After incubation either untreated or treated with PEDF 10 nM, TNF- α 10 ng/ml, VEGF 10 ng/ml and bFGF 10 ng/ml respectively for 24 hours, cells were lysed. Following RNA extraction, a cDNA pool was synthesised for real time RT-PCR of VEGF and PEDF mRNA in a Bio-Rad iQ iCycler.

Results: In comparison with the untreated cells, treatment with PEDF inhibited PEDF expression by 50%, indicating negative feedback. (p=0.003, n=4); TNF- α , bFGF and VEGF inhibited the expression of PEDF by 62% (p=0.006, n=4) 57% (p=0.004, n=4) and 33% (p=0.018, n=4), respectively. No significant effects on the expression of VEGF mRNA were identified with any above treatment.

Conclusion: There is negative feedback in the control of PEDF expression, an important inhibitor of angiogenesis. In addition, pro-angiogenic cytokines that are often elevated in diabetes complications (VEGF, TNF and bFGF) have powerful inhibitory effects on expression of PEDF but not VEGF.

1155

Lower somatostatin expression is an early event in diabetic retinopathy and is associated with retinal neurodegeneration

E. Carrasco¹, C. Hernández¹, A. Miralles², P. Huguet³, J. Farrés⁴, R. Simo¹;

¹Diabetes Research Unit, Institut de Recerca Hospital Vall d'Hebron,

²Tissue Bank and Cell Therapy Center, Hospital Vall d'Hebron, ³Pathology Department, Hospital Vall d'Hebron, ⁴Department of Biochemistry and Molecular Biology, Universitat Autònoma de Barcelona, Barcelona, Spain.

Background and Aims: To test the hypothesis that a reduction of somatostatin (SST) exists in patients without clinically detectable diabetic retinopathy and that it is associated with retinal neurodegeneration.

Materials and Methods: Human diabetic postmortem eyes (n=10) without clinically detectable retinopathy were compared with eyes (n=10) from non diabetic donors matched by age. SST mRNA (RT-PCR) and SST-28 immunoreactivity (confocal laser) were measured separately in neuroretina and retinal pigment epithelium (RPE). In addition, SST-28 (RIA) was measured in the vitreous fluid. Glial fibrillar acidic protein (GFAP) was assessed by immunofluorescence and Western-blot. Apoptotic cells were quantified using terminal dUTP nick-end labeling (TUNEL).

Results: A higher expression of SST was detected in RPE than in neuroretina in both groups. SST mRNA levels and SST-28 immunoreactivity were significantly lower in both RPE and the neuroretina from diabetic donors in comparison with non-diabetic donors. These results were in agreement with those obtained by measuring SST-28 in the vitreous fluid of the same donors. Increased GFAP and a higher degree of apoptosis were observed in diabetic retinas in comparison with non-diabetic retinas. These changes were most evident in those patients with the higher deficit of SST.

Conclusion: Underproduction of SST is an early event in the eyes of diabetic patients and is associated with glial activation and neural death. In addition, our results suggest that RPE is an important source of SST in the human eye. The possible role of the lower production of SST in the pathogenesis of diabetic retinopathy deserves to be investigated.

PS 117 Nephropathy and end-stage renal failure

1156

Association between diabetic nephropathy and carotid intima-media thickness and arterial stiffness

T. Otani, M. Higa, A. Yoshihara, M. Sue, Y. Tsuchida, N. Hiroi;
Internal medicine, Saiseikai kanagawaken hospital, Yokohama, Japan.

Background and Aims: The link between nephropathy, particularly microalbuminuria, and cardiovascular disease, is becoming increasingly apparent. Atherosclerosis involves a combination of fatty degeneration (atherosis) and of vessel stiffening (sclerosis) of the arterial wall. The aim of this study was to assess associations between diabetic nephropathy and structural changes in arteries, such as carotid intima-media thickness (IMT) and functional changes, such as arterial stiffness and the ankle-brachial index (ABI).

Materials and Methods: The subjects of this study were 56 type 2 diabetic patients (age 56.7±11.7 years, 27 males and 29 females). They were divided into 3 groups according to level of urinary albumin excretion: a group of 28 patients with normoalbuminuria (N-group), a group of 17 patients with microalbuminuria (M-group), and a group of 11 patients with macroalbuminuria (MA-group). The IMT of the common carotid artery was measured by ultrasonography. Arterial stiffness and ABI were measured using the cardio ankle vascular index (CAVI) (VaSera VS-1000, Fukuda Denshi). Blood pressure, plasma glucose, and lipid levels, and serum adiponectin levels were compared in the 3 groups.

Results: No significant differences in age, duration of diabetes, BMI, smoking, or kind of antihypertensive agent used were found between the 3 groups. Systolic blood pressure in the M-group was 138.2±13.3 mm Hg and significantly higher ($p<0.01$) than in the N-group (128.7±9.6 mm Hg) and MA-group (128.7±7.9 mm Hg). IMT level in the M-group was 1.19±0.44 mm and significantly higher than in the N-group and MA-group (0.87±0.28 mm, 0.99±0.23 mm, respectively). There were no significant differences in CAVI levels between the 3 groups. The ABI levels in the M-group was 1.06±0.26 and significantly lower than those in the N-group and MA-group (1.17±0.06, 1.16±0.04, respectively). There were no significant differences in HbA_{1c}, lipid, serum creatinine or adiponectin levels between the 3 groups.

Conclusion: The carotid IMT was significantly higher in the patients with microalbuminuria, while no significant difference was found in CAVI levels. Microalbuminuria is associated with structural changes in arteries, but no association between microalbuminuria and functional changes in arteries was found in this study. The risk factors for structural changes and functional changes in arteries might be partly different.

1157

Prevalence of anaemia in patients with diabetic nephropathy

S. A. Martynov, M. V. Shestakova;
Department of Diabetic Nephropathy, Endocrinology Scientific Center, Moscow, Russian Federation.

Background and Aims: Diabetes mellitus is the one of most common cause of chronic renal failure (CRF) and therefore the most common cause of renal anemia. The aim of the study is to compare the prevalence of anemia in patients with diabetic nephropathy (DN) and chronic glomerulonephritis (GN).

Materials and Methods: 107 patients with DN and 249 patients with biopsy proven GN were studied. Anemia was defined as hemoglobin (Hb) < 12 g/dl in men and for women aged > 50 years and Hb < 11 g/dl for women ≤ 50 years. Glomerular filtration rate (GFR) was calculated using the Cockcroft-Gault formula. Comparison of the prevalence of anemia based on stages of chronic kidney disease (CKD) of Kidney Disease Outcome Quality Initiative guidelines. Patients with GFR<15 ml/min/1.73 m² and treated by erythropoietin-stimulating agents were not included. Differences between DN and GN patients were in age (49.1±17.2 vs 31.2±13.2 years ($p<0.001$), duration of renal damage (13.6±6.9 vs 3.4±4.0 years, ($p<0.001$), Hb (12.7±2.2 and 13.2±1.7 g/dl, ($p<0.01$), proteinuria 2.2±2.7 vs 6.8±5.0 g/24h ($p<0.001$) and GFR (80.5±44.5 vs 88.7±35.7 ml/min/1.73 m², $p<0.01$)

Results: The prevalence of anemia in total DN patients was more frequent than in GN patients (29.9% vs 12.8%, $p<0.001$). No significant differences

in anemia prevalence in DN and GN patients were observed at GFR ≥90 ml/min/1.73 m² – 7.1% vs 5.2%, ($p=0.64$) and at GFR level of 60–89 ml/min/1.73 m² – 10.5% vs 14.1%, ($p=0.68$). Anemia prevalence was significantly greater in patients with DN compared to patients with GN in the CKD categories 30–59 ml/min/1.73 m² – 50% vs 25.5% ($p=0.02$) and 15–29 ml/min/1.73 m² – 83.3% and 37.5% ($p=0.03$). Mean Hb values were significantly lower in DN patients than GN patients only at GFR level below 30 ml/min/1.73 m² – 9.8±1.7 vs. 11.9±1.9 g/dl ($p=0.02$).

Conclusion: We conclude that anemia develops early in patients with DN compared to patients with chronic GN. The higher prevalence of anemia in diabetes related with advanced kidney damage in DN and contributes to progression CRF and cardiovascular complications.

1158

Serum prohepcidin is decreased in progressive diabetic nephropathy and related to iron storage in patients with type 2 diabetes

J. Brix¹, K. Krzyzanowska¹, S. Siller¹, W. Krugluger², F. Mittermayer³, G. Scherthaner¹;

¹Department of Internal Medicine I, Rudolfstiftung Hospital,

²Department of Clinical Chemistry, Rudolfstiftung Hospital,

³Department of Clinical Pharmacology, Medical University Vienna, Austria.

Background and Aims: Hepcidin, which is expressed by the liver, regulates the human iron metabolism and is increased in chronic inflammation. Furthermore, it has been suggested that it is responsible for the development of anemia in chronic disease. Its precursor prohepcidin was positively related to hematocrit in patients with end-stage renal failure. Microalbuminuria, a well known risk factor for the development and progression of cardiovascular disease in type 2 diabetes signifies incipient diabetic nephropathy while macroalbuminuria reflects progressive diabetic renal disease. To investigate if prohepcidin is related to diabetic nephropathy, red blood count, iron status or chronic inflammation we determined this parameter in patients with type 2 diabetes and different stages of albuminuria.

Materials and Methods: We included 92 type 2 diabetes patients (57 males) in a cross-sectional study. Serum prohepcidin was determined by ELISA. Micro- and macroalbuminuria were defined as 24 hour urinary protein excretion of more than 30 mg or 300 mg, respectively.

Results: Micro- and macroalbuminuria were present in 42 and 22 type 2 diabetes patients. Median circulating prohepcidin concentrations were 147.5 (IQR: 111.3 – 177.8) ng/ml, 172.3 (IQR: 106.1 – 242.7) ng/ml and 109.7 (67.0 – 164.1) ng/ml in patients with normo-, micro- and macroalbuminuria ($P=0.049$ for normo- vs. macroalbuminuria; $P=0.003$ for micro- vs. macroalbuminuria). Prohepcidin correlated with ferritin ($R=0.22$; $P=0.04$), HOMA-IR ($R=-0.27$; $P=0.03$), diastolic blood pressure ($R=0.21$; $P=0.049$) and HDL-cholesterol ($R=0.22$; $P=0.03$) but not with red blood count (hemoglobin: $R=0.12$, $P=0.31$; hematocrit: $R=0.08$, $P=0.47$) or hsCRP ($R=-0.09$; $P=0.40$). Multiple regression analysis revealed that ferritin was the only independent predictor of prohepcidin ($\text{Beta}=0.25$; $P=0.049$).

Conclusions: Patients with type 2 diabetes and macroalbuminuria had lower prohepcidin concentrations compared to those with normo- or microalbuminuria. Prohepcidin was related to ferritin but not to red blood count or chronic inflammation. Low levels of prohepcidin in progressive diabetic nephropathy could indicate a potential mechanism counteracting the development of anemia by increasing intestinal iron uptake.

Diabetic patients on chronic dialysis: complications and quality of life

V. R. Sørensen¹, E. R. Mathiesen², T. Watt², J. B. Bjørner³, M. V. N. Andersen⁴, B. Feldt-Rasmussen¹;

¹Department of Nephrology, Rigshospitalet, Copenhagen,

²Department of Endocrinology, Rigshospitalet, Copenhagen,

³Department of Health Promotion, National Research Center for the working environment, Copenhagen,

⁴Department of Ophthalmology, Rigshospitalet, Copenhagen, Denmark.

Background and Aims: Despite the improved treatment of diabetic patients during the last 20 years, diabetic patients, who are treated with chronic maintenance dialysis, often suffer from one or more diabetic complications

besides kidney failure and have an increased morbidity and mortality. Health related quality of life has become an important parameter, when evaluating the wellbeing of patients with end-stage renal disease. The aims of the study were to describe the prevalence of diabetic complications and to evaluate health related quality of life in diabetic dialysis patients. In addition we investigated predictors of physical and mental health and the importance of beliefs about control over health.

Materials and Methods: All diabetic patients treated with dialysis by January 2004 in our clinic (n=65) were characterised regarding cardiovascular diseases and diabetic complications and were asked to complete a kidney-specific (KDQOL) and a generic (SF-36) questionnaire. Non-diabetic dialysis patients (n=65), who were matched by age, sex and duration of end-stage renal disease and normo-albuminuric diabetic patients with normal kidney function (n=76), who were matched by age, type and duration of diabetes, served as controls. Generic quality of life was also compared with matched data from a survey in the Danish general population (n=2248). Diabetic patients were also asked to fill in a questionnaire regarding belief about control over health.

Results: Micro- and macrovascular complications were significantly more frequent in diabetic dialysis patients than in diabetic patients without renal disease with a frequency of current foot ulcers of 33% vs. 13%, amputations 14% vs. 4% and impaired vision 22% vs. 2%. Non-diabetic dialysis patients had a low frequency of these complications (4%, 3%, 0%). Diabetic dialysis patients reported significantly shorter school education compared with diabetic patients with normal kidney function. There were no significant differences in the kidney disease quality of life among diabetic versus non-diabetic dialysis patients. Generic physical health was however significantly worse in diabetic dialysis patients (mean (SD)): (35(9) n=38) compared with non-diabetic dialysis patients (41(10) n=40), diabetic patients with normal kidney function (45(12) n=38) and the matched general population (47(19) (p< 0.01). Mental health was comparable in the three patients groups: 50(8) vs. 49(10) vs. 49(11), whereas the score in the general population was 55(9). Reduced physical health was predicted by presence of end-stage renal disease, diabetes and lower education. Diabetic dialysis patients believed significantly more in chance in relation to their diabetes than diabetic patients with normal kidney function. Diabetic patients, who believed more on their own ability to control their diabetes and less on chance, reported better mental health.

Conclusion: Diabetic dialysis patients were characterised by a high prevalence of diabetic complications. Generic physical health was significantly reduced and the presence of end-stage renal disease was the most important predictor of physical health.

Supported by the Danish Society of Nephrology

Results: The number of patients on dialysis in 2004 ranged from 270 per million in Norway to 1855 per million in Japan (Table). Number of patients per million with DM as primary cause for dialysis is 16 times higher in Japan than in Norway. Prevalence of renal transplantation (% of total RRT in ESRD) as treatment modality in ESRD was less than 2% in Japan, 26% in Germany, 31% in the US, 33% in Denmark, 40% in Belgium, 54% in The Netherlands, 60% in Finland, and 62% in Norway.

	number of patients on dialysis (n/million)	DM as primary cause of ESRD requiring dialysis (%)	number of patients on dialysis with DM as primary cause (n/million)
Japan	1855	41.0	761
US	1099	45.6	501
Finland	275	33.1	253
Germany	740	34.2	237
Belgium	585	22.5	146
Denmark	325	20.8	68
Netherlands	325	17.0	55
Norway	270	17.3	47

Conclusion: These results show dramatic differences in the prevalence of patients on dialysis and in the prevalence of DM as the primary cause between developed countries. The low prevalence in The Netherlands and some Scandinavian countries can only partly be explained by the higher transplantation rate. Another reason for the differences might be the variation in DM prevalence in the general population, reported in 2004 to vary between 3.7% in The Netherlands and 10.2% in Germany. Finding explanations and workable solutions for these differences might help to alleviate the human and financial burden of ESRD in DM in the developed world.

1160

Remarkable differences in the prevalence of diabetics in dialysis in developed countries

H. J. G. Bilo^{1,2}, S. H. A. Diepeveen³, S. J. J. Logtenberg¹, R. T. Gansevoort⁴, K. J. Jager⁵, N. Kleefstra¹

¹Diabetes Centre, Isala Clinics, Zwolle, ²Internal Medicine, UMCG, Groningen, ³Internal Medicine, Isala Clinics, Zwolle,

⁴Nephrology, UMCG, Groningen, ⁵Stichting RENINE, Academic Medical Centre, Amsterdam, The Netherlands.

Background and Aims: Diabetes mellitus (DM) is considered one of the main causes of end stage renal disease (ESRD) necessitating renal replacement therapy (RRT; dialysis and kidney transplantation). It has passed virtually all other causes in many countries. The accelerating growth in ESRD and DM not only contribute to a worse quality of life and early death, but also to a vast increase in health-care expenditure worldwide. Still, there are large differences in prevalence, varying from less than 20% to over 40%. The aim of this search was to compare different developed countries regarding the prevalence of DM as cause of dialysis for ESRD.

Materials and Methods: Data concerning the percentage of DM as cause of dialysis for ESRD in the United States, Belgium, Germany, Denmark, Finland, Norway, Japan, and The Netherlands were derived from several relevant national and international databases (RENINE-, USRDS- and WHO-databases). In addition, data were derived from websites of various national diabetes and nephrological organizations. For 2004, number of patients on dialysis per million inhabitants per country are reported. Furthermore, prevalence of DM in that group and the number of patients on dialysis due to DM per million inhabitants are reported.

PS 118 Hypertension: clinical management

1161

Evaluation of artificial intelligence and clinical decision making in the management of patients with type 2 diabetes and uncontrolled hypertension

K. A. Earle¹, R. Squires¹, S. Anandarajah¹, P. Taylor², D. Sutton³;

¹Cellular and Molecular Medicine, St George's Hospital NHS Trust, London,

²Centre for Health Informatics and Medical Education, Royal Free & University College London Medical School,

³Computer Science, Oxford Brookes University, United Kingdom.

Background and Aims: Hypertension is a major, modifiable risk factor for cardiovascular disease. However, target blood pressure in the United Kingdom is achieved in <30% of patients. Recent data suggests a nurse-led approach is more effective than conventional care in the attainment of target blood pressure. It is unclear how these approaches vary in relation to concordance with published guidance for hypertension. Therefore, we analysed the therapeutic decisions for patients with diabetes and uncontrolled hypertension in these settings against those in a virtual clinic using artificial intelligence.

Materials and Methods: We studied 219 patients with type 2 diabetes and uncontrolled hypertension – systolic (SBP) >130 and/or diastolic (DBP) blood pressure >80 mmHg respectively receiving antihypertensive therapy. Evaluations of 143 patients attending a nurse-led (NLC) and 76 patients in conventional, physician-led (PLC) clinics were made. Seated BP was measured using a digital oscillometric device. Treatment, BP, glycated haemoglobin (HbA1c) by HPLC and clinical decisions were reported on a standardised proforma.

The artificial intelligence system was written in the PROforma language. It contained expressions representing clinical criteria to influence and plan treatment based on the National Institute for Clinical Excellence guidelines. Data of all 219 patients were uploaded to the VLC database. The variables for decisions were cardiovascular risk score (CVD) determined by the Joint British Societies calculator, SBP, DBP and use of first line drugs (FLD). The FLDs were classed as angiotensin converting enzyme inhibitors (ACEI) or receptor blockers (ARB), beta blocker, calcium channel blocker and thiazide diuretic and entered according to whether they were prescribed at the maximal dose. Therapeutic decisions were coded as: 1 = monitor only, 2 = increase FLD, 3 = start a new FLD or 4 = refer for second-line agent. Target SBP and DBP was <130 and <80 mmHg respectively.

Results: The patients seen the NLC and PLC clinics had similar mean [SD], age, SBP, DBP and HbA1C (63.2[12.8] vs. 61.6[13.5] yrs; $p=0.38$, 144.9[19.4] vs. 142.2[12.6] mmHg; $p=0.29$, 77.6[11.8] vs. 78.0[10.2] mmHg; $p=0.79$ and 8.0[1.8] vs. 8.1[1.5] %; $p=0.09$). All patients had a CVD score of >20%. There were no differences between the groups in the prescription of any class of FLD, second line agent or the proportion on a maximal dose within any class. Decisions to monitor only in the PLC group was significantly higher and treatment altering decisions 2, 3 and 4 significantly lower than in the NLC group (67.6 vs. 32.8 and 10.8 vs. 35.1, 13.5 vs. 21.6, 8.1 10.4; $p=0.0001$). Decisions in VLC did not recommend to monitor only, but suggested decisions 2 and 3 respectively for 81% and 19% of the PLC group. VLC decisions 1, 2, 3 and 4 were made for 15%, 63%, 19% and 3 % respectively of the NLC group. The K estimate for agreement with the artificial intelligence decisions of VLC was 0.1 (poor) in the PLC group and 0.3 (fair) for the NLC group.

Conclusion: This artificial intelligence system consistently recognises the impact of CVD risk and exposes FLD under-treatment by nurses and physicians. Use of such decision support could possibly improve practice and outcomes.

Blood pressure lowering-independent improvement of central arterial stiffness by valsartan, but not amlodipine, in type 2 diabetic patients with systolic hypertension

J. Karalliedde¹, A. Smith¹, L. De Angelis¹, V. Mirenda¹, A. Kandra², P. Ferber², G. Viberti¹;

¹Diabetes, King's College London, United Kingdom,

²Novartis Pharma AG, Basle, Switzerland.

Background and Aims: Raised systolic and pulse pressures (PP) and increased central arterial stiffness, as estimated from aortic pulse wave velocity (Ao-PWV), are powerful risk factors for cardiovascular disease (CVD) morbidity and mortality. Systolic hypertension is often associated with microalbuminuria (MA) and both are strong predictors of CVD and progressive renal failure in type 2 diabetic patients (T2D). In these patients angiotensin receptor blockers (ARBs) have cardio-renal benefits which seem independent of blood pressure (BP) lowering. Whether ARBs obtain these beneficial effects by improving central arterial stiffness to a greater extent than other equipotent anti-hypertensive medications remains unclear. We compared the effect of valsartan (Val), an ARB, with that of amlodipine, a calcium channel blocker, on Ao-PWV in 131 T2D patients with systolic hypertension, raised PP and MA in a 24 week randomized, double-blind parallel group active-controlled study.

Materials and Methods: In a 4-week run in wash out phase all patients received moxonidine (400mcg/day), which has minimal impact on the vessel wall properties, to avoid uncontrolled hypertension (SBP \geq 180mmHg). One hundred and thirty one (41%M, 59%F) patients with PP \geq 60mmHg and systolic blood pressure (SBP) \geq 140 mmHg were then randomized to receive Valsartan (n=66) 160mg or amlodipine 5 mg (n=65). After 4 weeks 25mg/day hydrochlorothiazide (HCTZ), which has minimal effect on Ao-PWV, was added to valsartan and amlodipine up-titrated to 10mg to ensure equivalent BP control.

Results: Mean (SD) age was 59.5 (9.4) years, SBP 158.0 (10.7) mmHg, PP 95.6 (11.0) mmHg, and duration of diabetes 10.0 (7.1) years. Albumin excretion rate (AER) median (interquartile range) was 27.5(7–97) μ g/min. All patients had serum creatinine below \leq 115 μ mol/l. At baseline there were no significant differences in age, duration of diabetes, HbA1c, SBP, PP, AER and Ao-PWV between the two groups. Brachial PP and SBP fell similarly in both groups after 24 weeks with attained mean (SD) PP of 61.6 (13.6) mmHg and 61.5(12.2) mmHg and SBP of 135.3(18.8) mmHg and 137.2(13.8)mmHg in the Val/HCTZ and amlodipine groups respectively. AER fell by 35% in the Val/HCTZ group as compared to a rise of 24% in the amlodipine group ($p=0.0004$). Glycaemic control was stable and similar in the two groups throughout the study. Following 24 weeks Ao-PWV fell from mean (SD) 12.5 (2.5) to 10.7 (2.5) m/s in the Val/HCTZ group and from 12(2.5) to 11.3 (2.6) m/s in the amlodipine group. Between treatment comparison for change from baseline in mean Ao-PWV [by ANCOVA which included treatment, gender, age and operator as fixed factors and baseline mean Ao-PWV, baseline mean PP as covariates] at week 24 showed a significantly greater reduction of, mean (95% CI), – 1.1 m/s (–1.8 to –0.5) for Val/HCTZ compared to amlodipine ($p=0.001$). This magnitude of Ao-PWV difference translates to approximately 10 years of vascular ageing.

Conclusion: Our findings suggest that in this high CVD risk group of T2D, treatment for 24 weeks with valsartan improves central arterial stiffness significantly more compared to amlodipine despite similar brachial BP control. This and the significantly greater reduction of albuminuria by valsartan may explain the specific cardio-renal protective effects seen with ARBs.

Clinical utility of single-pill amlodipine besylate/atorvastatin calcium for the attainment of blood pressure and lipid goals in patients of diverse ethnicity with diabetes: Results from the GEMINI-AALA StudyC. A. Aguilar-Salinas¹, Y. Ro², H.-F. Tse³, L. G. Howes⁴, H. Chaves⁵, S. Erdine⁶, R. Guindy⁷, P. Chopra⁸, R. A. Moller⁹, I. M. Schou⁹;¹Department of Endocrinology and Metabolism, Instituto Nacional de Ciencias Medicas y Nutricion, Mexico City, Mexico, ²Sejong Medical Research Institute, Korea University, Bucheon, Republic of Korea, ³Department of Medicine, University of Hong Kong, ⁴Griffith and Bond University Medical Schools, Gold Coast, Australia, ⁵Health Science Centre, Federal University of Pernambuco, Boa Vista, Brazil, ⁶Cerrahpasa School of Medicine, Istanbul University, Turkey, ⁷Faculty of Medicine, Ain Shams University Cairo, Egypt, ⁸Pfizer Inc, New York, United States, ⁹Pfizer Australia, West Ryde, Australia.**Background and Aims:** Patients with diabetes frequently have additional risk factors such as hypertension (HTN) and dyslipidemia (DYS), greatly increasing their risk of cardiovascular disease. This planned analysis of the GEMINI-AALA study evaluated the utility of single-pill amlodipine besylate/atorvastatin calcium for the attainment of blood pressure (BP) and lipid goals in diabetic patients of diverse ethnicity with HTN and DYS.**Materials and Methods:** GEMINI-AALA was a 14-week, multicenter, open-label study in patients with HTN/DYS from 27 countries across 5 continents. Eight dosages of single-pill amlodipine besylate/atorvastatin calcium (5/10–10/80 mg) were administered and electively titrated at Weeks 6, 10 (titration optional), and 12. The percentage of patients who attained JNC 7 and NCEP ATP III goals for BP (<130/80 mm Hg) and low-density lipoprotein cholesterol (LDL-C) (<100 mg/dL) at Week 14 was assessed. Changes from baseline in BP and LDL-C were also measured.**Results:** Of the 1638 patients included in the intent-to-treat (ITT) population, 605 patients had type 2 diabetes. For diabetic patients, the mean dose of amlodipine besylate/atorvastatin calcium during the study was 6.2 mg/18.3 mg. Mean BP and LDL-C at baseline were 145.0/86.2 mmHg and 120.6 mg/dL, respectively. After 14 weeks treatment, 41.3% of diabetic patients reached both BP and LDL-C goals (0.0% at baseline), 46.3% reached BP goal (0.2% at baseline), and 84.6% reached LDL-C goal (30.6% at baseline). Mean BP reduction was 18.1/10.2 mmHg, and mean decrease in LDL-C was 40.5 mg/dL (27.5%). Attainment of both goals for the Middle East/Africa, Asia-Pacific, and Latin America was 33.7%, 45.1%, and 40.6%, respectively. Among diabetic patients, 4.3% discontinued due to adverse events.**Conclusion:** Amlodipine besylate/atorvastatin calcium single-pill therapy was an effective and safe intervention that helped diabetic patients of diverse ethnicity with combined HTN/DYS to achieve BP and LDL-C goals.

Activity of renin-angiotensin-aldosterone axis in salt-sensitive and salt-resistant hypertensive type 2 diabetic patientsS. D. Jelic¹, M. N. Zamaklar², Z. Caparevic¹, V. Ilic¹, S. Ilic¹;¹University Clinic for Internal Medicine, CHC "Dr Dragisa Misovic" - Dedinje, ²Institute for endocrinology, diabetes and metabolic diseases, School of Medicine, University of Belgrade, Belgrade, Serbia.**Background:** Most of the investigators agree that plasma renin activity and plasma aldosterone levels are lowered or suppressed in hypertensive type 2 diabetic patients, compared with healthy controls. However, possible interrelations between the activity of renin-angiotensin-aldosterone axis and salt-sensitivity in these patients are not still fully elucidated.**Aim:** To assess the activity of renin-angiotensin-aldosterone axis in hypertensive type 2 diabetic patients and its relationship with the salt-sensitivity.**Methods:** *Subjects:* 1) 45 (24 female/21 male) hypertensive type 2 diabetic patients mean (SD) age 48.91 (6.49) years; mean (SD) duration of diabetes 10.87 (5.33) years and mean (SD) duration of hypertension 11.53 (6.30) years. 2) 10 healthy controls (5 female/5 male), mean (SD) age 36 (4) years. The increment of mean arterial pressure on high salt (300 mmol Na/day) diet vs. low salt (40 mmol Na/day) diet exceeding 10 mm Hg was used as the criterion for salt sensitivity (SS). According to the given definition 23 (51.11%) of studied hypertensive type 2 diabetic patients were salt-sensitive.**Assays:** Plasma renin activity (PRA) and urine and plasma aldosterone (U-A and P-A) levels were measured by CIS radioimmunoassay. **Statistical analysis** was performed using the STATISTICA 4.5 program (StatSoft, Tulsa, OK, USA).**Results:** PRA [0.23 (0.12) vs. 0.30 (0.17) vs. 0.28 (0.08) pmol/L/s; F=1.45, p=0.24] and P-A [0.16 (0.07) vs. 0.22 (0.17) vs. 0.24 (0.08) nmol/l; F=2.04, p=0.14] levels did not differ significantly between salt-sensitive and salt-resistant (SR) hypertensive type 2 diabetic patients, as compared with healthy controls. Urinary aldosterone excretion was significantly lower in salt-resistant patients than in healthy controls [SS: 18.15 (7.73) vs. SR: 17.97 (7.00) vs. controls: 24.75 (4.73) nmol/24h; F=3.77, p=0.03]. At the same time, positive correlation of borderline significance that existed between PRA and P-A levels among healthy controls ($r = 0.63014$, $P = 0.050839$) was lost among salt-resistant hypertensive type 2 diabetic patients ($r = -0.035806$, $P = 0.874305$). Among salt-sensitive patients correlation between PRA and P-A levels was significant but negative ($r = -0.442672$, $P = 0.034405$).**Conclusions:** This study demonstrated that activity of renin-angiotensin-aldosterone axis in hypertensive patients with type 2 diabetes did not differ significantly between salt-sensitive and salt-resistant subjects. However, urinary aldosterone excretion was lower especially in salt-resistant patients and there were signs of distorted feed-back between renin and aldosterone in hypertensive type 2 diabetic patients, when compared with healthy controls. Whether this disturbance represents one of the possible causes of diabetic renal lesion or its consequence remains to be elucidated.

1165

Salt sensitivity is associated with insulin resistance, sympathetic overactivity in human essential hypertensionM. S. Yatabe¹, H. Sanada¹, J. Yatabe¹, Y. Kusano¹, S. Hashimoto¹, M. Otsuki², T. Watanabe¹;¹Internal Medicine III, Fukushima Medical University, Fukushima,²Internal Medicine, Asaka Medical clinic, Koriyama, Japan.**Background and Aims:** Derangement of glucose metabolism and high blood pressure are two of the hallmarks of metabolic syndrome, however the association between these metabolic parameters still remains unclear. As both high blood pressure and impaired glucose metabolism are heterogeneous conditions, focusing on the salt sensitivity and insulin resistance may yield more information to delineate and unravel this problem. In this study, we aimed to clarify the relationship between salt sensitivity and insulin resistance, along with the effects of sympathetic nervous system and renin-angiotensin system on non-obese, non-diabetic essential hypertensive individuals.**Materials and Methods:** Twenty-four subjects with untreated essential hypertension (12 males and 12 females, aged between 29–67 years) were enrolled into the study. The state of glucose metabolism was assessed by the means of hyperinsulinemic, euglycemic glucose clamp and 75 g OGTT. Glucose infusion rate (GIR) from the glucose clamp was used as an index for insulin resistance. The subjects were classified as salt-sensitive (SS) or salt-resistant (SR) according to the 24-hour ambulatory blood pressure monitoring performed during the periods of low-salt (34 mmol/day) diet and high-salt diet (252 mmol/day). Urinary norepinephrine was measured by HPLC method.**Results:** Of the 24 hypertensive subjects, 10 were found to be SS, whereas 14 were classified as SR. Compared to SS group, SR group showed higher serum insulin levels after glucose ingestion ($p < 0.01$ at 60, 90, 120 minutes). Euglycemic glucose clamp revealed lower GIR in SS group compared with SR group (5.1 ± 0.7 vs. 6.7 ± 0.4 mg/kg/min, $p < 0.01$). Salt sensitivity index, which is the MBP increase from low- to high-salt diet divided by the MBP upon a low-salt diet, showed an inverse linear relationship with GIR ($r = 0.64$). GIR also had a positive correlation with the change in urinary sodium excretion ($r = 0.66$), and SS subjects have significant lower sodium excretion compared to SR with a similar GIR. Decline in hematocrit ($r = 0.65$) upon low- to high-salt diet showed an inverse correlation between SS and SR. GIR showed a significant inverse correlation with the change in urinary norepinephrine excretion ($r = 0.55$). Sodium loading was considered to suppress the sympathetic activity, however, significantly higher activity was still remained in SS subjects than in SR upon a high-salt diet.**Conclusion:** We have demonstrated that salt sensitivity of blood pressure is strongly associated with insulin resistance. Hyperinsulinemia, sympathetic overactivation may play a role in the relationship between salt sensitivity of blood pressure and insulin resistance.

1166

Predictive value of insulinaemic status, insulin resistance, urinary total protein and urinary calcium in the subsequent development of pregnancy induced hypertension

R. Helal, F. Jebunnesa, A. Akhter, S. Akhter, L. Ali;

Dept of Biochemistry & Cell Biology, Bangladesh Institute of Research & Rehabilitation in Diabetes, Endocrine and Metabolic Disorders, Dhaka, Bangladesh.

Background and Aims: Pregnancy induced hypertension (PIH) is known to be an insulin resistant condition. There are still controversies regarding the suitable predictive markers for this disorder. Prospective studies are needed but these are relatively scarce and still inconclusive due to technical and ethical issues in measuring appropriate parameters during pregnancy. In the present study we have investigated whether insulinemic status, insulin resistance, urinary calcium (UCa) and urinary total protein (UTP) can be used as predictive markers for the future development of PIH.

Materials and Methods: A total of 127 Bangladeshi pregnant women participated in the study up to their end of pregnancy. Among them 15 women (age in yrs, $M \pm SD$, 26.2 ± 5.1) developed PIH. By a nested case-control design, 48 age- and parity-matched normotensive pregnant women as controls were randomly selected from among the Non-PIH subjects. Serum was collected in early pregnancy and stored at -70°C for future analysis. PIH was diagnosed by standard criteria; UCa and UTP were measured by photometric methods. Insulinemic status was assessed by fasting serum C-peptide (by chemiluminescent immunoassay). Insulin sensitivity (HOMA% S) was assessed by Homeostasis Model Assessment. The cut-off value for higher serum C-peptide was determined from the 75th percentile and the cut-off value for lower HOMA S was calculated from the 25th percentile. The Sensitivity, Specificity, Positive Predictive Value (PPV) and Negative predictive value (NPV) were assessed by using the McNemar test.

Results: The PIH group showed significantly higher C-peptide (mmol/l; $M \pm SD$, 2.04 ± 0.54), UTP (mg/dl, 1.2 ± 0.29) and UCa (mg/l 2.9 ± 1.05) as compared to Control [C-peptide, 1.6 ± 0.42 , $p < 0.02$; UTP, 0.91 ± 0.36 , $p < 0.01$; UCa, 1.56 ± 0.73 , $p < 0.01$] in the early pregnancy. HOMA-S was significantly lower in PIH (% $M \pm SD$, 24.4 ± 8.7) as compared to Control (29.7 ± 7.2 , $p < 0.04$). For predicting the future development of PIH in later stages the early pregnancy serum C-peptide showed a Sensitivity of 53%, Specificity 81%, PPV 47% and NPV 84%. The corresponding values for UTP were 46%; 79%, 41% and 82%; and those for UCa were (60%, 83%, 52% and 86%).

Conclusion: The positive and negative values of various parameters suggest that hyperinsulinemia, insulin resistance, urinary calcium, and urinary total protein in early pregnancy may be useful tools for predicting PIH in late pregnancy. Among the four predictive markers UCa seems to be the most reliable one.

Chronic hyperglycaemia increases TNF- α -stimulated adhesion molecule expression in human umbilical vein endothelial cells (HUVEC) from gestational diabetic womenA. Pandolfi¹, P. Di Tomo¹, A. Giardinelli¹, P. Di Fulvio², S. Di Silvestre¹, N. Di Pietro¹, G. Formoso², P. Lanuti¹, M. Marchisio¹, A. Consoli²;¹Department of Biomorphology, ²Department of Medicine and Aging Sciences, University G. d'Annunzio, Aging Research Center, Ce.S.I., Chieti, Italy.

Background and Aims: Diabetes mellitus is associated with inflammatory endothelium activation and monocyte interactions with vascular adhesion molecules exert a relevant role in the development of vascular complications. Inflammatory cytokines, such as TNF α , can upregulate adhesion molecules expression and, in diabetic patients, their effects might be enhanced by hyperglycemia. To test this hypothesis, we evaluated TNF α -stimulated adhesion molecules expression in cultured Human Umbilical Vein Endothelial Cells (HUVEC) from umbilical cords obtained at delivery from healthy women and women with gestational diabetes used as a model of chronic exposure to hyperglycemia in vivo.

Materials and Methods: TNF α (1 ng/mL)-stimulated adhesion molecules expression were determined in cultured HUVEC from umbilical cords obtained at delivery from 10 healthy women (C) and 10 women with gestational diabetes (GD). Vascular cell adhesion molecules (VCAM-1) and intercellular cell adhesion molecules (ICAM-1) protein levels were evaluated by Western Blot; adhesion molecules surface expression was measured by biparametric flow cytometry analysis.

Results: After 12 hours of stimulation, TNF α -induced VCAM-1 protein levels were increased 8.8 fold in GD- and 3.5 in C-HUVEC (GD- expressing 37% more VCAM-1 than C-HUVEC); in the same conditions, GD- and C-HUVEC did not show any differences in ICAM-1 protein levels (4.6 and 4.7 folds increased in GD- and C-HUVEC respectively). Flow cytometry analysis demonstrated that 16 hours exposure to TNF α induced higher percentage of positive cells for VCAM-1 in GD-HUVEC (39%) as compared to C-HUVEC; in the same conditions no differences in percentage of positive cells for ICAM-1 were detected.

Moreover, VCAM-1 MFI Ratio (Mean Fluorescence Intensity) was higher in GD-HUVEC as compared to C-HUVEC after both 12 (26%) and 16 (48%) hours of TNF α stimulation; a similar result was obtained for ICAM-1 (21% and 56.8% respectively).

Conclusion: These data demonstrated that chronic exposure to hyperglycemia in vivo results in enhanced TNF α ability to elicit expression of potentially pro-atherogenic molecules such as VCAM-1 and ICAM-1 in cultured endothelial cells.

Linoleic acid increases TNF- α -induced monocyte adhesion to human aortic endothelial cells via Cox-2 and PKC

N. Matesanz, V. Jewhurst, L. A. Powell, E. R. Trimble;

Clinical Biochemistry and Metabolic Medicine Department, Queen's University Belfast, United Kingdom.

Background and Aims: Atherosclerosis is the main cause of increased mortality and morbidity in diabetes. It is initiated by endothelial dysfunction which involves the recruitment of circulating monocytes to the endothelium. This process is regulated by inflammatory mediators including adhesion molecules (E-selectin, VCAM-1, ICAM-1), cytokines (e.g. TNF- α), and signalling molecules (e.g. Cox-2, PKC). In diabetes, in addition to disturbances in glucose homeostasis, there is impairment of fatty acid metabolism which results in increased free fatty acids in the bloodstream. The aim of this work was to analyze the effects of linoleic acid, the main dietary fatty acid in a Western diet, on glucose-treated endothelial cells.

Materials and Methods: Human endothelial cells were cultured in 5 mM (NG) or 25 mM (HG) glucose (5% FCS) for six days. On the third day, linoleic acid (LA; 0.2 mM) was added using fatty acid free-bovine serum albumin

as a carrier. To mimic an inflammatory state, cells were stimulated with TNF- α (10 ng/ml; 4 hrs) before extraction. Cells were also treated with Cox-2 (indomethacin 10 μ M; 4 hrs) or PKC inhibitors (Ly397196 30 nM, 5 hrs; rottlerin 1 μ M, 4 hrs). Monocyte adhesion was assessed using fluorescently labelled THP-1 and fluorescence microscopy. Protein expression was quantified by ELISA and western blotting.

Results: TNF- α induced an increase in monocyte adhesion in NG and HG conditions ($p < 0.05$). This was accompanied by increased cell surface expression of E-selectin, ICAM-1 and VCAM-1 ($p < 0.05$). Treatment with LA further increased endothelial cell surface adhesion molecule expression ($p < 0.05$). The Cox-2-inhibitor indomethacin (10 μ M) prevented LA-induced monocyte adhesion ($p < 0.05$). LA enhanced PKC- δ isoform protein levels in HG ($p = 0.05$). Finally, PKC- δ inhibitor rottlerin (1 μ M) and PKC- β 1i inhibitor Ly397196 (30 nM) inhibited the LA-induced increase in E-selectin in HG and ICAM-1 surface expression in HG both glucose conditions ($p < 0.05$), and on VCAM-1 and E-selectin expression in NG ($p < 0.05$), respectively, confirming the role of PKC in this process.

Conclusion: The pro-inflammatory effects of linoleic acid may be mediated via Cox-2 and PKC isoforms.

Aspirin inhibit adhesion molecules expression and MMP-2 activity in resistin-induced endothelial dysfunction

W. H. H. Sheu¹, C.-M. Wu¹, W.-J. Lee², C.-S. Wu¹, I.-T. Lee¹;

¹Endocrinology and Metabolism, ²Research and Medical Education, Taichung Veterans Gen Hospital, Taichung, Taiwan.

Background and Aims: Obese subjects are characterised by dysregulated adipocytokines which cause endothelial dysfunction and vascular inflammation. Resistin, one of adipocytokines, has been shown to induce endothelial proliferation and upregulate several proinflammatory cytokines and adhesion molecules. However, the beneficial effects of aspirin, a well-known anti-inflammatory agent, on resistin associated with increased inflammation cytokines and adhesion molecules expressions, NO synthase and matrix metalloproteinase 2 (MMP-2) activity from endothelial cells are largely unstudied.

Materials and Methods: NF- κ B activity, measured by EMSA, expression of mRNA and protein levels of MCP-1, IL-6, IL-8, ICAM, VCAM, E-selectin and eNOS, detected by real time PCR and/or ELISA, MMP-2 activity, measured by zymography, were studied with resistin (100 ng/ml) in human umbilical vein endothelial cells (HUVEC) pretreated with aspirin 500 μ g/ml.

Results: Resistin induced increased activity of NF- κ B by 34.5 % ($p < 0.05$) in HUVEC, which was inhibited when pretreated with aspirin for 2 hours. Expression of mRNA of MCP-1, IL-6, IL-8, ICAM, VCAM and E-selectin were elevated by stimulation of resistin (all $p < 0.05$). All these increased expressions reduced significantly after pretreated with aspirin except in MCP-1. Protein concentrations of MCP-1, IL-6, IL-8, ICAM, VCAM and E-selection in the supernatant of HUVEC increased by 58.8%, 47.5%, 27.0%, 51.4%, 58.3% and 263.0%, respectively (all $p < 0.05$) after incubated with resistin, whereas these proteins reduced significantly after aspirin administration. Resistin reduced eNOS protein expression by 26.9% and elevation of MMP-2 activity by 21.3 % in HUVEC, which could be reversed after administration of aspirin.

Conclusion: We demonstrated that resistin induced enhancing expression of mRNA and proteins levels of MCP-1, IL-6, IL-8, VCAM, ICAM, and E-selectin presumably through activation of NF- κ B. Except in mRNA of MCP-1, all these detrimental effects could be reversed by treatment of aspirin. Aspirin also ameliorated resistin reduced eNOS protein and higher MMP-2 activity in human endothelial cells. Our findings further establish the cross-link between adipocytokines and endothelial dysfunction and shed light on protective effects of aspirin in obese individuals.

The eliminating effects of a prescribed traditional Chinese medicine preparation on endothelium derived superoxide anion and its molecular mechanism

X. Gao, B. Zhang;

Endocrinology & Metabolism, Zhongshan Hospital, Shanghai, China.

Background and Aims: Our previous study has revealed that a prescribed traditional Chinese medicine preparation (TCMP) can potentially eliminate oxygen radicals in vitro and can improve microvascular endothelial cells growth in high glucose medium with similar effect to NAC. This study was to investigate its effect on endothelium-derived superoxide anion and possible molecular mechanism.

Materials and Methods: Microvascular endothelial cells (bEnd.3 strain) were cultured in 10% fetal bovine serum media with 5.6mM glucose (NG group), 35mM glucose(HG group), 35mM glucose and TCMP with working concentration at 1:100 in volume(TCMP group), 35mM glucose and 10mM NAC(NAC group), and 35mM glucose and SOD(working concentration: 400 IU/ml) (SOD group) respectively. Electronic paramagnetic resonance (EPR) together with spin trap technique was applied to determine reactive oxygen species (ROS) in each group. ROS in 35mM glucose culture medium without endothelial cells (blank group) and methylated free radicals in endothelial cells cultured in a medium with 35mM glucose and 10mM DMSO (DMSO group) were also determined to differentiate the origin of ROS. Spin trapper DPMO with a working concentration of 100mM were used in this study. The gene expression of MAPK, TNF- α , UCP-1,UCP-2, and UCP-3 in NG, HG, TCMP, and NAC group was quantitatively analyzed by real-time RT-PCR and the content of UCP-2 protein molecule in each group was analyzed by Western blot analysis.

Results: Apparent hydroxyl free radical signals with an peak-to-peak amplitude of 2.0×10^4 were detected in HG group cells in EPR spectrometer examination while no obvious ROS signal in NG group cells or blank group was observed. This indicated that the detected signals of hydroxyl free radicals were from endothelial cells and due to high glucose level in culture media. The peak-to-peak amplitude of hydroxyl free radical signals in SOD group decreased to 9.63×10^3 and no identifiable signal of methylated free radicals appeared in DMSO group. This suggested the detected hydroxyl free radical by EPR spectrometer came from superoxide anions produced by endothelial cells in high glucose media. The peak-to-peak amplitude of hydroxyl free radical signals in TCMP and NAC group were 6.97×10^3 and 1.11×10^4 respectively, indicating TCMP had an effect similar to SOD. Levels(mean \pm SD) of UCP-2 gene expression in NG, HG, TCMP, and NAC group were 2.920 ± 0.028 , 3.500 ± 0.212 , 4.070 ± 0.099 , and 3.875 ± 0.050 respectively (ANVOA, $p = 0.002$; HG vs NG, $p = 0.009$; TCMP vs NG, $p = 0.001$; TCMP vs HG, $p = 0.009$; TCMP vs NAC, $p = 0.181$) whileas no significant difference was observed in gene expression of MAPK, TNF- α , UCP-1 and UCP-3 among the four groups (ANVOA, $p = 0.57$, 0.223 , 0.129 , and 0.447 respectively). Western blot analyses also showed that UCP-2 in HG group, compared with NG group, was up-regulated, and was further up-regulated in TCMP group.

Conclusion: TCMP can extinguish superoxide anion produced by endothelial cells cultured in high glucose milieu and this effect may partially relate to upregulation of UCP-2 molecule, which plays a role in reducing mitochondrial superoxide anion production through lowering transmembrane electrochemical proton gradient.

Mitochondrial DNA oxidation and MnSOD activity in peripheral blood mononuclear cells from type 2 diabetic patients

M. Garcia-Ramirez¹, G. Francisco¹, E. Garcia-Arumi², C. Hernandez¹, A. L. Andreu², R. Simo¹;

¹Diabetes Research Unit, ²Centre d'Investigacions en Bioquímica i Biologia Molecular, Institut de Recerca Hospital Universitari Vall d'Hebron, Barcelona, Spain.

Background and Aims: Mitochondrial DNA (mtDNA) is markedly vulnerable to oxidative stress, resulting in both qualitative and quantitative changes. These changes can impair cell function and participate in the apoptosis mediated by hyperglycemia that occurs in the target tissues suffering from late diabetic complications. The aim of the study was to investigate the

balance between parameters of oxidative stress and antioxidant defenses in the mitochondria of peripheral blood mononuclear cells (PBMCs) of type 2 diabetic patients with late complications

Materials and Methods: Ten type 2 diabetic patients with late diabetic complications and ten age-matched healthy volunteers (control group) were prospectively recruited. Mitochondrial DNA (mtDNA) oxidative damage and mtDNA content were measured as indices of oxidative stress. Manganese superoxide dismutase (MnSOD) activity has been used as an index of mitochondrial antioxidant defense. Finally, mitochondrial respiratory chain function (cytochrome C oxidase activity) was also assessed.

Results: mtDNA oxidation was significantly higher in the PBMCs of diabetic patients than in control subjects ($p < 0.0001$). mtDNA content was lower in the diabetic group but without statistical significance. MnSOD activity was significantly increased in PBMCs of type 2 diabetic patients as compared with healthy controls (1366 ± 187 vs. 686 ± 167 U/g protein, $p=0.01$), and it was related to mtDNA oxidative damage. No differences in mitochondrial respiratory chain function were found between diabetic patients and the control group.

Conclusion: PBMCs from type 2 diabetic patients with late diabetic complications exhibit high mtDNA oxidative damage. The degree of mtDNA oxidation was associated with a reduction of mtDNA content as well as an increase of MnSOD as an adaptive response against oxidative stress. The consequences of mtDNA oxidative damage on PBMC function and in the progression of diabetic complications remain to be elucidated.

Glucose-potentiated vascular smooth muscle cell (VSMC) migration to angiotensin II is modulated through PKC $_{\beta 1}$ -dependent protein phosphatase (PP) 2A activation

M. Campbell¹, J. Mussen¹, L. A. Powell¹, E. R. Trimble^{1,2};

¹Clinical Biochemistry & Metabolic Medicine, Queen's University,

²Clinical Biochemistry, Royal Group of Hospitals, Belfast, United Kingdom.

Background and Aims: Atherosclerosis occurs prematurely in diabetic subjects. A key event in atheroma formation is VSMC migration into, and subsequent retention within, the cytokine-rich plaque. *In vitro*, a rise in glucose concentration lowers the threshold at which angiotensin II causes VSMC migration; thus, with glucose ≥ 10 mM, VSMC migrate to circulating levels of angiotensin II (10 nM). However as angiotensin II levels increase migration is lost. The aim of this work is to identify those glucose-potentiated pathways which prevent VSMC migration to elevated levels of angiotensin II, which may therefore promote VSMC retention within hyperglycaemic plaques.

Materials and Methods: Explant-derived VSMC were exposed to normal glucose (5 mM: NG) or high glucose (10–25 mM for 6–18 h: HG) conditions and circulating or raised (<100 nM) angiotensin II levels \pm inhibitors. Migration was assessed using the Dunn chamber (cyclical statistics). Western blots and commercial activity assays were carried out on whole cell lysates (ANOVA and Student's t-test).

Results: Migration in NG without/with 20 mM L-glucose was only detected for cells exposed to high angiotensin II levels (20–30 nM; $p < 0.01$). Migration in HG (10–25 mM) conditions occurred to circulating angiotensin II levels (10 nM; $p < 0.01$) but was lost at higher levels (≥ 15 nM; $p = \text{ns}$).

Migration to angiotensin II (1–100 nM) was prevented by inhibition of Angiotensin II Type 1 receptor (Losartan: 10 nM) or ERK/MAPK pathway (PD98059: 10 μ M; Pravastatin: 10 nM) in NG or HG. Glucose, through aldose reductase-dependent *de novo* synthesis of diacylglycerol, activates PKC $_{\beta 1}$ in VSMC. As expected aldose reductase pathway inhibition (Alrestatin: 12 μ M) had no effect on migration in NG. Aldose reductase or PKC $_{\beta 1}$ (LY379196: 200 nM) inhibition prevented migration to 10 nM angiotensin II in HG; crucially both inhibitors restored migration at 15 nM angiotensin II in HG ($p < 0.01$). Phosphatases are key negative regulators of signalling pathways and may be responsible for the loss of migration at high angiotensin II levels. PP2A is a target of Angiotensin II type 2 receptor signalling, can be activated by PKC, and inhibits ERK MAPK signalling. Angiotensin II type 2 receptor (PD123319: 10 nM) or PP2A (Endothall: 90 nM) inhibition permitted migration at both 10 and 15 nM angiotensin II in HG and at 30 and 35 nM in NG. Other protein phosphatase or protein tyrosine phosphatase inhibitors had no effect compared to solvent controls.

It was predicted that in HG PKC $_{\beta 1}$ may augment the Angiotensin II type 2 receptor-dependent activation of PP2A and so inhibit ERK signalling and migration. PP2A activity (activity assay) was significantly decreased in 15 nM angiotensin II conditions in HG by PKC $_{\beta 1}$ or Angiotensin II type 2 receptor inhibition ($p < 0.01$ for both) while PP2A inhibition significantly increased ERK activity under these conditions (ERK activity assay: $p < 0.01$).

Conclusion: Loss of glucose-potentiated migration at moderately raised levels of angiotensin II is due to PKC $_{\beta 1}$ -dependent PP2A activation which inactivates ERK1/2 and prevents migration.

Multifactorial treatment increases circulating endothelial progenitor cell number in type 2 diabetic patients

H. Reinhard¹, P. K. Jacobsen¹, M. Lajer¹, N. Billestrup¹, T. Mandrup-Poulsen^{1,2}, J. Kastrup³, H.-H. Parving⁴, P. Rossing¹;

¹Steno Diabetes Centre, Gentofte, Denmark, ²Department of Molecular Medicine, Karolinska Institutet, Stockholm, Sweden, ³The Heart Centre, Rigshospitalet, University Hospital of Copenhagen, Denmark,

⁴Department of Medical Endocrinology, Rigshospitalet, University Hospital of Copenhagen, Denmark.

Background and Aims: Circulating bone marrow-derived endothelial progenitor cells (EPC) augment vascular repair and neovascularisation. A reduced number of circulating EPC has been suggested to play a role in the progression of cardiovascular disease. Type 2 diabetic patients suffer from an increased risk of cardiovascular disease; this risk is reduced with multifactorial intervention. The aim of our study was to evaluate how EPC numbers in type 2 diabetic patients are influenced by multifactorial treatment.

Materials and Methods: We enrolled 8 type 2 diabetic patients (mean age: 55, known diabetes duration: 4.6 years) referred to Steno Diabetes Centre for initiation of multifactorial treatment. This included improving glycaemic control, lipid lowering, antihypertensive and antithrombotic therapy and lifestyle modification. The number of EPC was assessed by *in vitro* cultures and by flow cytometry analysis at baseline and after 30 days of treatment. Mononuclear cells were isolated from peripheral blood, using a Ficoll density gradient centrifugation.

1) Cells were seeded on plates coated with human fibronectin in endothelial basal medium. After 7 days in culture, we performed fluorescent chemical detection of the attached cells using 1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine-labelled acetylated low density lipoprotein (aLDL-DiI) and fluorescein isothiocyanate-labelled *Ulex europaeus* agglutinin-1 (UEA-1) for cell staining. We counted double-stained cells for both UEA-1 and aLDL-DiI as EPC in 10 randomly selected fields in each patient at each visit.

2) Numbers of EPC were also assessed by flow cytometry. Fluorochrome labelled monoclonal antibodies against human CD34Fic, CD133APC, VEGFR-2 and CXCR4PE-CY5 were used to identify EPC.

Results: All patients started 75 mg aspirin and 40 mg simvastatin therapy between first and second visit. Two patients started angiotensin II receptor blockers. HaemoglobinA_{1c} declined from 7.8% (SD 1) to 7.5% (SD 0.9) $p < 0.012$ total cholesterol decreased from 4.9 mmol/l (SD 0.77) to 3.7 mmol/l (SD 0.7) $p < 0.01$, systolic blood pressure from 137 mmHg (SD 9) to 133 mmHg (SD 12) (ns) and diastolic blood pressure from 90 mmHg (SD 5) to 85 mmHg (SD 6) $p < 0.066$. There were no changes in body weight or smoking habits. Multifactorial intervention significantly increased the EPC number *in vitro* cultures by 41% from 83 (SD 43) cells per field to 117 (SD 39) ($p < 0.037$). EPC defined by CD34/CD133 increased non-significantly by 58% from 1.54 (SD 0.98) to 2.43 (SD 1.9) $\times 10^3$ /ml ($p = 0.29$) and EPC defined by CD34/CXCR-4 increased non-significantly by 21% from 1.11 (0.43) to 1.34 (0.88) $\times 10^3$ /ml ($p = 0.46$). EPC defined by CD34/VEGF-2 was unchanged from 0.76 (SD 0.53) to 0.77 (SD 0.57) $\times 10^3$ /ml (ns).

Conclusion: Our preliminary data demonstrates that EPC assessed by *in vitro* cultures increased significantly by multifactorial intervention in type 2 diabetic patients. These changes may contribute to the beneficial effects of multifactorial intervention on cardiovascular risk profile. The changes observed by flowcytometri were not significant, possibly due to a low number of experiments.

1174

Diabetes impairs the number of Bradykinin-sensitive circulating stem cellsN. Kraenkel^{1,2}, V. Adams³, M. Schönauer⁴, P. Madeddu^{1,2};¹Bristol Heart Center, University of Bristol, United Kingdom,²Instituto Nazionale di Biosistemi e Biostrutture, Roma, Italy,³Dept. of Cardiology, University of Leipzig, Germany,⁴Diabetes-Schwerpunktpraxis Leipzig, University of Leipzig, Germany.

Background and Aims: Reduced availability of vascular and endothelial progenitor cells (VPC) has been associated with an increased incidence of ischaemic complications in diabetic patients. In the past we demonstrated that adenoviral overexpression of human tissue kallikrein (hTK) is able to rescue diabetes-induced impairment of revascularisation in a mouse model of hindlimb ischaemia. However, the underlying mechanisms of hTK-facilitated neovessel growth are not well understood. We therefore investigated the hypothesis that bradykinin (BK), the physiologic product of hTK serves as a chemoattractant for VPC and that BK-signalling in VPC is impaired in diabetic patients.

Materials and Methods: Mononuclear cells (MNC) were isolated from peripheral blood of healthy (H; n=10) and diabetic donors (D; n=7). Expression of components of the kallikrein-kinin system were analysed by RT-PCR and flow cytometry. Furthermore, migration of VPC towards BK was studied in the presence or absence of BK-receptor antagonists using a modified Boyden chamber assay and scratched wound assay. The abundance of VPC expressing the BK-B2-receptor (B2R) was analysed by flow cytometry. BK-responsive cells were isolated from total blood MNC and the ability to give rise to endothelial cells was studied in an outgrowth assay in the BK-responsive and non-responsive cell fractions.

Results: Expression of kininogens, B2R and TK was present in VPC. In healthy subjects, the B2R was coexpressed on 71.5±3.6% of circulating CD133⁺ cells and in 53.3±4.4% of circulating CD34⁺ cells. The majority of B2R expressing VPC obtained from healthy individuals was also positive for the SDF-1 receptor CXCR4 (72.5±4.9% of CD133⁺B2R⁺ cells and 78.1±3.0% of CD34⁺B2R⁺ cells). KDR was coexpressed in a smaller subfraction of B2R expressing VPC (26.5±7.8% of CD133⁺B2R⁺ cells and 3.6±0.7% of CD34⁺B2R⁺ cells). In diabetic patients, coexpression of B2R on VPC was decreased (65.3±4.6% of CD133⁺ cells, p=n.s. vs. (H group) and 35.1±2.8% CD34⁺ cells; p=0.002 vs. H). A reduced number of circulating CXCR4⁺ coexpressing B2R⁺ cells was furthermore detected in D subjects (p=0.01 vs. H). VPC migrated dose-dependently towards BK. BK-induced migration was significantly reduced in the presence of B2R antagonist icatibant and PI3-kinase inhibitor LY294002. In MNC migrating towards BK, a larger number of cells was able to give rise to endothelial cells (17.7±3.0%) as compared to the non-BK-responsive subpopulation (7.1±1.7%; p=0.01 vs. BK-responsive).

Conclusion: BK induced migration of VPC might represent a novel alternative signalling pathway mediating circulating stem cell recruitment to facilitate vasculogenesis. Reduction of BK sensitive circulating VPC in diabetic patients might contribute to the development of ischaemic complications via reduction of neovascularisation.

Effects of C-peptide on several parameters of endothelial cell function in non diabetic healthy controls and in patients with type 1 diabetes during euglycaemic normo- and hyperinsulinaemic clampsB. Wilhelm¹, T. Forst¹, K. Ekberg², A. Pfuetzner¹, C. Ries¹, M. Kugler¹,K. P. Kreiselmeier³, J. Wahren³, M. M. Weber³;¹IKFE, Mainz, Germany, ²Creative Peptides, Stockholm, Sweden,³Endocrinology, University Hospital, Mainz, Germany.

Background and Aims: During the recent years, C-peptide, which is released from the pancreatic beta cells, has been assigned a couple of biological activities. C-peptide was shown to exert endothelial, vascular, renal and metabolic effects in patients with type 1 diabetes. The aim of this study was to determine the effect of C-peptide on several markers of endothelial cell function at different insulin concentrations.

Materials and Methods: 13 patients with diabetes mellitus type 1 (mean age 36.6 ± 11.8 years; diabetes duration 23.5 ± 11.0 years; HbA_{1c} 7.3 ± 0.7 %) and 13 non-diabetic healthy controls (C: age 27.3 ± 5.5 years) were randomized to an euglycemic clamp procedure with either low (0.25 mU/kg/body weight) or high dose (1 mU/kg/body weight) insulin infusion on two different days. After stabilizing blood glucose to a target level of 100 mg/dl for 120 minutes, C-peptide was infused in a concentration of 8 pmol/kg/min for another 120 min. At baseline (tc0), after 60 (tc60) and 120 (tc120) minutes blood was drawn for the determination of asymmetric dimethylarginin (ADMA) and cyclic guanosinmonophosphat (cGMP) as parameters of endothelial function.

Results: C-peptide infusion resulted in comparable plasma levels of C-peptide in either group (DM 14.9 ± 4.9; C 16.1 ± 2.9 ng/ml; n.s, mean ± SD). In non-diabetic healthy controls cGMP and ADMA decreased especially during low dose insulin infusion (low dose insulin cGMP: -0.67 ± 0.7 pmol/ml, p<0.01; ADMA: -29.7 ± 107.3 nmol/l, p<0.001; high dose insulin cGMP: -0.54 ± 1.06 pmol/ml, p=0.08; ADMA: -42.8 ± 81.8 nmol/l, p=0.07). In patients with diabetes mellitus type 1 similar, but less pronounced effects were detectable (low dose insulin cGMP: -0.36 ± 0.96 pmol/ml, n.s; ADMA: -56.1 ± 190.2 nmol/l, n.s; high dose insulin cGMP: -0.47 ± 0.74 pmol/ml, p<0.05; ADMA: -9.6 ± 158.8 nmol/l, n.s).

Conclusion: In the setting of an euglycemic clamp procedure the substitution of C-peptide resulted in a decrease of cGMP and ADMA plasma concentrations. These effects were more pronounced in the non diabetic healthy control subjects and partly antagonized by insulin.

1176

Postprandial endothelial dysfunction, hyperglycaemia and hyperinsulinaemia in insulin resistance: is there a link?A. Major-Pedersen¹, N. Ihlemann¹, T. S. Hermann¹, B. Christiansen¹,H. Dominguez¹, B. Kveiborg¹, D. Nielsen¹, C. R. Madsen², L. Køber³,C. Torp-Pedersen¹;¹Cardiology, Bispebjerg Hospital, Copenhagen, Denmark,²Joslin Diabetes Center, Boston, United States,³Cardiology, Rigshospitalet, Copenhagen, Denmark.

Background and Aims: Postprandial hyperglycemia is considered an independent risk factor for cardiovascular disease, even before the development of overt diabetes. We aimed to determine if attenuation of postprandial hyperglycemia (with nateglinde administration – an oral antidiabetic of ultra-rapid action that stimulates postprandial first-phase insulin secretion) during three months could diminish endothelial dysfunction, one of the earliest markers of atherosclerosis.

Materials and Methods: We assessed post-oral glucose load endothelial function in 56 insulin-resistant subjects with impaired glucose tolerance (IGT) [Homeostasis Model Assessment (HOMA) 6.41 ± 0.7; body mass index (BMI) 34.4 ± 5.68 kg/m; Oral Glucose Tolerance Test (OGTT): 0 min 6.2 ± 1.0 mmol/l and 120 min. 11.9 ± 2.7 mmol/l; HbA1C 6.4 ± 0.82 %; waist circumference 115.8 ± 20.5 cm; age 57.5 ± 7.3 years], randomized

to either intervention or time control group, at baseline (**day 1**) and after 3 months (**day 4**). Subjects in the intervention group received an initial dose of nateglinide (NAT) on a second day (**day 2**), 10 min. before oral glucose load and during a 3 month study period. Thereafter, these subjects met for a last NAT dose (**day 3**) on which acute and chronic effect of NAT was measured. Chronic NAT effect was measured on day 4. Flow-mediated dilation (FMD) technique was used to measure endothelial function.

Results: The following postprandial Delta FMD values (fasting FMD value subtracted from postprandial FMD value) \pm SEM were seen in intervention and control groups respectively: $[(-3.42 \pm 1.67\%) p = 0.04$ and $-2.20 \pm 1.19\%) p = 0.07]$. On day 2, when NAT was administered 10 min. prior to glucose-load in the intervention group, Delta FMD values increased to $2.32 \pm 1.45\%$, $p = 0.02$. After 3 months NAT treatment postprandial delta FMD values were significantly impaired both on day 3 and day 4 $[(-2.09 \pm 0.80) p=0.01$ and $(-4.25 \pm 1.15) p=0.001]$. The following delta glucose values (fasting glucose value subtracted from postprandial glucose value) were seen on day 1, day 2, day 3 and day 4 respectively in the intervention group: $[(6.41 \pm 0.5), (4.22 \pm 0.45), (4.12 \pm 0.5)$ and (5.83 ± 0.5) . Blood glucose levels in the control group resembled values on day 1 and day 4 in the intervention group. We found no influence of the different blood glucose concentrations on FMD. There was a steep rise in postprandial insulin concentrations on day 2 and day 3 in the intervention group compared to day 1 and day 4 in both groups. On day 2 the fall in insulin concentration was sharper after 2 hours post glucose load, while insulin fall on day 3 was blunted.

Conclusion: We found no link between postprandial hyperglycemia and postprandial endothelial function. The enhancement of endothelial function observed after the initial NAT dose could be due to restoration of first phase insulin secretion, while deterioration of endothelial function observed after 3 months NAT treatment, could be due to sustained hyperinsulinemia. These surprising findings suggest that hyperinsulinemia might be tighter linked to endothelial dysfunction and atherogenesis, than is hyperglycemia.

Treatment of endothelial dysfunction with glimepiride + metformin in patients with type 2 diabetes mellitus: evaluation with positron emission tomography

E. Alexanderson¹, G. Alexanderson², C. Sierra¹, P. Cruz¹, J. Talayero¹, L. Garcia-Rojas¹, M. Rodriguez¹, A. Meave³;

¹PET Ciclotron Unit, Mexico National Autonomous University School of Medicine, ²Internal Medicine Department, Mexico General Hospital, ³Magnetic Resonance and Computed Tomography Department, Mexico National Cardiology Institute, Mexico.

Background: Diabetes Mellitus (DM) has been considered an important risk factor for coronary artery disease. Elevated levels of blood glucose are responsible for endothelial dysfunction (ED) in the coronary arteries. ED is considered the first step in the development of atherosclerosis. Therefore, its opportune identification and treatment can importantly change the natural course of the disease. Glimepiride + Metformin has been used for the treatment of DM2 with excellent results in the achievement of glyemic goals and prevention of chronic complications. ¹³N-ammonia PET has become a useful non invasive method for the identification of ED by quantifying the coronary blood flow (CBF) during rest, cold pressor test (CPT), and pharmacologic stress with adenosine. With these data it is possible to calculate the endothelial dependent vasodilation index (EDVI) which is the most important marker for ED ($EDVI = CPT\ CBF / rest\ CBF$), the coronary flow reserve ($CFR = stress\ CBF / rest\ CBF$) and the percentage of the change between rest and CPT ($\% \Delta CBF$). The aim of this study was to evaluate the effect of Glimepiride + Metformin in the endothelial function of patients with DM2.

Method: We enrolled 16 patients with recent diagnosis of DM2. The patients were randomized into two different groups, one group was treated with Glimepiride + Metformin (4mg/1000mg) daily for eight weeks and the other group was treated with Metformin 1000mg daily for 8 weeks. ¹³N-ammonia PET coronary blood flows were assessed after and before treatment. We compared the results of EDVI and MFR between both groups after treatment. Statistical analysis was performed using SPSS software v 13.0

Results: 62.5% (10) of all patients enrolled in this study showed ED prior to any treatment (EVDI Pre-Treatment was 1.21 ± 0.37 in the glimepiride/metformin group and 1.30 ± 0.29 in the metformin group with no significant differences between both groups). Patients treated with glimepiride/

metformin combination or metformin alone showed improvement in their endothelial function. The group treated with the combination had a greater improvement than those treated with metformin alone (EVDI Post Treatment 1.87 ± 1.02 and 1.51 ± 0.61 respectively, $p < 0.001$). We observed only a slight improvement in CFR after treatment with combination or metformin alone (2.74 ± 1.33 to 3 ± 1.21 and 2.42 ± 0.84 to 2.99 ± 0.96 $p = n.s.$)

Conclusions: ED is present in the majority of DM2 patients, even in the initial phases of the disease. Effective glyemic control is crucial to improve endothelial function. Combination therapy with glimepiride/metformin can improve the endothelial function in DM2 patients, offering better results than those achieved with metformin alone therapy. ¹³N-Ammonio PET is an excellent method for non invasive assessment of ED in patients with cardiovascular risk factors.

Rosiglitazone improves postprandially endothelial dysfunction in patients with type 2 diabetes

G. Ioannidis¹, S. Pastromas², S. Koulouris², D. Sakellariou², D. Tousoulis³, N. Zakopoulos⁴, A. Nikou¹, C. Stefanadis³, A. Manolis²;
¹Endocrinology, Diabetes and Metabolism, Hosp. "Evangelismos",
²1st Cardiology, Hosp. "Evangelismos", ³1st Cardiology of the University of Athens, Hosp. "Hippokraton", ⁴Therapeutic Clinics of the University of Athens, Hosp. "Alexandra", Athens, Greece.

Background and Aims: An oral fat load impairs brachial artery flow mediated dilatation (FMD) of both in healthy individuals and in patients with diabetes. Rosiglitazone ameliorates endothelial dysfunction (ED) in patients with type 2 diabetes. The aim of this study was to assess the effect of rosiglitazone on postprandially induced ED in these patients.

Materials and Methods: We enrolled 15 patients (7 men, 8 women) 62 ± 4 years old, with adequately controlled type 2 diabetes ($HbA_{1c} < 7\%$) with sulfonylureas or metformin and without clinical symptoms of cardiovascular disease. In all patients we assessed the lipidemic profile and the endothelial function before and after ingestion of an oral fat load (35 % weight/volume fat emulsion at a dose of 50 gr fat/m² body surface). The endothelial function was estimated by ultrasound measurement of brachial artery FMD. Then, in all patients rosiglitazone was added to their regimen at a dose of 4 mg / day and the same measurements of lipids and brachial artery FMD were repeated after 12 weeks of therapy.

Results: After oral fat meal ingestion, there was a postprandial reduction in HDL cholesterol levels which was significant during the baseline measurement (from 53.0 ± 12.2 mg/dl to 48.6 ± 11.8 mg/dl $p < 0.001$) but non – significant after the 12 – week rosiglitazone therapy (51.8 ± 12.9 mg/dl to 49.3 ± 10.7 mg/dl, $p = ns$). Postprandial FMD was significantly impaired during baseline measurements (from $11.5 \pm 5.2\%$ to $7.7 \pm 3.4\%$, $p = 0.03$) but remained essentially unchanged after rosiglitazone treatment ($12.8 \pm 4.4\%$ to $11.0 \pm 5.3\%$, $p = ns$).

Conclusion: Rosiglitazone seems to have beneficial effect in postprandial endothelial dysfunction as it appears to attenuate postprandial HDL reduction and prevents FMD impairment in patients with type 2 diabetes. This may have clinical implications in cardiovascular risk reduction conferred by the addition of rosiglitazone in these patients.

1179

Peripheral endothelial dysfunction and cardiac autonomic neuropathy in patients with type 2 diabetes

A. Belhadj-Mostefa¹, D. Roula¹, P. Valensi²;
¹Internal Medicine, CHU Constantine, Algeria,
²Department of Endocrinology-Diabetology-Nutrition, Jean Verdier Hospital, Bondy, France.

Background and Aims: Autonomic nervous system plays an important role in vasomotricity. Some data also suggest that it may change endothelium function. The aim of the present study was to examine the relationship between peripheral endothelium-dependent vasodilation and cardiac autonomic neuropathy in patients with type 2 diabetes.

Materials and Methods: 82 patients were included, mean age : 54.7 ± 8.4 years with a high cardiovascular risk : hypertension 61%, lipid disorders

52.4%, obesity 48%. Mean (SD) HbA1c was $8.1 \pm 1.9\%$. Cardiac autonomic neuropathy was assessed on three standardised tests for heart rate variations (deep-breathing, lying-to-standing, Valsalva). These tests were interpreted with age being taken into account. Peripheral endothelial function was assessed by post-occlusive hyperemia of the brachial artery and evaluated by the changes in blood flow velocity: $V2/V1 =$ one minute after occlusion removal/basal.

Results: Cardiac autonomic neuropathy was found in 64 patients. $V2/V1$ was 4.63 ± 1.75 . $V2/V1$ was significantly lower in the patients with cardiac autonomic neuropathy than in those without: 4.36 ± 1.68 vs 5.58 ± 1.70 ($p = 0.006$). There was no significant correlation between $V2/V1$ and HbA1c, age or BMI.

Conclusion: The present results suggest that cardiac autonomic neuropathy is associated with peripheral endothelial dysfunction in patients with type 2 diabetes. Since the alterations in heart rate variations during the tests we used are mainly indicative of a parasympathetic defect, a relative sympathetic override might be involved in the impairment of endothelial function.

1180

Daily glycaemic variability and arterial stiffness in type 1 diabetes

D. Gordin^{1,2}, C. Forsblom^{1,2}, M. Rönnback^{1,2}, V. Mäkinen^{1,2}, M. Saraheimo^{1,2}, P.-H. Groop^{1,2};

¹Folkhälsan research center, Folkhälsan Institute of Genetics, ²Helsinki University Central Hospital, Department of Medicine, Division of Nephrology, Helsinki, Finland.

Background and Aims: The DCCT demonstrated that glycaemic control is important in order to prevent diabetic microvascular complications. In contrast, hyperglycaemia has not unequivocally been proven a risk factor for macrovascular complications. Furthermore, it is not yet known whether it is the total glucose exposure or the glucose variability that is linked to diabetic complications. Therefore the objectives of this study were to investigate whether daily glycaemic variations influence blood pressure and arterial stiffness, an early sign of macrovascular disease, at baseline and during a hyperglycaemic clamp in patients with T1D.

Materials and Methods: Twenty-two male patients with T1D without any diabetic complications, and who were non-smokers participated in this study. The patients were monitored for 72 h using the continuous glucose monitoring system (CGMS). The CGMS records glucose concentrations in each patient every fifth minute. As an index of hyperglycaemic episodes we calculated the area under the curve for values exceeding 10 mmol/l (AUC-10) of each 24-h glucose profile. For low glucose excursions we used the area under the curve below 5 mmol/l (AUC-5). The mean amplitude of glycemic excursions (MAGE) was calculated to describe glucose fluctuations during the day. During a 2 h hyperglycaemic clamp (15 mmol/l), pulse wave analysis and pulse wave velocity (PWV) were performed. Correlation coefficients were calculated using the Pearson's, Kendall's tau-b or Spearman's tests. Values were adjusted for BMI and duration of diabetes in a multiple regression analysis.

Results: The subjects were young males (25.9 ± 5.6 years) with an intermediate glycaemic control (HbA_{1c} $7.4 \pm 0.9\%$). All of them had normal kidney function [eGFR 117 ± 6 ml/min per 1.73m^2 and AER 2.0 ($0.1\text{--}13.2$) mg/24h] and their duration of diabetes was 9.5 ± 4.4 years. There was no correlation between MAGE and arterial stiffness at baseline. However, there was a univariate correlation between MAGE and aortic DBP ($R = -0.48; P = 0.039$) at baseline but it disappeared after adjustment for BMI and duration of diabetes. Notably, there was no correlation between any of the other indices of glycaemic control and BP at baseline. There was also a correlation between mean daily glucose and aortic PWV after adjusting for BMI and duration of diabetes ($r = 0.46; P = 0.033$). Similarly, there was an independent correlation between AUC-5 and aortic PWV ($r = -0.62; P = 0.001$), but not between AUC-10 and aortic PWV. MAGE correlated independently with differences in aortic SBP ($r = 0.52; P = 0.014$) and aortic DBP ($r = 0.49; P = 0.037$), and AUC-10 with aortic DBP ($r = 0.61; P = 0.010$) during the clamp. None of the measures of glucose control correlated with any of the variables of arterial stiffness during the clamp.

Conclusion: This study suggests that high mean daily blood glucose but not glycaemic variability *per se* increases arterial stiffness in patients with T1D. Daily glycaemic variability and episodes of hyperglycaemia are positively associated with the central blood pressure during a hyperglycaemic clamp.

Vascular reactivity of brachial artery is altered in type 2 diabetes but unaltered by hyperchylomicronaemia

L. A. Groisne¹, A. Sérusclat², M. Ronze¹, A. Sassolas³, P. Moulin¹;

¹Endocrinologie-Diabétologie, ²Département d'Imagerie,

³Laboratoire de Biochimie, Groupement Hospitalier Est, Lyon-Bron, France.

Background and Aims: Vascular reactivity of brachial artery is considered as an early step in atherosclerosis and as an independent marker of cardiovascular risk. We studied hyperchylomicronemic patients with and without type 2 diabetes (D2) in order to establish the relative impact of both metabolic disease on early vascular alteration.

Materials and Methods: Prospective, unblinded study with longitudinal follow-up. Four groups were compared. Group CM ($n=10$): hyperchylomicronemic patients (history of TG > 15 mM, TG > 11 mm the day of the test) with metabolic syndrome (according NCEP-ATPIII), and insulin treated D2 ($5/10$), group CN ($n=7$): hyperchylomicronemic patients (history of TG > 15 mm, TG > 11 mm the day of the test) without metabolic syndrome: genetic LPL deficiency or alcohol ingestion, group ND ($n=12$): normo triglyceridemic (TG < 1.7 mm) patients with type 2 diabetes, group NN ($n=14$): normo triglyceridemic subjects free of cardiovascular risk factors. Flow mediated dilation response to hyperaemia of brachial artery (FMD) and carotid intima-media thickness (cIMT) were measured using a 8.0 MHz linear transducer.

Results:

	CM	CN	ND	NN
Age years	47±9	47±13	58±7	47±12
FMD %	7.08 ± 3.9	6.1 ± 3.2	3.9 ± 1.6	5.8 ± 2.4
cIMT mm	0.71±0.11	0.65±0.06	0.85±0.14	0.66±0.10

FMD was only decreased in group ND versus group CM ($p=0.016$). Additionally cIMT was significantly increased only in group ND (ANOVA $p < 0.001$). In univariate and multivariate analysis no correlation was found between triglyceridemia and FMD after adjustment for metabolic syndrome, age, tobacco, systolic arterial blood pressure and LDL cholesterol. In the longitudinal follow up ($n=$ six CM or CN), following the decrease of triglyceridemia < 5.6 mmol/l, FMD remained unchanged ($6.25 \pm 3.7\%$ vs $5.27 \pm 3.7\%$ $p=0.23$).

Conclusion: Whereas FMD and cIMT are altered in type 2 diabetes, there is no evidence for an FMD alteration in hyperchylomicronemic subjects with or without metabolic syndrome and D2. Our data suggest that A) hyperchylomicronemia does not induce a major alteration in vascular reactivity and B) that acute insulin treatment upon hyperchylomicronemia might alleviate the alteration in vascular reactivity observed in type 2 diabetes.

Mechanisms of platelet hyperreactivity in type 1 and type 2 diabetes

S. Giubilato¹, D. Pitocco², A. Leo¹, S. Riondino³, T. Musella², L. M. Biasucci¹, F. Crea¹, F. Pulcinelli³, G. Ghirlanda²;

¹Cardiology, Catholic University, ²Internal Medicine, Catholic University,

³Biochemistry, La Sapienza University, Rome, Italy.

Background and Aims: Evidences from clinical trials suggest that aspirin is less effective in reducing cardiovascular events in both type I and II diabetic patients, compared to nondiabetics. Despite of different pathogenetic and atherothrombotic implications, chronic hyperglycemia, in both diabetes types, could affect response to aspirin (ASA) in terms of impaired platelet membrane acetylation and protein glycation.

Materials and Methods: We sought to investigate TXA2 production following platelet stimulation with collagen and platelet COX-1 and COX-2 expression in 50 type II diabetics, in 15 type I diabetics and in 50 nondiabetics, all under chronic aspirin treatment

Results: TXA2 production in response to collagen was significantly higher ($p < 0.005$) both in type I (807.4 ± 280.5 pg/ 10^8 cells) and in type II (896.4 ± 232.3 pg/ 10^8 cells) diabetic patients compared to nondiabetics (130.5 ± 31.5 pg/ 10^8 cells). The in vitro addition of aspirin prior to stimulation reduced

collagen-induced TXA₂ formation (32.3 + 10.2 pg/10⁸ cells in type I and 46.3 + 9.6 pg/10⁸ cells in type II). Expression of both isoforms of cyclooxygenase, demonstrated that while COX-1 was highly expressed in all groups, COX-2 was expressed in all diabetic patients, both of type I and type II, analyzed but only in 40% nondiabetics, suggesting that the residual TXA₂ produced, might be consequent to COX-2 activation.

Conclusion: Our study demonstrates that both type I and type II diabetes are less sensitive to aspirin, due to a persistent TXA₂ production, compared to nondiabetics, suggesting a reduced inhibitory action on platelet COX-1 and the expression of platelet COX-2. Our data strongly suggest that an extensive protein glycation secondary to hyperglycemia may reduce aspirin ability to acetylate target platelet proteins in diabetic patients of both type I and II.

In vivo catabolism of glycated and glycoxidized LDL: a comparative study with LDL modified in vitro or LDL isolated from prediabetic and diabetic patients

J. Pietzsch¹, C. Haase¹, S. Hoppmann¹, S. Richter², J. Graessler³, S. Kopprasch³, U. Julius³;

¹Radiopharmaceutical Biology, Institute of Radiopharmacy, Research Center Dresden-Rossendorf, ²Radiopharmaceutical Chemistry, Institute of Radiopharmacy, Research Center Dresden-Rossendorf, ³Internal Medicine III, Carl Gustav Carus Medical School, University of Technology, Dresden, Germany.

Background and Aims: Modified LDL (modLDL) have been implicated in the pathogenesis of accelerated atherosclerosis in diabetes. Since atherogenesis already may occur at an early stage of diabetes, we investigated whether circulating LDL isolated from subjects with IGT (LDL-IGT) and newly diagnosed diabetes mellitus (DM; LDL-DM) showed an altered metabolic fate in vivo when compared with LDL isolated from subjects with NGT (nLDL) or LDL obtained from in vitro glycation (glycLDL-low/high) and glycoxidation (glycoxLDL-low/high) experiments.

Materials and Methods: We used a well-characterized methodology for radiolabeling of apolipoprotein B-100 of nLDL and modLDL with the positron emitter fluorine-18 (18F) by conjugation with N-succinimidyl-4-[18F]fluorobenzoate ([18F]SFB) and the use of 18F-radiolabeled LDL particles in dynamic positron emission tomography (PET) studies in male rats using a dedicated small animal PET camera. The extent of LDL apoB-100 modification was evaluated by sensitive gas chromatography-mass spectrometry analysis of highly specific products of oxidation and glycation of amino acid side chain residues.

Results: 18F-radiolabeling of nLDL and modLDL caused neither additional oxidative structural modifications of LDL constituents nor alteration of their biological activity and functionality in vitro, respectively. Dynamic PET data in rats demonstrated a significantly delayed catabolism of glycLDL when compared with nLDL (mean plasma retention time, RT; glycLDL-low/glycLDL-high: 5.2±0.6/6.1±0.7 h vs. nLDL: 3.4±0.5 h; p<0.05; n=10). In contrast, glycoxLDL showed a significantly enhanced catabolism when compared with nLDL (RT; glycoxLDL-low/glycoxLDL-high: 0.5±0.2/0.3±0.1 h; p<0.05; n=10). Imaging and functional characterization of in vivo distribution and kinetics of both nLDL and modLDL correlated well with the anatomical localization of LDL receptors, scavenger receptors, and receptors for advanced glycation end products in rats. Different interaction of modLDL with these receptors may discriminate modLDL particles in vivo into particles that show fast or low plasma clearance. In this line, LDL-IGT (RT; 4.2±0.4 h; p<0.05 vs. nLDL; n=10) and LDL-DM (RT; 4.7±0.6 h; p<0.05 vs. nLDL; n=10) mimicked the metabolic properties obtained with in vitro glycated LDL species, which underwent a similar extent of glycation and oxidation, respectively, as those isolated from subjects with IGT and newly diagnosed DM.

Conclusion: Radiolabeling of LDL with 18F and the use of small animal PET provides a valuable tool to discriminate the kinetics and the metabolic fate of different modLDL particles in animal models in vivo. We suggest that, in particular, glycation of LDL even in an early stage of diabetes contributes to a diminished catabolism of LDL and, thus, to accelerated atherogenesis in IGT and newly diagnosed DM.

Glycated elastin and anti-elastin antibodies in patients with type 2 diabetes mellitus

M. K. Petkova¹, S. Ganeva¹, G. Nikoloff²;

¹Clinic of Endocrinology, University Hospital,

²Department of Biology, Medical University, Pleven, Bulgaria.

Background: Accumulation of advanced glycation end-products (AGE) in the arterial wall plays a key role in the pathogenesis of micro- and macrovascular complications in patients with diabetes mellitus (DM). Identification

of glycosylated proteins with different half-life may be used for evaluation of glycaemic control during certain time.

Aim of the study was to investigate the levels of: circulated elastin peptides (CEP), glycosylated elastin as a marker of AGE deposition, and anti-elastin antibodies (AEAB) in sera of patients with different duration of type 2 DM and in non-diabetic subjects.

Subjects and Methods: The levels of: circulated elastin peptides, glycosylated elastin, and AEAB in the sera of 32 patients with newly-diagnosed Type 2 DM and in 23 patients with 3 years-duration of Type 2 DM were measured. The results of diabetic patients were compared with these of 22 non-diabetic control subjects.

Results: Mean age of the patients with Type 2 DM and control subjects was not statistically different. The level of HbA1c was statistically significant higher in patients with newly-diagnosed type 2 DM compared to the patients with 3-years duration of the disease (11.5 ± 0.6 vs. $8.08 \pm 1.62\%$; $p < 0.005$). The levels of glycosylated elastin were significantly higher in both groups of diabetic patients compared to the controls ($p < 0.05$). There were not any statistically significant differences between the levels of glycosylated elastin in diabetic patients from both groups. The levels of AEAB were statistically significant higher in patients with 3-years duration of DM compared to the patients with newly-diagnosed DM and controls ($p < 0.05$). We found statistically significant positive correlation between the levels of HbA1c and glycosylated elastin in patients with type 2 DM from both groups.

Conclusion: The higher levels of glycosylated elastin in our patients with newly-diagnosed type 2 DM compared to the control subjects suggested that the processes of the protein glycation preceded the diagnosis of the disease. The positive correlation between levels of HbA1c and glycosylated elastin show that improvement of glycaemic control may prevent synthesis and accumulation of AGE's. Investigated glycosylated protein was long-lived and may be used for long-term glycaemic control evaluation.

Increased N ϵ -(carboxymethyl)-lysine (CML) levels in cerebral blood vessels of diabetic patients and in a (streptozotocin-treated) rat model of diabetes mellitus

A. W. van Deutekom¹, H. W. Niessen^{2,3}, C. G. Schalkwijk⁴, R. J. Heine¹, S. Simsek¹;

¹Department of Endocrinology/Diabetes Center, VU University Medical Center, Amsterdam, ²Department of Pathology, VU University Medical Center, Amsterdam, ³Department of Cardiac Surgery, VU University Medical Center, Amsterdam, ⁴Internal Medicine, Maastricht University Hospital, Maastricht, The Netherlands.

Objective: To evaluate the association between diabetes mellitus and the accumulation of advanced glycation end-products (AGE) in cerebral vessels.

Materials and Methods: Brain tissue samples were obtained by autopsy from 23 DM patients and 13 age-matched controls. In addition, we investigated brain tissue samples of 7 streptozotocin-induced diabetic rats and 6 nondiabetic control rats. We used an immunohistochemical staining method to examine the N ϵ -(carboxymethyl)-lysine (CML) immunoreactivity in the cerebral vessels.

Results: Staining intensity of CML was significantly higher in cerebral vessels of diabetic patients than in nondiabetic subjects. (1.16 ± 0.68 vs. 0.55 ± 0.18 score/cm²; $p < 0.005$) Furthermore, there was a similar significant difference in CML staining pattern between diabetic rats and nondiabetic control rats. (1.19 ± 0.42 vs. 0.27 ± 0.17 score/cm²; $p < 0.05$)

Conclusion: Accumulation of CML-modified proteins is significantly greater in the cerebral vessels of the diabetic patients than their age-matched controls. This association has been confirmed in the rat model. It may be possible that the excessive accumulation of AGE-modified proteins in the cerebral vasculature alters the local environment and microcirculation and thereby contributes to the development of cognitive impairments in diabetes. Therefore, additional study on the causal link between AGE accumulation and cognitive dysfunction and the potential benefits of AGE-blocking reagents is indicated.

Human EPCs and HUVECs exposed to high glucose: expression of antioxidative enzymes

L. Pucci¹, D. Lucchesi¹, M. Barsotti², R. Di Stefano², A. Balbarini², R. Miccoli¹, S. Del Prato¹, G. Penno¹;

¹Dept Endocrinology and Metabolism,

²Dept Cardiac, Thoracic and Vascular, University of Pisa, Italy.

Background and Aims: Adult bone marrow is a rich reservoir of tissue-specific stem and progenitor cells. Among these, a population of cells known as EPCs, endothelial progenitor cells, the precursors of mature endothelial cells, can be mobilized to the circulation and contribute to the neoangiogenic processes. Vascular diseases, including hypertension, diabetes and atherosclerosis, are characterized by elevated levels of reactive oxygen species (ROS). When the rate of ROS formation exceeds the capacity of the antioxidative defense system, a condition of oxidative stress occurs which can lead to cell death and genetic instability. Since recent studies demonstrated that EPCs are more resistant to oxidative stress than HUVECs, we analysed the expression of intracellular antioxidative enzymes catalase (CAT), glutathione peroxidase (GPX1) superoxide dismutase (SOD2) and expression of the transforming growth factor-beta 1 (TGF-beta1) in human EPCs and HUVECs exposed to constant high glucose.

Materials and Methods: We studied the expression profile of the antioxidative enzymes by real-time PCR. Human EPCs, isolated from peripheral blood mononuclear cells of healthy donors, and HUVECs, isolated from fresh umbilical cords, were exposed over a 96 hours period to following experimental conditions: C, control, constant exposure to 5 mM D-glucose; LG20, osmotic control, constant exposure to 20 mM L-glucose + 5mM D-glucose; HG25, high constant exposure to 25 mM D-glucose.

Results: The results are expressed as means \pm SD as fold increase in control mRNA. In EPCs the transition from 5 (C) to 25 mM D-glucose (HG25) induced an increase of 1.87 ± 0.39 fold in the expression of GPX1; 1.40 ± 0.55 in SOD2 mRNA levels; the levels of catalase mRNA was not significantly affected (1.32 ± 0.25). No increase in TGF-beta1 mRNA expression was observed (1.06 ± 0.23). The exposure of HUVECs to 25 mM D-glucose or 20 mM L-glucose induce a weakly increase in TGF-beta1 mRNA expression (1.32 ± 0.88 ; 1.56 ± 1.05 respectively). The exposure to 25 mM induces a decrease of GPX1 mRNA (0.67 ± 0.07) and of SOD2 mRNA (0.53 ± 0.26) and of catalase mRNA (0.61 ± 0.08) in HUVECs. Exposure to LG20 did not induce differences in enzymes expression from control (C).

Conclusion: In conclusion, comparison of EPCs and HUVECs antioxidative enzymes expression highlights that CAT, SOD2, GPX1 are more strongly expressed in EPCs. So, these cells seem to be better equipped to be protected against oxidative stress.

1187

Delayed intervention with AGE cross-link breaker alagebrum and ace-inhibitor quinapril attenuates diabetes-accelerated atherosclerosis in apoE^{-/-} mice

A. Soro-Paavonen, A. M. D. Watson, K. Sheehy, L. Jiase, A. C. Calkin, M. C. Thomas, M. E. Cooper, K. A. Jandeleit-Dahm;

Diabetic Complications, Baker Heart Research Institute, Melbourne, Australia.

Background and Aims: Advanced glycation end-products (AGEs) participate in the development of microvascular and macrovascular damage in diabetes by forming "cross-links" between and within proteins, changing structure and function. Cross-link breakers such as alagebrum chloride (ALT-711) can prevent the development of atherosclerosis in diabetic mice when administered directly after the induction of diabetes. Clinically, however, patients are likely to already have some degree of atherosclerosis before initial treatment, thus studies using delayed intervention of treatment are urgently needed. The aim of this study was to investigate whether delayed treatment with ALT-711 (ALT) or the ACE-inhibitor quinapril (Q) decreases established diabetes-accelerated atherosclerosis in apolipoprotein E-deficient (apoE^{-/-}) mice.

Materials and Methods: Mice were rendered diabetic with streptozotocin and followed for 20 weeks. The mice received either no treatment, ALT-711 (1mg/kg/day), or quinapril (30mg/kg/day) from week 10–20 of diabetes (n=15 per group). Atherosclerotic lesion area was quantified by en face analysis. Gene

expression of the 2 angiotensin II receptor subtypes, AT1a and AT2, which reflect and are likely to participate in the atherogenic process were examined by RT-PCR.

Results: The delayed intervention with ALT-711 significantly decreased aortic atherosclerosis when compared to the untreated diabetic mice (total plaque area; ALT, $9.12 \pm 1.6\%$ vs untreated, $15.1 \pm 1.5\%$, $P < 0.05$). The significant reduction in the plaque area was observed in the aortic arch as well as the abdominal aorta. Mice treated with quinapril from 10–20 weeks also showed a significant reduction of atherosclerosis (Q, $9.5 \pm 1.6\%$ vs untreated, $15.1 \pm 1.4\%$, $P < 0.05$). The treated animals also had reduced aortic gene expression of the AT1a (control, 1 ± 0.3 ; diabetic, 7.0 ± 2.1 , diabetic + Q, $1.5 \pm 0.6^*$, diabetic + ALT, $1.6 \pm 0.5^{**}$, $*P < 0.05$, $**P < 0.01$ vs diabetic) and the AT2 receptor (control, 1 ± 0.2 ; diabetic, 4.8 ± 1.0 , diabetic + Q, $2.4 \pm 0.4^*$, D + ALT, $2.8 \pm 0.4^{**}$, $*P < 0.05$, $**P < 0.01$ vs diabetic). These changes were independent of glycaemic control or serum lipids.

Conclusions: Delayed intervention with both ALT-711 as well as ACE-inhibitor quinapril significantly decreased established atherosclerosis in the diabetic aorta. Indeed, ALT-711 may partly confer its anti-atherosclerotic effects via effects on the intra-aortic renin-angiotensin system. These findings re-affirm the importance of ACE-inhibitor treatment in diabetes, and provide evidence that targeting AGEs could be effective in combating established diabetic macrovascular disease.

In vitro selection of DNA aptamers that block toxic effects of AGE on cultured retinal pericytes

Y. Higashimoto¹, S.-I. Yamagishi², M. Takeuchi³, M. Noguchi¹, H. Inoue⁴;

¹Department of Medical Biochemistry, Kurume University School of

Medicine, ²Department of Medicine, Kurume University School of

Medicine, ³Department of Pathophysiological, Hokuriku University,

Kanazawa, ⁴Radioisotope Institute for Basic and Clinical Medicine, Kurume University School of Medicine, Japan.

Background and Aims: Microvessels are composed of two types of cells, endothelial cells (ECs) and pericytes. We have previously shown that AGE not only inhibit DNA synthesis, but also induce apoptotic cell death in cultured retinal pericytes, thereby being involved in pericyte loss, the earliest histopathological hallmark of diabetic retinopathy. Since pericytes play a central role in the maintenance of microvascular homeostasis in the retina, blockade of the harmful effects of AGE on retinal pericytes may become a novel therapeutic strategy for the treatment of diabetic retinopathy. In this study, we selected DNA aptamers directed against AGE *in vitro* and then examined their cytoprotective effects on AGE-exposed retinal pericytes.

Materials and Methods: AGE were prepared by incubating human serum albumin (HSA) with D-glyceraldehyde for 7 days. Synthetic DNA templates (106-mer) with 56 random nucleotides, 5'-AGCTCAGAATGGATCCAAA-CGCTCA-(N)₅₆-TTCGACATGAGAATTCGGCCGATC-3', were amplified over 12 cycles of PCR. From the purified PCR products, single-stranded DNAs were obtained by an additional PCR using 5'-primer only. The single-stranded DNA pool was then loaded onto an AGE- HSA-immobilized column. Bound DNA was eluted, recovered, and amplified by PCR. After repeating this procedure five times, the sequences of AGE specific DNA aptamers were determined.

Results: DNA aptamers specific for AGE-HSA were isolated by an *in vitro*-selection process from a pool of $\sim 10^{15}$ different nucleic acid sequences. We identified 15 DNA aptamers directed against AGE-HSA, but not non-glycates HSA, using combinatorial chemistry techniques *in vitro*. Structural analysis revealed that they had bulge-loop structures with cytosine-rich sequences. One hundred $\mu\text{g/ml}$ AGE-HSA for 24 h decreased DNA synthesis in cultured retinal pericytes to about 20% of control cells ($p < 0.01$). Further, 100 $\mu\text{g/ml}$ AGE-HSA for 10 days increased apoptotic cell death in pericytes to about 3-folds, compared with the control ($p < 0.01$). All of the cloned aptamers, but not non-binding control ones, were found to significantly inhibit the AGE-induced decrease in DNA synthesis as well as increase in apoptosis in retinal pericytes ($p < 0.01$). Among the selected aptamers, the clone 9 aptamer completely blocked the toxic effects of AGE, and its dissociation constant was $1 \mu\text{mol/l}$. The sequence of clone 9 aptamer was TAACACTCCATAC-TCACTTGCTGATTCCGCAACAACACACCCTTAAACAGTCCC.

Conclusion: These results indicate that DNA aptamers are a useful tool for inhibiting the cytotoxic effects of AGE on cultured retinal pericytes. Our study suggests that blockade of the AGE effects by DNA aptamers may lead to a novel therapeutic strategy for the treatment of diabetic retinopathy.

Effect of AGEs and rosiglitazone on the expression of galectin 3 in human renal mesangial cells

Z. Sun, C. Ma, H. Jin, N. Liu;

Department of Endocrinology, Zhongda hospital, Southeast University, Nanjing, China.

Background and Aims: To investigate the effects of advanced glycation end products (AGEs) and rosiglitazone on the expression and secretion of galectin-3 in cultured human renal mesangial cells (HRMCs).

Materials and Methods: 1. HRMCs were incubated with different concentrations of AGE-bovine serum albumin (AGE-BSA) for different time, and exposed to AGE-BSA (200 mg/L) in presence of different concentrations of rosiglitazone. 2. The mRNA and protein expression of galectin-3 in HRMCs were analyzed by use of RT-PCR and Westernblot respectively. 3. The culture medium of HRMCs was collected and concentrated. Then the content of galectin-3 in the culture medium was detected by Westernblot.

Results: 1. Both RT-PCR and Westernblot revealed that AGE-BSA upregulated the expression of galectin-3 in HRMCs in a concentration- and time-dependent manner compared with DMEM and BSA ($p < 0.05$). 2. Compared with DMEM and BSA, AGE-BSA elevated the content of galectin-3 in the culture medium of HRMCs ($p < 0.05$) time- and concentration- dependently. 3. Exposure of HRMCs to different concentrations of rosiglitazone in presence of AGE-BSA but not to rosiglitazone alone and, to a lesser extent, AGE-BSA alone, increased both protein and mRNA expression of galectin-3, and its secretion in the medium ($p < 0.05$). Rosiglitazone in presence of AGE-BSA increased the expression and secretion of galectin-3 dose-dependently ($p < 0.05$).

Conclusion: 1. AGEs upregulates the expression and secretion of galectin-3 in HRMCs. These results indicate that galectin-3 might serve as a protective mechanism toward AGE-induced injury by favoring the removal of AGEs. 2. Rosiglitazone further upregulates the expression and secretion of galectin-3 in HRMCs. The data suggests rosiglitazone plays their role of reno-protection via upregulation of galectin-3.

Expression of glycolysis-derived advanced glycation endproducts (AGEs) in human cancer; regulation of tumor progression by AGE-AGE receptor interactions

T. Atsumi¹, T. Umino¹, T. Kondo¹, H. Miyoshi¹, N. Yoshioka¹, M. Takeuchi², T. Koike¹;

¹Department of Medicine II, Hokkaido University Graduate School of Medicine, Sapporo, ²Department of Pathophysiological Science, Hokuriku University, Kanazawa, Japan.

Background and Aims: The association between diabetes mellitus and cancer risk has been suggested in recent reports. However, molecular mechanisms have not been well understood. Advanced glycation endproducts (AGEs) and receptor for AGE (RAGE) have been demonstrated to play a role in the development of diabetic vascular complications. RAGE is a cell surface receptor belonging to the immunoglobulin superfamily and is a recognized factor regulating cancer invasion and metastasis. Amphoterin is one of the ligands for RAGE and amphoterin-RAGE interactions link to the migration of cancer cells. We hypothesize that cancer cells produce AGEs and AGE-RAGE interactions are associated with the progression of cancer. The aim of this study is to determine the association between AGEs and cancer.

Materials and Methods: Glyceraldehyde-3-phosphate is an intermediate of glycolytic pathway and glyceraldehyde-derived AGEs, termed AGE2, have been demonstrated to play an important role in the pathogenesis of diabetic complications. Malignant tumors are characterized by increased glucose uptake accompanied with accelerated glycolysis. We have studied the expression of AGE2 in human tumor tissue by immunohistochemistry using anti AGE2 antibody.

6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase (PFK-2/F2,6BPase) is the enzyme responsible for the synthesis and degradation of fructose-2,6-bisphosphate (F2,6BP). F2,6BP in turn is a powerful allosteric activator of 6-phosphofructo-1-kinase (PFK-1), which is the rate-limiting enzyme for glycolysis. An inducible isoform of PFK-2 (iPFK-2) have been discovered to mediate F2,6BP production in cancer cells. We analyzed the correlation of the expression iPFK-2 and AGE2 in human tumor by immunohistochemistry.

To investigate the association between the progression of cancer and diabetes, we measured serum concentration of AGE2 in tumor bearing db/db mice. B-16 mouse melanoma cells were subcutaneously injected to db/db mice. After 14 days, the serum concentration of AGE2 was determined by ELISA.

Results: High expression of AGE2 was observed in human tumor tissue, such as colon and breast carcinoma. The expression of AGE2 in tumor tissue is significantly higher than in normal epithelium. The positive correlation of the expression of AGE2 and the expression of iPFK-2 in human tumor tissue was observed. High concentration of serum AGE-2 level was observed in tumor bearing db/db mice compared to normal control mice.

Conclusion: These findings suggest that increased glucose uptake by tumor cells leads to excess formation of AGE2 via F2,6BP mediated activation of glycolysis. Moreover, elevated serum glucose further increases the formation of AGE2 in tumor cells and AGE-RAGE interactions maybe associated with tumor progression.

Systemic osteoprotegerin delivery shows pro-atherosclerotic activity in diabetic apolipoprotein-E null mice

R. Candido¹, B. Toffoli², P. Secchiero³, S. Bernardi², F. Corallini³, E. Manca¹, E. Caroli¹, D. Belgrado², P. Da Col¹, R. Carretta², G. Zauli⁴, B. Fabris²,

¹Diabetic Centre, A.S.S. 1 Triestina, Trieste,

²Department of Clinical Medicine and Neurology, University of Trieste,

³Department of Morphology and Embryology, University of Ferrara,

⁴Department of Normal Human Morphology, University of Trieste, Italy.

Background and Aims: Diabetes mellitus is associated with a marked increase in atherosclerosis. Although clinical studies have suggested that systemic levels of osteoprotegerin (OPG) are elevated in diabetic vascular disease, the specific role of OPG in the pathogenesis of diabetic atherosclerosis has not been investigated.

Materials and Methods: Three groups of apolipoprotein E (apoE)-null mice (n=12 for each group) were obtained at 6 weeks of age and studied for 16 weeks: 1. Non-diabetic apoE control (C), 2. Untreated streptozotocin-induced (55 mg/kg daily for 5 days) diabetic apoE mice (D), and 3. Diabetic apoE mice treated with recombinant human OPG injected every 15 days intraperitoneally (D-OPG). Tail cuff systolic blood pressure, glycated haemoglobin, plasma lipid levels, atherosclerotic lesion area of the aorta and atherosclerotic lesion complexity were evaluated.

Results: Diabetes in apoE-null mice was associated with a significant increase in total atherosclerotic plaque area (D: 12.2±4.12% vs C: 1.8±0.85%; p<0.01) and complexity in the aorta, as assessed by a marked increase in interstitial collagen, cellular proliferation, macrophage and smooth muscle cell infiltration. Repeated intraperitoneal injections of recombinant human OPG significantly increased the development of atherosclerotic plaques in diabetic apoE-null animals (D-OPG: 20.7±2.65% vs. D: 12.2±4.12%; p=0.034). OPG also markedly affected the cellular composition of plaque lesions by increasing plaque collagen content, cellular proliferation, macrophage and vascular smooth muscle cell infiltration without influencing blood pressure, lipids or glycaemic control.

Conclusion: The present study shows that OPG delivery leads to significant acceleration of atherosclerotic lesion formation in diabetic apoE-null mice, thus suggesting an important role for OPG in the accelerated progression of atherosclerosis in diabetes.

1192

The effects of angiotensin II receptor antagonist on left ventricular diastolic function in OLETF rats

J.-H. Noh, J.-H. Doh, N.-Y. Jang, D.-J. Kim;

Internal medicine, Inje medical school, Ilsanpaik Hospital, Koyang, Republic of Korea.

Background and Aims: Angiotensin II has been shown to involve the development of diabetic cardiomyopathy via promoting myocardial fibrosis, myocyte apoptosis, endothelial dysfunction, inflammation, increased insulin resistance and oxidative stress. The objective of the present study is to examine the effects of angiotensin II receptor antagonist on left ventricular (LV) diastolic function in obese diabetic OLETF rats.

Materials and Methods: The rats were divided into 4 groups: untreated OLETF rats (n=10), telmisartan (10 mg/kg/day; oral) treated OLETF rats (n=9), insulin treated OLETF rats (n=8; s.c.), or both telmisartan and insulin treated OLETF rats (n=10) at 30 weeks of age. After 12 weeks of treatment, LV diastolic function examined by doppler echocardiography.

Results: The frequency of DM or IGT was 95% without differences among the four groups at 42 weeks of age. Echocardiographic study of left ventricle showed that a ratio of the peak early diastolic velocity wave to the late diastolic wave (E/A ratio) was increased (2.25 +/- 0.30 vs. 1.53 +/- 0.14, P=0.03), and isovolumic relaxation time (18.2 +/- 1.7 vs. 25.2 +/- 0.4 ms, P=0.004) and deceleration time (DT, 54.7 +/- 3.2 vs. 42.5 +/- 3.1 ms, P=0.012) was decreased in both telmisartan and insulin treated rats compared with untreated OLETF rats at 42 weeks of age. E/A ratio and DT in telmisartan only or insulin only treated rats were not different to those of control. There were no significant

differences in percent fractional shortening of LV diameter or ejection fraction among the four groups.

Conclusion: These data suggested that early simultaneous treatment of angiotensin II receptor antagonist and insulin could be protective for diabetic cardiomyopathy.

1193

Rimonabant inhibits platelet activation, positively modulates circulating leukocytes, and reduces RANTES in type 2 diabetic Zucker-Rats

A. Schäfer, J. Pfrang, G. Ertl, J. Bauersachs;

Department of Internal Medicine, Cardiology, University of Würzburg, Germany.

Background and Aims: Diabetes is characterised by vascular inflammation and enhanced platelet reactivity. Both phenomena contribute to the exaggerated cardiovascular morbidity and mortality of diabetic patients. The first CB₁-antagonist rimonabant has been shown to improve cardiometabolic risk factors such as waist circumference, HbA1c, HDL-cholesterol and triglycerides in overweight/obese patients. We investigated the effect of rimonabant on platelet activity in type-II Zucker rats.

Materials and Methods: We fed rimonabant for 2 weeks to 3-month-old male obese Zucker rats as a model for impaired glucose tolerance and for 10 weeks to 6-month-old male obese Zucker rats as a model for the metabolic syndrome. Treatment effects were compared to lean Zucker rats of both ages as the respective control strains. RANTES serum levels were determined by ELISA. Platelet activation was assessed by flow cytometry for platelet-bound fibrinogen, platelet aggregation and adhesion of isolated platelets to immobilized fibrinogen in a flow-chamber under arterial flow conditions. Leukocyte populations were quantitatively assessed using a veterinary differential blood cell counter. The activity of endogenous platelet inhibition was assessed by the basal phosphorylation state of platelet vasodilator-stimulated protein (VASP).

Results: RANTES serum levels were increased in obese vs. lean Zucker rats and significantly reduced by chronic treatment with rimonabant, which slowed body weight gain, in rats with the metabolic syndrome. Circulating numbers of neutrophils and monocytes were significantly increased in young and old obese vs. lean Zucker rats. Rimonabant significantly reduced both leukocyte subpopulations. Platelet-bound fibrinogen was significantly increased in obese vs. lean Zucker rats of both age, which was reduced by rimonabant. Platelets from obese rats were more sensitive to thrombin-induced aggregation as well as adhesion to fibrinogen, which was decreased by rimonabant therapy. Basal platelet VASP phosphorylation was significantly reduced in obese vs. lean Zucker rats of both ages and partially improved by chronic treatment with rimonabant.

Conclusion: Rimonabant demonstrates positive modulation of circulating neutrophil and monocyte numbers, reduces platelet activation and lowers RANTES levels in an animal model of impaired glucose tolerance as well as of the metabolic syndrome. Clinical studies are underway to evaluate the effect of rimonabant on reduction of cardiovascular risk.

Evaluation of the relationship between depression, diabetes and ischaemia/reperfusion injury following global ischaemia in rat hearts

L. Solskov¹, B. Lofgren², H. E. Botker², T. T. Nielsen², D. H. Overstreet³, O. Schmitz^{1,4}, G. Wegener⁵, S. Lund⁴;

¹Department of Pharmacology, Aarhus University, Denmark, ²Department of Cardiology, Aarhus University, Denmark, ³Department of Psychiatry and Centre for Alcohol Studies, University of North Carolina, Chapel Hill, United States, ⁴Medical Research Laboratory and Medical Department M (Endocrinology and Diabetes), Aarhus University Hospital, Denmark, ⁵Centre for Basic Psychiatric Research, Aarhus University, Risskov, Denmark.

Background and Aims: Depression is among the leading global causes of years lived with disability and is often associated with medical comorbidities such as heart disease and diabetes. Depression may accelerate the onset of diabetes complications and thereby has a significant impact on patients with diabetes. Therefore it is of considerable importance to get insight into the

medical comorbidities associated with depression. The Flinders Sensitive Line (FSL) rat is a genetic animal model of depression, bred from the Sprague-Dawley rat, which exhibits behavioral, neurochemical, and pharmacological features similar to depressed individuals. The aim of the study was to elucidate if the FSL rats were more susceptible to ischemia and reperfusion injury compared to the healthy Sprague-Dawley (SD) control rats and furthermore to determine if the FSL rats were pre-diabetic.

Materials and Methods: Hearts were perfused in a Langendorff model and subjected to 40 minutes of global ischemia followed by 120 minutes of reperfusion. Myocardial infarct size was measured and used as a marker of susceptibility to ischemia. As the FSL and SD rats had comparable fasting glucose and insulin levels an oral glucose tolerance test (OGTT) was performed to determine if the FSL rats also exhibited normal glucose tolerance. Rats were fasted for 12 hours prior to the test and blood was drawn from the tail vein.

Results: Infarct size was significantly larger in the FSL rats (I/R: 62.4±4.2% vs. 46.9±2.9%, $p < 0.01$, $n=9$) compared to the SD rats. No significant difference was found in blood glucose levels between the two groups during the OGTT although there was a tendency towards higher plasma insulin levels in the FSL compared to the SD rats though not statistically significant.

Conclusion: The data indicates that the depressed FSL rats are more susceptible to ischemia and reperfusion injury compared to the healthy SD rats. This animal model may be useful in future studies when looking more detailed at mechanisms that contribute to the medical complications associated with depression.

1195

MB07811, a liver-targeted prodrug of a novel thyroid hormone receptor agonist, does not cause hyperglycaemia in Sprague Dawley rats or diet-induced obese mice

D. L. Linemeyer¹, E. E. Cable¹, X. Yang¹, B. R. Ito¹, P. D. van Poelje¹, M. D. Erion²;

¹Biological Sciences, ²Research & Development, Metabasis Therapeutics, La Jolla, CA, United States.

Background and Aims: MB07811, a HepDirect prodrug of a phosphonate-containing thyroid hormone receptor agonist, MB07344, is under clinical investigation for the treatment of hyperlipidemia. First-pass extraction of MB07811 arising from CYP 3A-dependent activation to MB07344 and limited distribution of MB07344 to extrahepatic tissues confers a high degree of liver selectivity to the pharmacological effects of this novel agent. Liver selectivity was incorporated into the drug design because triiodothyronine (T3) exposure, in addition to beneficial liver-mediated lipid lowering effects, can adversely affect cardiac function, the thyroid hormone axis, lean muscle mass, and bone integrity. Excess T3 can also cause hyperglycemia by accelerating endogenous glucose production via increased gluconeogenic gene expression and extrahepatic effects including increased free fatty acid (FFA), amino acid and glycerol flux to the liver. The purpose of these studies was to compare the effects of MB07811 and T3 on glycemic control and to assess the cholesterol and triglyceride lowering activity of MB07811.

Materials and Methods: In protocol 1, male Sprague Dawley (SD) rats ($n=6$ /group) were dosed daily for 8 days with vehicle, T3 (650 µg/kg/day, s.c.), or MB07811 (1, 10 or 50 mg/kg/day, p.o.). Blood glucose was measured after a 9-h fast on days 1, 4, 5, 6 and 8. Plasma insulin and FFA levels were analyzed prior to the first dose and on day 5. On day 6, plasma insulin and blood glucose levels were measured prior to and at selected times after administration of an oral glucose load (2 g/kg). In protocol 2, diet-induced obese (DIO) mice were produced by feeding 4-week-old C57BL/6 mice a high-fat diet (60% fat by kcal) for ~90 days. Groups of mice ($n=8$ /group) were then gavaged daily for two weeks with MB07811 (0.3, 1, 3, 10 and 30 mg/kg/day) or vehicle and maintained on the same high-fat diet. Plasma cholesterol, triglycerides and blood glucose were measured at baseline and on days 7 and 14 of the treatment period. Liver triglyceride content was assessed at sacrifice.

Results: SD rats treated with T3 for 8 days showed increased fasting blood glucose (up to ~17 mg/dL) and plasma FFA (by 540 µmole/L), with no change in plasma insulin. In contrast, MB07811 treatment did not affect fasting blood glucose, plasma FFA, or plasma insulin. Neither T3 nor MB07811 treatment changed the blood glucose excursion or the plasma insulin response to an oral glucose challenge performed on day 6. Treatment with T3, but not MB07811, resulted in weight loss (16%). In DIO mice treated for 2 weeks with MB07811, plasma cholesterol was reduced dose-dependently with the highest

dose resulting in 61% lowering relative to vehicle controls. Furthermore, MB07811 treatment reduced plasma and liver triglycerides (up to 40% and 42%, respectively) and did not increase blood glucose levels at any dose.

Conclusions: MB07811, unlike T3, did not cause fasting hyperglycemia in SD rats. In addition, MB07811 lowered plasma cholesterol and plasma and liver triglycerides without increasing blood glucose levels in DIO mice. T3-induced hyperglycemia may be due primarily to its extrahepatic actions. Targeting of thyroid hormone receptor agonists to the liver appears to be a promising strategy for harnessing the antihyperlipidemic activity of T3 while avoiding extrahepatic side effects.

1196

A direct effect of ghrelin to augment cardiac AMPK activity is compromised by hyperglycaemia following ischaemia/reperfusion

S. Samsuddin¹, M. Glyn², B. Kola³, M. Korbonits³, M. J. Holness¹, M. C. Sugden¹;

¹Institute of cell and molecular science, London,

²Leukocyte Biology, Imperial College, London, ³Department of Endocrinology, Barts and the London Medical School, United Kingdom.

Background: 5AMP activated protein kinase (AMPK) is a serine/threonine kinase that is activated through AMP and upstream kinases. Both ghrelin gene expression and ghrelin receptors are found in the heart. Increasing evidence indicates that AMPK may exert an important cardioprotective function in the heart during ischaemia and reperfusion (I/R). Use of mice expressing a dominant negative AMPK mutant in the heart suggested that AMPK activation protects cardiac ATP levels and reduces infarct size and damage to myocytes during ischaemia.

Aims: Hyperglycaemia is a major cause of cardiac and vascular complications associated with diabetes. Therefore, hyperglycaemia may represent an important predictive risk factor for myocardial infarction and hypertension in patients with diabetes. The aim was to investigate whether direct cardioprotective effects of ghrelin could be mediated through AMPK activation and whether this action is adversely affected by hyperglycaemia.

Materials and Methods: Langendorff heart perfusions with low (5 mM) and high (18 mM) glucose were performed in the absence or presence of 10^{-4} pM des-acyl ghrelin (60 mins or 30 mins for I/R hearts), with or without a 20 min period of ischaemia, with subsequent 15 min reperfusion (I/R). Cardiac AMPK was analysed in extracts of hearts freeze-clamped at the end of the perfusions using immunoprecipitate kinase assays. AMPK activity in the immune complex was determined by phosphorylation of SAMS, a synthetic peptide substrate of AMPK.

Results: Ghrelin addition to the perfusate augmented cardiac AMPK activity, especially at low glucose (377% of control) and low glucose with I/R (439% of control). AMPK activity following perfusion with high glucose was also greatly enhanced by ghrelin compared to the control (339% $P < 0.05$). However, the ability of ghrelin to activate AMPK was greatly impaired with perfusion at high glucose and subjected to I/R, with $< 50\%$ of the activation of AMPK observed with I/R hearts in the presence of low glucose.

Conclusions: Ghrelin exerts a direct acute effect to activate AMPK in the heart, suggesting that ghrelin could be an endogenous cardioprotective factor. Targeting ghrelin receptors, ghrelin signalling and/or AMPK may provide novel means for treating myocardial ischemia. Importantly, the putative cardioprotective effect of ghrelin exerted via AMPK activation is opposed by high glucose following ischaemia and reperfusion. These data highlight the importance of good glycemic control, particularly in diabetic patients with macrovascular complications, to optimise cardioprotection via AMPK.

1197

Peculiarities of heart function and coronary circulation changes provoked by sympathovagal balance modification in diabetic dogs

A. Nescheret;

Laboratory of Epidemiology of Diabetes Mellitus, Institute of Endocrinology and Metabolism of AMSUkr, Kyiv, Ukraine.

Background and Aims: Recent studies suggest a close relation between abnormal nervous autonomic function and diabetic cardiohaemodynamic

complications. Impaired cardiac autonomic activity, coronary heart disease and myocardial infarction are associated with worse outcome in diabetic patients. So there exists a very important question concerning the tactics of sympathetic-vagal balance modulation in diabetological practice. The aim of our study was to determine peculiarities of heart function and coronary artery (CA) regulation changes after cholinergic and adrenergic receptors blockade during progressive development of hyperglycemia in diabetic dogs (DD).

Materials and Methods: Our investigations were carried out on dogs under alpha-chloralose anaesthesia (50–100 mg/kg, i.v.). Catheterization and programmed autoperfusion of left CA, heart and main vessels catheterization were performed in experiments without opening chest. Cardiohaemodynamics, CA perfusion pressure (CAPP), with another clinical and biochemical parameters were registered. In metabolically healthy dogs (CD, level of glycemia: 3.8 ± 0.5 mmol/l; $n=27$) and alloxane-diabetic dogs (75 mg/kg of alloxane, i.v.) beta-adrenoreceptors (beta-AR) and M-cholinergic receptors (M-ChR) blockades were induced respectively by propranolol (2.0 mg/kg, i.v.) and atropine (0.5 mg/kg, i.v.). Due to different levels of hyperglycemia development in DD all of them were divided into three groups: DD1: hyperglycemia 7.2 ± 1.7 mmol/l (mild form; $n=9$); DD2: 9.8 ± 1.7 mmol/l (moderate form; $n=7$) and DD3: 15.6 ± 3.4 mmol/l (severe form; $n=10$).

Results: The typical cardiohaemodynamics reaction 5–10 min after M-ChR blockade (at the nadir of the action) in CD due to a rise of sympathetic heart nerves activation was followed by an increase of heart rate (HR, $+59.5 \pm 2.5$ beats/min, $p < 0.001$) and CAPP decrease (-1.5 ± 0.1 kPa, $p < 0.001$). In all DD groups M-ChR blockade was associated with significantly diminished degree of HR increase (DD1: to $+32.2 \pm 2.7$; DD2: to $+19.9 \pm 6.4$; DD3: to $+1.3 \pm 0.1$ beats/min; $p < 0.001$ for all), CAPP decrease (DD1: to -3.2 ± 0.1 ; DD2: to -3.4 ± 0.2 ; DD3: to -3.5 ± 0.2 kPa; $p < 0.001$ for all) compared with CD. On the contrary, beta-AR blockade in CD due to depression of sympathetic heart nerves activity induced HR decrease (-25.3 ± 1.3 beats/min; $p < 0.001$) and CAPP increase ($+1.2 \pm 0.1$ kPa; $p < 0.01$). But in DD2 and DD3 blockade of beta-AR induced more pronounced HR depression (to -39.4 ± 2.2 and to -39.2 ± 3.9 beats/min resp.; $p < 0.01$ for both). In all DD groups beta-AR blockade caused CAPP augmentation (DD1: to $+3.6 \pm 0.5$; DD2: to $+4.1 \pm 0.6$; DD3: to $+2.6 \pm 0.5$ kPa; $p < 0.001$ for all). Both blockade of M-ChR and beta-AR after bolus intracoronary injection of epinephrine (5.0 mcg) in CD provoked alpha-adrenergic CA constriction and elevation of CAPP ($+2.1 \pm 0.2$ and $+3.3 \pm 0.3$ kPa, resp.; $p < 0.001$ for both). Nevertheless, in DD2 and DD3 the degrees of alpha-adrenergic CA constriction induced by epinephrine after M-ChR and beta-AR blockades were diminished (to $+2.0 \pm 0.1$ and $+2.9 \pm 0.1$ kPa, resp., $p < 0.001$ for both).

Conclusion: Our data suggest that continuing progression of hyperglycemia in DD seems to represent the most important factor in influencing the heart's autonomic nervous system activity. The obtained results demonstrate dynamics of the relationship between sympathetic and vagal nervous systems in regulation of heart function and coronary circulation in diabetes.

1198

Dysregulated inflammation predicts reduced connective tissue growth factor expression in a baboon wound healing model of type 1 diabetes

S. E. Thomson¹, S. V. McLennan², A. Hennessy³, J. Bonner², H. Zoellner⁴, D. K. Yue⁵, S. M. Twigg⁵;

¹Renal Medicine, Royal Prince Alfred Hospital, ²Endocrinology, Royal Prince Alfred Hospital, ³Medicine, University of Western Sydney,

⁴Oral Pathology and Medicine, Westmead Hospital,

⁵Endocrinology, University of Sydney, Australia.

Background and Aims: Transient macrophage infiltration is important early in normal wound healing, as is resolution of neutrophil infiltration and progressive induction of growth factors. Macrophage infiltration is impaired in diabetic wounds and while connective tissue growth factor (CTGF) is induced during normal wound healing its regulation in diabetic wounds is unknown. The aim of this study was to determine whether early abnormalities in macrophage and neutrophil infiltration in diabetic wound healing predict subsequent CTGF protein levels in a baboon wound healing model.

Materials and Methods: Wound tissue was obtained from drums placed subcutaneously in the thighs of 8 diabetic (D: average age 13.2yr, wt 18.8kg, HbA1c 9.2%) and 7 control (C: average age 12.8yr, wt 25.1kg, HbA1c 3.8%) baboons. Drums were removed after 2 and 4wks for histological examination

of wound tissue volume using Massons Trichrome stain. Macrophages, neutrophils and CTGF were detected with specific antibodies. Aspirated drum fluid was used to measure wound protease activity (total and active MMP-9 levels) by zymography and MCP-1 levels by ELISA. The CTGF staining intensity was graded from 0–3, and the number of macrophages and neutrophils were counted and averaged/20 fields, by 2 observers blinded to tissue source. Data was expressed as Mean \pm SEM and analysed by either, T-Test or where appropriate analysis of variance (ANOVA).

Results: At 2 wks the diabetic wound tissue volume and MCP-1 was not different to control, the macrophage infiltration was reduced and active MMP-9 was increased. At 4 weeks, the diabetic wound tissue volume tended to be less than control ($p=0.06$) and it contained less CTGF, active MMP-9 persisted and neutrophil clearance was delayed. For the entire group MCP-1 concentration at 4 wks correlated with macrophage number ($r=0.56$, $p=0.05$) at 4wks. In addition macrophage number at 2wks correlated inversely with active MMP-9 ($r=-0.77$, $p<0.02$), and positively with CTGF ($r=0.64$, $p=0.01$) each at 4 wks.

Conclusion: As there is a decrease in wound tissue formation and alterations in cellular infiltration this drum model of wound tissue formation appears to be a valid model for the study of wound healing in diabetes. In addition this data supports the hypothesis that delayed and sustained macrophage infiltration predicts reduced CTGF levels in diabetic wound tissue. Whether macrophage chemoattractant therapy will normalise wound healing in experimental diabetes requires further study.

Animal	Week	Macrophage number	Active MMP-9 (% of total)	Total MMP-9 ($\times 10^3$)	Neutrophil number	CTGF Score
Control	2	5.99 ± 0.57	13.57 ± 2.71	34.95 ± 8.83	2.56 ± 0.48	1.63 ± 0.24

Insulin stimulation of myocardial perfusion and glucose uptake in patients with diabetes and idiopathic dilated cardiomyopathy: a PET study

S. Masi¹, P. Iozzo¹, C. Simi¹, F. Frassi¹, A. Sironi¹, P. Pisani¹, S. Pardini¹, C. Porciello¹, A. Giorgetti¹, D. Petroni¹, D. Giannessi¹, P. Di Cecco¹, P. A. Salvadori¹, D. Neglia¹, E. Ferrannini^{1,2};

¹Institute of Clinical Physiology, CNR – National Research Council,

²Department of Internal Medicine, University of Pisa School of Medicine, Pisa, Italy.

Background and Aims: Idiopathic dilated cardiomyopathy (IDC) is associated with a high prevalence of diabetes, insulin-resistance, chronic neurohormonal activation and myocardial microcirculatory dysfunction. Insulin has mild vasodilatory properties in healthy individuals. We sought to evaluate the effect of an acute euglycaemic insulin infusion on myocardial blood flow and glucose uptake in patients with IDC and diabetes.

Materials and Methods: Seven male patients (age [mean \pm standard deviation]: 65 ± 6 years, body mass index 27.8 ± 2.4 kg/m²) with a diagnosis of IDC and diabetes underwent the current baseline characterization on myocardial responses to acute insulin stimulation, before entering a pilot study (insulin glargine/4053) on insulin treatment and cardiovascular risk. Positron emission tomography (PET) was used to quantify myocardial blood flow at rest (r-MBF), during euglycaemic insulin stimulation (i-MBF) and during dipyridamole stress (d-MBF), and to assess insulin-stimulated myocardial glucose uptake (MGU). MBF and MGU were estimated in 13 myocardial wall segments per patient ($n=91$) according to standardized segmentation procedures. Patients underwent an echocardiographic examination and repeated biohumoral characterization. Coronary flow reserve (CFR) was calculated as the ratio of d-MBF/r-MBF. Myocardial glucose extraction (MGE%) was calculated as MGU divided by the product of steady-state plasma glucose and i-MBF ($\times 100$).

Results: Left ventricular ejection fraction and end-diastolic diameter were $39 \pm 11\%$ and 63 ± 9 mm, respectively. Whole-body insulin-stimulated glucose uptake was 3.4 ± 0.3 mg/kg/min. Insulin and dipyridamole increased MBF in a similar fashion (i-MBF 0.732 ± 0.384 mL/min/g vs. d-MBF 0.750 ± 0.223 mL/min/g, $p=ns$) relative to r-MBF (0.520 ± 0.143 mL/min/g, $p<0.05$). Thus, values of CFR and i-MBF/r-MBF were correlated ($r=0.671$, $p<0.0001$). The increment in MBF during insulin infusion and CFR were inversely related to MGE% ($r=0.465$, $p<0.0001$; $r=0.492$, $p<0.0001$, respectively). Consistently, myocardial segments with lower CFR had an augmented MGU ($p=0.0014$). Whole-body glucose uptake was negatively associated with glycosylated haemoglobin levels ($r=0.91$, $p=0.01$). Neither MGU nor MBF showed independent associations with left-ventricular function or diameter.

Conclusion: Insulin stimulated MBF by 40% in patients with IDC and diabetes, equalling the maximal microcirculatory response to dipyridamole. Segments with a lesser blood flow response showed a compensatory increase in glucose extraction, which may help preserve the global left-ventricular systolic function in patients with diabetes and IDC.

LPL und PPAR γ in the pathogenesis of "diabetic cardiomyopathy"

M. Lüttig-Rakowski¹, B. Stratmann¹, H. Milting², G. Tenderich³, R. Körfer³, D. Tschöpe¹;

¹Heart and Diabetes Center NRW, ²Erich and Hanna Klessmann Institute,

³Clinic for Thoracic and Cardiovascular Surgery, Heart and Diabetes Center NRW, Bad Oeynhausen, Germany.

Cardiomyopathy may be triggered by metabolic influences associated with diabetes. However, the molecular mechanisms remain to be elucidated. Amongst others the lipoprotein lipase (LPL) and the peroxisome proliferator activated receptor γ (PPAR γ) are important proteins in the myocardial lipid metabolism. LPL is a key enzyme of lipid metabolism that hydrolyses triglycerides, providing free fatty acids for cells and affecting the maturation of circulating lipoproteins. Triglyceride-rich lipoproteins are known to play an important role in the progression of atherosclerosis.

LPL requires Apolipoprotein-CII as a cofactor and LPL deficiency leads to hypertriglyceridemia. Insulin is known to enhance LPL synthesis in adipocytes and its placement in the capillary endothelium. High fat diets have been shown to cause tissue specific overexpression of LPL which has been implicated in tissue specific insulin resistance and consequent development of type 2 diabetes mellitus. To explore the role of LPL and PPAR γ in the diabetic myocardial metabolism for the pathogenesis of dilated cardiomyopathy, the mRNA-expression of LPL and the ligand activated transcription factor PPAR γ was analysed by real-time RT-PCR. Left ventricular samples of 14 patients with cardiomyopathy (CM) and 13 with cardiomyopathy and diabetes (CM+DM) were investigated and compared to 7 non-failing donor hearts (NF), which could not be transplanted for technical reasons.

The left ventricular LPL mRNA level was increased in CM ($211 \pm 13\%$ vs. NF, $p=0.003$) and CM+DM ($173 \pm 14\%$ vs. NF, $p=0.023$) compared to NF. The PPAR γ mRNA level of CM shows neither a significant difference in comparison to NF nor to group CM+DM. The PPAR γ mRNA level of CM tended to be decreased in comparison NF whereas the PPAR γ mRNA level of CM+DM was non-significantly decreased compared to NF. The increase of the myocardial LPL mRNA level in terminal failing hearts might be associated with heart failure, since ongoing myocardial damage could be through an increased fatty acid uptake and oxidative stress which could result in cardiomyopathy. The alterations of the LPL mRNA expression are not in line with the PPAR γ mRNA expression indicating that the expression of LPL is not only regulated through PPAR γ . In addition to the proven alterations in mRNA expression, further studies concerning the protein expression are necessary. A decreased protein expression of PPAR γ could hind to a participation of PPAR γ in the pathogenesis of cardiomyopathy.

Metabolic effects of co-administered simvastatin and ω -3 polyunsaturated fatty acids in type 2 diabetic patients with cardiomyopathy

V. A. Serhiyenko, A. M. Urbanovich, A. A. Serhiyenko; Endocrinology, Medical University of Lviv, Ukraine.

Background and Aims: Long-term administration of statins can be accompanied by essential infringements of function of a liver. ω -3 polyunsaturated fatty acids (ω -3-PUFA), such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) possess essential positive properties, including hepatoprotective effects. The aim of this study was to assess the effects of simvastatin (SIM), ω -3 PUFA and their combinations on dynamics of such biochemical parameters in Type 2 diabetic patients with diabetic cardiomyopathy (DCMP).

Materials and Methods: 86 patients with Type 2 DM and DCMP ($51,2 \pm 4,3$ years), BMI $26,3 \pm 2,79$ kg/m 2 , DM duration $7,6 \pm 2,4$ years, HbA1c $8,8 \pm 2,7$ % were allocated to three groups. Patients of group A ($n=25$) received SIM 20 mg tid; B ($n=37$) – capsules of fish oil (1,0 g EPA, 1,0 g DHA and 0,1% α -tocopherol acetate tid), C ($n=24$) – SIM 10 mg tid plus capsules of fish oil. All patients were on the same diet. Research joined patients with the diagnosed lipid abnormalities (NCEP ATP III). The duration of the study was 3 months. We investigated total cholesterol (TC), low (LDL-C), high density lipoprotein-cholesterol (HDL-C), triglycerides (TG), the 125 I-6-ketoprostaglandin F $_{1\alpha}$ (6-ketoPGF $_{1\alpha}$), 125 I-thromboxane B $_2$ (TXB $_2$) concentrations, activities of alaninaminotransferase, γ -glutamyltranspeptidase in the blood plasma; Na $^+$, K $^+$ -ATPase, fatty acids in the membranes of RBC's; activities of superoxide dismutase (SOD), glutathion peroxidase (GPO) in the RBC's, level of conjugated dienes (CD). Statistics: ANOVA.

Results: Lipid disorders [high level of total TC, LDL-C, TG ($7,3 \pm 10,1$; $4,5 \pm 0,3$; $2,87 \pm 0,2$ mmol/l, $p < 0,05$) and decrease level of HDL-C] in the patients with DCMP is accompanied by a decrease of the activities of Na $^+$, K $^+$ -ATPase in the RBC's membranes, SOD, GPO in the RBC's. There is a considerable increase in the TXB $_2$ level, level of CD and a decrease in serum 6-keto-PGF $_{1\alpha}$, ω -3-PUFA in the RBC's membranes. It has been discovered that the monotherapy by SIM is accompanied by negative dynamics of activity of enzymes of a liver that proved by of ultrasonic scanning. After 3 months of treatment there was a more significant decrease in LDL-C, TC, TG concentration, TXB $_2$ level ($152,5 \pm 16,9$ pg/ml, $p < 0,001$), level of CD ($p < 0,01$) with simultaneous increases in EPA level, EPA/arachidonic acid ratio, Na $^+$, K $^+$ -ATPase ($0,04 \pm 0,003$ vs $0,09 \pm 0,004$ mMol PI/mg protein per 1 hour, $p < 0,001$) and the concentration

of 6-ketoPGF $_{1\alpha}$, increases activity of SOD, GPO ($10,94 \pm 0,22$; $321,7 \pm 19,2$ mcmol GSH/min 1 g Hb, $p < 0,001$) in the 3-rd group (table).

Mean % change from baseline at 3 months	SIM (n=25)	ω -3 PUFA (n=37)	SIM / ω -3 PUFA (n=24)
LDL-C	-34,2*	-12,8	-52,9**
HDL-C	+15,3	+7,1	+26,8*
TC	-8,2	-12,5	-19,5
TG	-12,6	-35,4*	-57,4**
6-ketoPGF $_{1\alpha}$	+13,6	+35,6*	+46,1**
TXB $_2$	-18,6	-51,5**	-59,5**
Na $^+$, K $^+$ -ATPase	+5,9	+89,4**	+92,7**
SOD	+12,7	+36,8*	+48,4**
GPO	+7,9	+31,9	+45,7**

Treatment difference presented with 95% CI. * $p < 0,01$, ** $p < 0,001$

Conclusion: SIM and ω -3-PUFA treatment following 3 months significantly improve the lipid profile, state of prostacyclin I $_2$ -thromboxane A $_2$ system, activeness of membrane-bound enzymes, some indexes of the oxidative stress. The combined purpose SIM and ω -3 PUFA allows to lower a doze SIM, that allows to recommend their combination in the rational-proved treatment of lipid disorders in patients with DCMP.

1202

Microalbuminuria is correlated with early right ventricular diastolic function abnormalities in patients with type 1 diabetes mellitus

D. K. Levisianou 1 , A. Melidonis 1 , A. Koutsovasilis 1 , D. Beldekos 2 , G. Tsiaousis 2 , I. Protopsaltis 1 , S. Handanis 2 , S. Foussas 2 ;

1 Diabetes Center, 2 Cardiology Dpt., Tzanio Gen Hospital, Piraeus, Greece.

Background and Aims: Left ventricular dysfunction (systolic and diastolic) is well documented in patients with Type 1 Diabetes Mellitus (T1DM). There are not enough data for the function of the right ventricular in these patients. The aim of the study was the early detection of right diastolic dysfunction in asymptomatic patients with Type 1 Diabetes Mellitus (T1DM) by the use of tissue Doppler imaging (TDI) indices and its correlation with diabetological parameters

Materials and Methods: We examined 45 patients (aged $39,2 \pm 9,9$ years) with T1DM (Group A) and 31 normal controls (Group B) of comparable age and gender. All participants underwent a standard 2-D and color Doppler echocardiographic study. Pulsed TDI was performed in apical 4-chamber view. We measured the LV ejection fraction (EF), transmitral flow velocity (E, A, E/A) and Tran tricuspid flow velocity (E', A', E'/A'). In addition, TDI measurements of mitral (mitral Em, Am, Sm) and tricuspid annulus velocities (tricuspid Em, Am, Sm) were evaluated. A possible correlation was examined for age, diabetes duration, HbA1c, microalbuminuria, heart rate, Body Mass Index (BMI), peripheral neuropathy, retinopathy and echocardiographic measurements of left and right ventricle with univariate analysis. The volume of right atrium, (RA volume) was calculated from the apical 4-chamber view using Simpson's method and subsequently indexed to body surface area (RAVI). Statistical analyses were performed using the SPS software version 13.0. All continuous variables are expressed as mean \pm standard deviation. Comparisons of echocardiographic variables of T1DM subjects and NC were performed using Student *t* test for unpaired data. Chi-square tests were used for comparison of categoric variables. Pearson's correlation coefficients were used to assess the strength of the relationship between continuous variables.

Results: All participants had normal ejection fraction, dimensions and wall thickness of the ventricle. Group A patients had impaired right diastolic function compared to the controls of group B (E'/A' = $0,94 \pm 0,34$ vs $1,77 \pm 0,25$, $p < 0,001$, Em/Am = $0,89 \pm 0,39$ vs $1,38 \pm 0,22$, $p < 0,001$, E/A = $0,95 \pm 0,18$ vs $1,8 \pm 0,16$, $p < 0,001$). The presence of T1DM significantly correlated with all of the measures of LA and RA function: E/A, E'/A', Mitral Em/Am, Tricuspid Em/Am ($p < 0,0001$, $p < 0,001$, $p < 0,0001$, $p < 0,001$, respectively). In the multivariate model most significant was the presence of microalbuminuria ($p < 0,001$). T1DM duration and heart rate were the only other variables in the univariate analyses that correlated significantly with all measures of LA and RA function ($p < 0,01$).

Conclusion: Asymptomatic microalbuminuric patients with T1DM have early right diastolic dysfunction that can be reliably detected using indices of tissue Doppler echocardiography. Our data suggest that microalbuminuria is associated with significant changes of right ventricular diastolic function. Microalbuminuria may be an early biochemical marker of these abnormalities. Therefore TDI should be used in all microalbuminuric patients with T1DM.

1203

Nt-BNP as a short-term predictor of cardiovascular hospitalization or death in diabetic patients without history of cardiac disease compared to classical risk-factors

S. Neuhold¹, M. Hülsmann¹, M. Clodi², M. Riedl², D. Mörtl¹, R. Berger¹, R. Pacher¹, A. Luger²;

¹Department of Cardiology,

²Department of Endocrinology, Medical University Vienna, Austria.

Background and Aims: Nt-BNP is known to be an excellent marker for screening patients with a suspected cardiac disease. Cardiovascular morbidity contributes to the main causes of hospitalisation and death in diabetic patients. Also there is some information, that Nt-BNP predict worse outcome in diabetic patients on long-term, no data are available on short-term, especially in the subset of patients with no cardiac history. We compared Nt-BNP, beside known risk-markers for developing a cardiac disease in diabetic patients.

Material and Methods: We investigated 441 patients out of a tertiary care hospital diabetes out-patient unit. No patient had a history of cardiac disease. A number of clinical variables and Nt-BNP (Roche Diagnostics) was obtained in all patients. If Nt-BNP levels were increased over the normal limit (125 pg/ml) the treating physician was informed, that further investigations and probably optimization of treatment might be necessary. Patients were followed up 7.7 months on average (range 0.5–13 months). Unplanned cardiovascular hospitalisation or death was used as the endpoint.

Results: All over 13 patients experienced unplanned cardiovascular hospitalisation and 7 patients died. 19 patients reached the combined endpoint. Of the subset of patients with increased levels of Nt-BNP we received 69 records of echocardiography. Systolic dysfunction was present in 6%, diastolic dysfunction in 55% and 39% had no evidence of heart disease. Patients reaching the endpoint were significantly older (57 ± 14 vs 66 ± 15 years ($p < 0.01$), had statistical significant, but not clinical relevant higher levels of creatinine (1 ± 0.4 vs 1.3 ± 0.6 mg/dl ($p < 0.05$)) and higher Nt-BNP (169 ± 262 vs 536 ± 701 pg/ml ($p < 0.0001$)). There was no difference in therapy, blood pressure, LDL-Cholesterine or HbA1c. Outcome was similar, whether patients were above or below the cut-point as follows: 135 mmHg as a threshold for blood pressure (4% vs 4%), 100 mg/dl (4% vs 4%) or 130 mg/dl (3% vs 5%) for LDL-Cholesterine, and 7% for HbA1c (3% vs 5%) for below and above the cut-point, respectively. There was only a significant difference for Nt-BNP (for 125 pg/ml 1 vs 9% event-rate $p < 0.0001$) and for creatinine (for 1.5 mg/dl 3 vs 13% $p < 0.01$) This held true in Kaplan-Meier analysis only for Nt-BNP ($p < 0.001$).

Conclusion: Beside a number of variables only age, creatinine and Nt-BNP are significant higher in patients with an event. Using a cut-point of 125 pg/ml, Nt-BNP appears to unmask diabetic patients with a cardiac risk. This was not true for markers like HbA1c, blood pressure, kidney dysfunction or LDL-Cholesterine.

1204

Rosiglitazone, but not glimepiride, improves myocardial diastolic function in association with a reduction of oxidative stress and inflammation in patients with type 2 diabetes mellitus

H. von Bibra¹, M. Diamant², P. Scheffer², T. Siegmund¹, P.-M. Schumm-Draeger¹;

¹Endocrinology, Academic Hospital Bogenhausen, München, Germany,

²Endocrinology, VU University Medical Centre, Amsterdam, The Netherlands.

Background and Aims: Recent evidence indicates that thiazolidinediones (TZD) reduce cardiovascular disease (CVD) in high-risk patients with type 2 diabetes mellitus (DM2), however, their effect on cardiac function is under

debate. On one hand, TZD improve lipotoxic diabetic cardiomyopathy in animal models, whereas their use in patients has been associated with an increased rate of congestive heart failure. In animals, direct and indirect actions of TZD may favourably affect cardiac function by improving insulin sensitivity and reducing inflammation and oxidative stress. Given the high occurrence of diastolic myocardial dysfunction in DM2 and its prognostic relevance, we tested the hypothesis, that rosiglitazone (R), versus glimepiride (G), may improve diastolic myocardial function in patients with DM2 by simultaneously reducing oxidative stress and inflammation.

Materials and Methods: This randomised cross-over study investigated 12 patients with DM2 (aged 59 ± 13 years) on monotherapy with metformin with normal systolic ventricular function (2-d echocardiography) and without history and signs of coronary artery disease or congestive heart failure before and after 4 months additional therapy with R (8mg daily) and with G (3mg daily) in the fasting state and 2 hours after a standardized breakfast (48 g carbohydrates). Left ventricular function was assessed by tissue Doppler as systolic (Vs) and diastolic myocardial velocity (Ve) averaged from six basal myocardial segments and also by standard 2-d echocardiography. Oxidative stress was evaluated by measuring levels of plasma malondialdehyde (MDA). Additionally, the inflammatory markers myeloperoxidase (MPO) and high-sensitive C-reactive protein (CRP) were determined.

Results: With R, Ve improved significantly from 7.9 ± 1.7 to 8.8 ± 1.2 cm/s ($p = 0.04$) both in the fasting and the postprandial state ($p = 0.04$). Concomitantly, MDA decreased significantly (8.1 ± 2.1 to 7.1 ± 1.5 μ M, $p < 0.01$). The change of Ve correlated significantly with the change of MDA ($r = -0.67$, $p = 0.03$). The improvement of HbA1c was not significant (from 7.0 ± 1.0 to 6.8 ± 0.8 %, $p = 0.15$) but postprandial blood glucose decreased ($p = 0.007$) and so did CRP ($p = 0.01$), whereas MPO reduction missed significance ($p = 0.09$). With G, patients had similar effects on HbA1c (from 6.7 ± 0.6 to 6.5 ± 0.5 %, $p = 0.19$) but no significant reduction of fasting or postprandial blood glucose, of Ve (8.5 ± 1.3 to 8.3 ± 1.6 cm/s), MDA, CRP and MPO. Other metabolic, haemodynamic and cardiac parameters remained unchanged in both therapy regimens.

Conclusion: In patients with type 2 diabetes mellitus, additional therapy with rosiglitazone improved diastolic myocardial function, in association with reduced oxidative stress and inflammation. These observed effects are prognostically important and could be relevant in the therapy choice for patients with type 2 diabetes mellitus without a history of heart disease.

Prevalence and determinants of T-wave alternans in type 2 diabetes

D. T. Martin¹, A. Shoraki¹, R. W. Nesto¹, M. K. Rutter²;

¹Dept of Cardiology, Lahey Clinic Medical Center, Burlington, United States, ²Dept of Medicine, University of Manchester, United Kingdom.

Background and Aims: Microvolt T-wave alternans (MTWA) positivity is defined as abnormal beat-to-beat variability in the T-wave amplitude of the ECG. Subjects with MTWA in association with structural heart disease have an increased risk for ventricular arrhythmias and sudden cardiac death. The presence of diabetes (DM) is associated with an increased risk of sudden death but there is limited data on the impact of DM and previous myocardial infarction (MI) on MTWA prevalence. In this study we describe the prevalence and clinical correlates of MTWA in a large cohort of out-patients with and without a history of DM and/or MI.

Materials and Methods: We studied 143 patients (mean (SD) age 58 (12), 20% female) referred to a large general hospital for treadmill exercise testing. Classification of DM and MI status was based on patient history: group 1 ($n = 54$: DM -, MI -); group 2 ($n = 47$: DM+, MI -); group 3 ($n = 26$: MI +, DM -); group 4 ($n = 13$: DM +, MI +). Exclusion criteria included: ectopic beats, atrial fibrillation, unstable angina, severe hypertension, inability to exercise, severe aortic stenosis or digoxin therapy. A symptom-limited exercise test was performed using a standardized protocol. MTWA was assessed by the spectral method using commercially available equipment (Cambridge Heart Inc). Sustained alternans (>2 minutes) in the absence of electrical interference or ectopy at heart rate <110bpm in contiguous orthogonal or precordial ECG leads was required for definition of a positive test; unequivocally negative tests were those in which adequate heart rate was achieved and both electrical interference and ectopy were absent. Test interpretation was performed blind to patient status; using conventional criteria for MTWA assessment all indeterminate tests (18%) were considered positive in this analysis.

Results: Age and gender were similar in all groups. The prevalence of positive MTWA in groups 1–4 was 24%, 20%, 48%, and 62% respectively (between group $p=0.002$). Logistic regression analysis in all patients showed that positive MTWA was related to prior MI (OR (95% CI): 4.0 (1.8–8.9), $p<0.001$) but not to prevalent DM (OR (0.4–1.8), $p<0.001$). The power of the study was 80% for a 16% between-group (1 and 2) difference in MTWA prevalence. Echocardiographic assessment of left ventricular ejection fraction was available for 92 (64%) patients. Mean (SD) ejection fraction was 61 (6)%, 63 (7)%, 53 (16)%, and 44 (11)% in groups 1–4 respectively. In patients with DM the prevalence of MTWA was related to ejection fraction ($p=0.034$) but not to BMI, DM duration, glycemic control, insulin use, lipid profile or the presence of microvascular complications.

Conclusion: MTWA positivity is related to a history of MI and impaired LV function, but is not strongly related to a history of DM, diabetes complications, or glycemic control in this cohort of patients referred for treadmill testing. Prospective studies are required to establish the prognostic value of MTWA in the diabetic population.

Strong association between cardiac autonomic dysfunction and reduced pulmonary diffusing capacity (DLCO) in type 1 diabetes

P. Santangeli¹, D. Pitocco², L. Fuso², F. Zaccardi², G. Sgueglia¹, F. Infusino¹, L. Maugeri², E. Navarese¹, G. Lanza¹, F. Crea¹, G. Ghirlanda²; ¹Cardiology, ²Internal Medicine, Catholic University, Rome, Italy.

Background and Aims: Type 1 diabetes produces damage in small blood vessels characterized by morphologic and biochemical alterations which may result in pulmonary microvascular dysfunction leading to a loss of alveolar microvascular reserve. Abnormal peripheral autonomic function is detectable in type 1 diabetes mellitus. In this study we aimed at assessing the relation between cardiac autonomic function and subclinical loss of alveolar microvascular reserve in patients with type 1 diabetes.

Materials and Methods: We studied 20 patients with type 1 diabetes (age 50.1±9 years, 13 men) without any clinical evidence of pulmonary abnormalities and systemic autonomic dysfunction. Carbon monoxide diffusing capacity (DLCO) was measured non-invasively by single-breath method. Cardiac autonomic function was assessed by time- and frequency-domain heart rate variability (HRV) analysis on 24-hour electrocardiographic Holter recordings

Results: A significant direct correlation was found between DLCO and several HRV variables, with the strongest association being found with SDNN-index (i.e. standard deviation of RR intervals for all 5-minute segments in the 24 hour) ($r=0.61$, $p=0.006$) in the time domain and with low frequency (LF) power ($r=0.65$, $p=0.002$) in the frequency domain (Table 1).

	R coefficient	P
RR	0.22	0.36
SDNN	0.54	0.016
SDANN	0.52	0.023
SDNN-i	0.61	0.006
rMSSD	0.33	0.16
pNN50	0.49	0.035
TP	0.54	0.017
VLF	0.60	0.006
LF	0.65	0.002
HF	0.36	0.12

Conclusion: Our data show a strong association between cardiac autonomic dysfunction and reduced pulmonary diffusing capacity in patients with type 1 diabetes without any clinical evidence of pulmonary abnormalities or peripheral autonomic dysfunction. Our findings further support the hypothesis that autonomic dysfunction is linked to subclinical reduction of alveolar microvascular reserve, as assessed by DLCO. DLCO may be an early sensitive marker of autonomic neuropathy in type 1 diabetes.

UKPDS risk engine and French guidelines to select the diabetic patients to screen for silent myocardial ischaemia: a follow-up study

E. Cosson, C. Balta, M. Nguyen, J. Pariès, S. Balta, P. Valensi; Department of Endocrinology-Diabetology-Nutrition, Jean Verdier Hospital, Bondy, France.

Background and Aims: French Societies of Diabetology and Cardiology recommended in 2004 to screen for silent myocardial ischemia (SMI) the diabetic patients selected on the following criteria: those with nephropathy or carotid or peripheral artery disease, those with ≥ 2 other cardiovascular risk factors if type 1 diabetic patients older than 45 yrs or with diabetes duration >15 yrs, and if type 2 diabetic patients older than 60 yrs or with diabetes duration >10 yrs. The aim of the study was to evaluate these criteria and also the UKPDS risk engine for the 10-yr risk of coronary events (UKPDS-CHD).

Materials and Methods: Between 1992 and 2006, a total of 781 diabetic patients were screened for SMI, defined as an abnormal stress myocardial scintigraphy, and for significant ($>70\%$) coronary stenoses (CS) on angiography in those with SMI. We followed up 643 patients for cardiac events (cardiac death, myocardial infarction, cardiac failure, coronary revascularisation, unstable angina). In this population, 406 patients fulfilled the French screening criteria (C+), 345 did not (C-) and 30 were unclassified.

Results: SMI was present in 227 (29%) patients. The prevalence of SMI was higher in the C+ (133/406, 32.8%) than in the C- group (85/345, 24.6%). Odds ratio 1.49 confidence interval 95% [1.08–2.05] $p<0.05$, and was associated with a higher UKPDS-CHD score ($32\pm 19\%$ versus $24\pm 16\%$, $p<0.0001$). Coronary angiography was performed in 209 patients with SMI, and CS were identified in 83 patients (40%). The positive predictive value of SMI for identifying the patients with CS was unchanged considering French recommendations or UKPDS-CHD score. A total of 55 cardiac events occurred follow-up 4.4±3.9 yrs. SMI was predictive of events (Kaplan Meier: log rank 29, $p<0.0001$). In the patients with SMI, the presence of CS was associated with a poorer prognosis as compared with the patients without CS (Kaplan Meier: log rank 18.5, $p<0.0001$). UKPDS-CHD score correlated with the incidence of cardiac events ($p=0.03$).

Conclusion: SMI and silent CS are the main predictive factors of cardiac events in the diabetic population. The current French guidelines and UKPDS-CHD risk are helpful in identifying the diabetic patients with a high risk of SMI.

1208

Leptin predicts glucose perturbations and future risk after acute myocardial infarction in patients without previously known diabetes

M. Wallander¹, S. Söderberg², K. Malmberg¹, A. Norhammar¹, L. Rydén¹; ¹Dep. of Medicine, Cardiology Unit, Karolinska Institutet, Stockholm, ²Department of Internal Medicine, Umeå University, Sweden.

Background and Aims: High levels of leptin and low adiponectin are associated with type 2 diabetes (T2DM) and cardiovascular (CV) disease. We studied the prognostic importance of leptin and adiponectin for glucose tolerance (GT) and future CV events in patients with acute myocardial infarction (AMI) without known T2DM.

Materials and Methods: 168 AMI-patients (67% men) were classified after an OGTT at hospital discharge (DIS; day 4–5) as having normal or abnormal GT (AGT), defined as impaired GT or T2DM. 185 sex- and age matched healthy persons served as controls. Fasting serum-leptin and adiponectin at hospital admission (ADM) and discharge were related to AGT and CV events (CV mortality (8), non-fatal stroke (6), reinfarction (15) or severe heart failure (10)) during a median follow up of 34 months. Values are presented as means. All analyses are adjusted for age, sex and BMI.

Results: Leptin values were higher in patients at admission than in controls (women: 21.1 vs. 17.0 ng/ml; $p=0.029$; men: 9.1 vs. 6.4 ng/ml; $p<0.001$) but decreased before hospital discharge to 18.1 (women) and 7.4 (men) ng/ml respectively. High levels of leptin at admission and discharge related to AGT ($OR_{ADM} = 2.2$; $p=0.016$; $OR_{DIS} = 2.1$; $p=0.040$) and to increased risk for CV events during follow up ($HR_{ADM} = 1.8$; $p=0.014$; $HR_{DIS} = 1.7$; $p=0.040$). The

relationship to CV events at admission but not at discharge was significant after multiple adjustment. The figure presents Kaplan-Meier curves of CV events in patients above or below the median of leptin (women: 22.6, men: 8.9 ng/ml) at admission. Adiponectin levels did not differ between patients and controls and did not relate to AGT or CV events.

Conclusion: Elevated levels of leptin at admission and discharge in patients with AMI were related to AGT and independently of the glucometabolic state, leptin at admission related to a more serious prognosis.

Prevalence of abnormal glycaemia in patients with acute cardiac-sounding chest pain

A. A. Tahrani¹, J. Geen², P. W. Jones³, F. W. F. Hanna¹;

¹Diabetes and Endocrinology, University Hospital of North Staffordshire, Stoke-On-Trent, ²Diabetes and Endocrinology, North Glamorgan NHS Trust, Merthyr Tydfil, ³Department of Mathematics, Keele University, Stoke-On-Trent, United Kingdom.

Background and Aims: To assess the prevalence of diabetes, impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) based on random plasma glucose (RPG), fasting plasma glucose (FPG) and oral glucose tolerance test (OGTT) on admission in patients with acute cardiac-sounding chest pain.

Materials and Methods: 200 consecutive patients admitted to a district general hospital in the UK with cardiac-sounding chest pain were included. Data collected on admission included: RPG, FPG, fasting lipid profile, troponin I, waist measurement, BMI, smoking status. OGTT was done during the admission.

Results: Diabetes prevalence was 4.5% and 3% based on admission RPG and FPG respectively. 89.5% had normal FPG on admission and 7.5% had IFG. OGTT on admission showed that 20.5% had diabetes, 31.5% had IGT, 2% had IFG and 45% were normal. The OGTT samples from 2 patients (1%) were not usable.

In the raised troponin sub-group: 45.5% of our patients had raised troponin I levels. Diabetes prevalence was 6.5% and 4.4% based on admission RPG and FPG respectively. 89% had normal FPG and 6.6% had IFG. OGTT on admission showed that 26.4% had diabetes, 38.5% had IGT, 1.1% had IFG and 33% were normal. OGTT sample from 1 patient (1.1%) was not usable. 66.7% of patients with raised vs 44.4% with normal troponin had abnormal OGTT on admission ($p=0.002$). 11% of patients with elevated vs 10.1% with normal troponin had abnormal FPG on admission ($p=0.83$). Admission RPG also showed no statistically significant difference between high and normal troponin groups ($p=0.55$).

Conclusion: In patients admitted with cardiac sounding chest pain:

1. More than half of the patients had abnormal OGTT.
2. Fasting and random plasma glucose underestimate the prevalence of diabetes in our cohort considerably compared to OGTT.
3. Fasting/random glucose should not be used to rule out diabetes in this high-risk group of patients.
4. It is important not to miss the diagnosis of diabetes in this group as early treatment could delay the development of microvascular complications.

In patients with elevated troponin:

1. Only one third of the patients had normal OGTT.
2. Fasting and random plasma glucose underestimate the prevalence of diabetes considerably compared to OGTT.

Comparing the raised to normal troponin groups:

1. The prevalence of abnormal OGTT was significantly higher in the raised troponin group.
2. The prevalence of abnormal fasting and random plasma glucose levels was similar between both groups.

1210

Prolonged corrected QT interval is associated with microalbuminuria and left ventricular hypertrophy in male subjects with type 2 diabetes mellitus

A. Jawa, M. Hasan, U. Chaudhary, S. Abaidullah, J. Zaheer, S. Iqtadar; Medicine, King Edward Medical University, Lahore, Pakistan.

Background and Aims: Patients with type 2 diabetes mellitus are at high risk for future cardiovascular events. Microalbuminuria is a strong predictive risk factor for all-causes and cardiovascular mortality in type 2 diabetes. Prolonged QTc interval is an independent predictor of cardiovascular mortality in type 2 diabetic patients. Both microalbuminuria and prolonged QTc interval are risk factors for cardiovascular disease in type 2 diabetic subjects. The link between microalbuminuria and premature death in type 2 diabetes is not fully explained by conventional cardiovascular risk factors. We investigated whether QT prolongation is associated with microalbuminuria and Left Ventricular Hypertrophy in patients with type 2 diabetes.

Materials and Methods: We conducted a case-control study from 1st September 2006 to 31st January 2007 at Diabetes Clinic of King Edward Medical University and allied hospitals. Microalbuminuria was defined to be present as two of three urinary albumin excretion rate of 20–200 µg/min. Prolonged QT interval was defined as > 440 milliseconds (ms) and was corrected with Bazette's formula. All male subjects with type 2 diabetes aged between 35–75 years with no clinical evidence of coronary disease were offered participation in the study. None of the subjects were on QTc interval prolonging drugs. After obtaining informed consent, fifty subjects were enrolled and tested for fasting blood sugar, HbA1c, creatinine, triglycerides and HDL-cholesterol and blood pressure were measured. Urine was tested for the presence of microalbuminuria using standardized semi quantitative dipstick technique (MICRAL, Roche, USA). Electrocardiograms were performed and two independent trained physicians blinded to the subject's medical history analysed these electrocardiograms for rate, rhythm, axis, ST segment changes and corrected QT interval. Data was analysed using statistical software SPSS 14.0.

Results: Subjects enrolled were divided in two groups. Group A consisted of 25 male subjects who did not have microalbuminuria and Group B consisted of 25 male subjects who had microalbuminuria. The mean age for Group A was 51.24 ± 12.02 years and 56.36 ± 11.06 years for Group B (p -value=0.1). BMI, pulse, systolic and diastolic blood pressures, HbA1c, creatinine, serum triglycerides and HDL-cholesterol levels of both the groups were compared and did not differ in statistically significant manner. Eight percent (2/25) of the subjects in Group A had prolonged QTc interval whereas in group B 60% (15/25) of subjects had prolonged QTc interval. In Group A mean QTc interval was 420 ± 20 ms where as it was 460 ± 40 ms in Group B (p -value = 0.0001). The correlation coefficient using Pearson's Correlation coefficient for microalbuminuria and prolonged QTc was statistically significant ($r = 0.38$, 1-tailed significance=0.003, Table 2).

Conclusion: Our study clearly shows that rate-corrected QT interval (QTc) is associated with presence of microalbuminuria and Left Ventricular Hypertrophy in type 2 diabetic subjects. Our findings support the hypothesis that QT prolongation and microalbuminuria have common determinants such as Left Ventricular Hypertrophy in Type 2 diabetes Mellitus. While treating patient with type 2 diabetes mellitus, physicians should pay special attention to non-conventional cardiovascular risk factors such as prolonged QT interval, an indicator of increased risk of sudden cardiac death.

1211

Relationship of prolonged QTc interval with other risk factors than glycaemic control in individuals with type 2 diabetes

C. Bala, C. Nita, A. Rusu, G. Nicolescu, D. Giurgiuiman, G. Roman, N. Hancu;

Department of Diabetes, Nutrition, Metabolic Diseases, Iuliu Hatieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania.

Background and Aims: Ventricular myocardial depolarization and repolarization are reflected in QT interval. QT prolongation in patients with diabetes may contribute to ventricular fibrillation and sudden death. In individuals with diabetes, cardiac autonomic neuropathy is well known to be associated with QT prolongation. Hyperglycemia per se can also affect QT interval. The effect of other factors frequently associated with diabetes on the duration of QT interval is less investigated. The aim of the study is to examine the relationship between prolonged QTc interval and other risk factors such as waist circumference, microalbuminuria, lipid parameters, diabetes duration, and presence of hypertension.

Materials and Methods: 100 consecutive patients with diabetes attending the outpatient clinic from Clinical Center of Diabetes, Nutrition and Metabolic Diseases Cluj-Napoca have been included in a larger epidemiological study aiming to assess the prevalence of heart failure among persons with diabetes. A complete medical history, physical exam (weight, waist, blood pressure) and questionnaire for the presence of suggestive heart failure symptoms and signs have been performed. Blood sampling for HbA_{1c}, lipid profile, a urine exam for microalbuminuria and ECG were performed for all patients who agreed to participate. Statistical methods consisted in a factor analysis followed by a linear regression model.

Results: The study group had a median age of 59 years (min 34, max 77 years), 60 % females, median duration of diabetes 3 years (min 0, max 13 years), stratification by antidiabetic treatment: 14% diet alone, 14% metformin, 10% sulphonylurea, 10 % combined oral therapy, 45% insulin alone, 7% insulin+ oral therapy. 76% had metabolic syndrome according to IDF criteria. By factor analysis we extracted three factors that explained 86% of the variance in QTc interval [Factor 1 with positive loadings of diabetes duration, waist circumference, systolic blood pressure, and microalbuminuria, Factor 2 with positive loadings of age, HDL-cholesterol, presence of hypertension and Factor 3 with positive loadings of HbA_{1c}, total cholesterol and serum triglycerides]. In the linear regression model including the three factors identified, the model was significantly associated with QTc interval ($p=0.017$). Within the model, Factor 1 displayed a p value of 0.263 and was excluded from the analysis. The second regression included Factor 2 and 3, the model remaining statistical significant ($p=0.01$, F change 5,979, significance of F change= 0.01).

Conclusion: In a linear regression model, QTc interval was significantly associated with HbA_{1c}, HDL-cholesterol, serum triglycerides, presence of hypertension and total cholesterol. Our results suggest that controlling other factors than hyperglycaemia might result in less cases of sudden death in people with type 2 diabetes.

Fasting glucose predicts development of restenosis after PCI in patients with type 2 diabetesC. A. Hage¹, A. Norhammar¹, N. Sarkar¹, B. Svane¹, L. Grip², J. Öhrvik³, K. Malmberg³, L. Rydén³;¹Dep. of Cardiology, Karolinska University Hospital, Stockholm,²Dept. of Cardiology, Sahlgrenska University Hospital, Göteborg, ³Dept. of Medicine, Cardiology Unit, Karolinska Institutet, Stockholm, Sweden.

Background and Aims: Diabetic patients are at increased risk for restenosis after percutaneous coronary intervention (PCI). We investigated if insulin (I) based glucose control (GC) may reduce target lesion restenosis (TLRest) after PCI in patients with type 2 diabetes (T2DM).

Materials and Methods: 93 consecutive T2DM patients accepted for PCI were randomised to I-based GC (I-group; $n=44$) or to continue ongoing treatment (C-group; $n=49$). Glucose target was fasting blood glucose (FBG) 5–7 mmol/L and HbA_{1c} <6.5%. Information on TLRest after 6 months was available in 80 patients via angiography ($n=71$) or angio and/or revascularisation before that time ($n=9$) while a second angiography was not performed in 13 patients (medical reasons = 5; refusal = 6; data missing = 2).

Results: At baseline there was no difference in HbA_{1c} (6.5 vs. 6.5%) or FBG (7.0 vs. 7.4 mmol/L; $p=0.2$) in the I- and C-groups respectively. Physical findings, previous medical history or medication at baseline did not differ. At end of follow up HbA_{1c} (-0.2 vs. -0.1%; $p=0.2$) and FBG (+0.2 vs. -0.3 mmol/L; $p=0.2$) did not change significantly in the I- and C- groups. TLRest did not differ after 6 months (I- vs. C-group = 39% vs. 43%; $p=0.8$). Significant unadjusted predictors for TLRest were previous MI (OR 4.1; $p=0.003$) and previously known hyperlipidemia (OR 3.2; $p=0.03$). FBG at baseline (OR 1.2; $p=0.06$) was almost significant. In a multiple analysis including univariate predictors with p -value <0.2, remaining predictors of restenosis were previous MI (OR 7.7; $p=0.001$) and FBG at baseline (OR 1.5; $p=0.013$).

Conclusion: Insulin based GC did not reduce TLRest in T2DM patients which, however, was predicted by baseline FBG. This suggests that future trials should target glucose normalisation and that the tool to achieve this seems to be of secondary importance.

1213

The association between left ventricular mass and adipocytokine in type 2 diabetic patients

M. Harada, A. Sato, T. Onai, N. Aki, Y. Iwamoto;

Diabetes Center, Tokyo Women's Medical University, Tokyo, Japan.

Background and Aims: Left ventricular hypertrophy (LVH) is an independent risk factor for cardiovascular morbidity and mortality. It is well-known that obesity affects the development of LVH. Metabolic syndrome (Met S) results from the accumulation of abdominal fat which secretes adipocytokine, and composes atherosclerosis which in turn leads to cardiovascular diseases. However, it is not clear whether adipocytokine has a direct effect on LVH. The purpose of this study is to identify the relationship between LV mass and adipocytokine in type2 diabetic patients.

Materials and Methods: Type 2 diabetic patients without history of coronary disease, stroke, chronic kidney disease, or taking antihypertensive drug were recruited. Echocardiography was performed in 46 type2 diabetes [30 men, age 51±12 y.o., (mean±SD)] and LV internal diameter was measured by using M-mode, and fractional shortening and LV mass were calculated. LV mass was indexed by body surface area (LVMI) and body height to the power of 2.7. Met S was defined, according to the Japanese criteria of 2005, as a waist circumference level ≥ 85 cm in men and ≥90cm in women, and two or three of the following three risk factors: hypertension (blood pressure level ≥130/85mmHg), dyslipidemia (HDL cholesterol level <40 mg/dl or TG level ≥150 mg/dl), and glucose intolerance (fasting glucose level ≥110 mg/dl). Subjects taking medications for any of the three components were also considered to have the corresponding risk factor. In addition, we also measured visceral(V) subcutaneous(S) fat area and total fat area using computed tomography. Fasting plasma glucose, HbA_{1c}, fasting insulin, serum total cholesterol, triglycerides, HDL cholesterol and LDL cholesterol were measured. Adipocytokine such as fasting leptin, adiponectin, total PAI-1, IL-6 and TNF- α were measured. Atherosclerosis was evaluated through pulse wave velocity (PWV) and ankle-brachial index (ABI).

Results: The average metabolic parameters of 46 type 2 diabetes were BMI: 26±5kg/m², HbA_{1c}: 9.0 ±2.0%, waist circumference: 95.3±9.2cm, blood pressure: 124±11/77±10 mmHg, TG: 157±77 mg/dl, and HDL-C: 43±11 mg/dl. Met S was present in 29 patients (63%). Patients with Met S had a significantly higher LVMI than patients without Met S (107±19 vs. 89±16 g/m², respectively). ($p<0.05$). LVMI was increased in the patients with the higher BMI and increased subcutaneous fat area ($p<0.05$). In contrast, LVMI had no correlation with visceral fat, V/S, blood pressure, lipid and waist circumference. Among adipocytokines, PAI-1 and IL-6 level were significantly related to LVMI ($p<0.005$). The increasing of LVMI tended to correlate with the increasing of leptin and the decreasing of adiponectin, although there was no significant correlation. The elevated IRI was the most significant factor for the LV mass increase. In multiple regression analysis, IL-6 and IRI were independent risk factors for increased LVMI.

Conclusion: Met S was associated with the increased LV mass in type 2 diabetes. The results suggest that adipocytokine directly affects progression of LVH in type 2 diabetic patients with Met S.

Macrovascular disease in type 1 diabetes in children and adolescents: subclinical atherosclerosis?

L. Trifone¹, V. Osta², A. Sardella³, H. Vazquez³, H. Cozzani⁴, V. Vaccarezza¹; ¹Nutrition and Diabetes Section, ²Central laboratory, ³Service of Cardiology, ⁴Radiology, Children Hospital R. Gutiérrez, Buenos Aires, Argentina.

Background and Aims: Diabetes mellitus is an established risk factor for atherosclerosis. Vascular complications of diabetes are not clinically evident in diabetic children. Aims: to detect subclinical atherosclerosis and risk factors in type 1 diabetic children and adolescents and its association with microangiopathic complications, metabolic control and markers of subclinical inflammation

Materials and Methods: Ninety children and adolescents with type 1 diabetes were evaluated: medical history, familial history of obesity, high blood pressure (HBP), cardiovascular disease and dyslipidaemia, diabetes duration, physical examination (weight and height, Tanner pubertal stage and blood pressure). Metabolic control: HbA1c; microangiopathic complications: microalbuminuria and direct ophthalmoscopy. Laboratory analysis: lipid profile, white blood cells count (WBC), fibrinogen and hs-CRP. Cardiovascular evaluation: electrocardiogram, color Doppler electrocardiography, tread mill and spect. Measurements of intimal-media thickness of both carotids with ultrasound scanning.

Results: 51% (54) of the evaluated patients were male. Median age 15.4 ± 3.0 years. Overweight 12/90 (13%), diabetes duration 6.8 ± 3 years; HbA1c median 9.9 ± 1.9 %, with 62,3 % poor control (HbA1c > 8%); high total cholesterol 10/82 (12%), high tryglicerides 13/82 (16%) combined dyslipidaemia 4/82 (5%), high blood pressure 5/89 (6%), microalbuminuria > 20 µg/min 15/90 (17%); direct ophthalmoscopy normal in all. Hs-CRP > 3mg/l in 5% (n); 1–3 mg/l 28.3% (n); fibrinogen > 400mg% 28.8% and WBC > 10×10^3 /ml 12.3%. Abnormal ECG in 2/86. Diastolic dysfunction was present in 28% (19/67), 6 out of 19 were severe; tread mill was abnormal in 23% (8/34) with hypertension during maximal effort; Spect only in 27 patients all of them normal. Those patients with WBC > 10×10^3 had increase IM thickness ($p < 0.05$) as well as those with microalbuminuria ($p < 0.05$). Tread mill induced hypertension was significantly associated with the increase in hs-CRP ($p < 0.05$). Basal hypertension was associated to fibrinogen > 400 mg% ($p < 0.05$).

Conclusion: Early structural and functional cardiac alterations and elevated plasma markers of endothelial activation and injury are presents in children with diabetes. This data provides the best currently available non invasive marker of preclinical atherosclerosis in children with type 1 diabetes.

PS 125 Epidemiology of cardiovascular risk factors in diabetes

1215

Asymmetric dimethylarginine is associated with incident cardiovascular disease in the general population. The Hoorn Study

T. Teerlink¹, R. J. Heine², C. D. A. Stehouwer³, J. M. Dekker⁴; ¹Department of Clinical Chemistry, VU University Medical Center, Amsterdam, ²Department of Endocrinology / Diabetes Center, VU University Medical Center, Amsterdam, ³Department of Internal Medicine, Academic Hospital Maastricht, ⁴Institute for Research in Extramural Medicine, VU University Medical Center, Amsterdam, The Netherlands.

Background and Aims: Asymmetric dimethylarginine (ADMA), an endogenous inhibitor of nitric oxide synthase (NOS), is a novel risk marker for cardiovascular disease (CVD). ADMA independently predicts the incidence of cardiovascular events in patients with renal failure and patients with coronary or peripheral artery disease. Only limited data exist regarding the association of ADMA and incident CVD in the general population. To address this question, we investigated the predictive value of ADMA in the Hoorn Study, a prospective community-based cohort study.

Materials and Methods: ADMA was measured by HPLC in baseline plasma samples from participants of the Hoorn Study (age 50 to 75 years). The main outcome measure was the combined incidence of fatal and non-fatal CVD in 1715 subjects (159 with type 2 diabetes) during a 10-year follow-up period.

Results: In a multivariate linear regression model, higher age and BMI, and female sex and smoking were associated with higher levels of ADMA, whereas diabetes and higher glomerular filtration rate, serum albumin, and HDL-cholesterol were associated with lower levels. Together these variables explained only 10% of the variation in ADMA concentration. During follow-up, 379 subjects (63 with diabetes) experienced a cardiovascular event. Separate analyses for non-diabetic and diabetic individuals were performed, because of a significant interaction term in the Cox proportional-hazards models between ADMA and diabetes ($p=0.002$). After adjustment for age, sex and established CVD risk factors, the hazard ratio for CVD in the highest quintile of ADMA versus the combined lowest four quintiles was 1.38 (95% CI, 1.08 to 1.77) in individuals without diabetes and 0.37 (95% CI 0.17 to 0.81) in individuals with diabetes. In non-diabetic individuals the increased CVD risk associated with high ADMA did not significantly differ between subjects with normal and impaired glucose metabolism. Likewise, there were no significant differences in hazard ratios between males and females, smokers and non-smokers, and between individuals with and without prevalent CVD (all $p > 0.4$).

Conclusion: This study shows that in the general population a high plasma concentration of ADMA independently predicts CVD in individuals without type 2 diabetes. The inverse association between high ADMA and incidence of CVD in individuals with diabetes was unexpected and needs confirmation. Possibly, uncoupling of NOS, leading to a shift from NO production to superoxide production, plays a role in this paradoxical observation. As opposed to the anti-atherogenic effects of normally functioning NOS, uncoupled NOS accelerates atherosclerosis, and its inhibition by high ADMA may be beneficial.

Human complement C3 as a risk factor for coronary artery disease: relation with insulin, but not inflammation (the CODAM study)

M. M. J. van Greevenbroek¹, C. J. H. van der Kallen¹, E. J. M. Feskens², E. H. J. Jansen³, C. G. Schalkwijk³, C. D. A. Stehouwer¹; also on behalf of the CODAM study group,

¹Department of Internal Medicine / Cardiovascular Research Institute Maastricht, Maastricht University, ²Division of Human Nutrition, Wageningen University, Wageningen, ³Laboratory for Toxicology, Pathology en Genetics, National Institute for Public Health and the Environment, Bilthoven, The Netherlands.

Background: Complement C3 is an emerging risk factor for coronary artery disease (CAD), and several studies have indicated that their relation is independent of, at least some, other known CAD risk associates.

Hypothesis: Since the larger part of plasma C3 is derived from liver and the presence fatty liver is, by itself, related to CAD, we hypothesize that the relation between C3 and CAD may be related to presence of fatty liver.

Materials: The relation between C3, CAD and an indicator of fatty liver (plasma ALT concentration) was studied in the CODAM study (Cohort on Diabetes and Atherosclerosis Maastricht). This cohort consists of 301 normal glucose tolerant, 127 impaired glucose tolerant and 146 type 2 diabetes mellitus (T2DM) subjects, invited from a large population-based cohort on basis of an elevated risk for T2DM. The relation between C3 and a self-reported history of CAD (defined as myocardial infarction, bypass surgery of the coronary arteries, balloon dilatation and / or stent placement) was evaluated by logistic regression. The relation between plasma C3 and fatty liver was evaluated in linear regression analysis.

Results: Plasma C3 levels were significantly associated with increased CAD prevalence, also after adjusting for age, gender, smoking and glucose tolerance status (model 1, OR per unit C3 is 3.2 [95% CI: 1.6–6.5], $p < 0.001$). Additional adjustment for known CAD risk factors showed that this relation was independent of: the metabolic syndrome, markers of inflammation (CRP, VCAM, ICAM, IL-6), markers of lipid metabolism (total and HDL-cholesterol and triglycerides), and markers of an acute phase / complement response (C4, ceruloplasmin, haptoglobin, transferrin, serum amyloid A). It was, however, affected by fasting insulin level (OR C3 is 2.1 ([CI 95% 1.0–4.6], $p = 0.06$), with a significant contribution of insulin in this model ($p = 0.011$). The partial correlation between C3 and ALT was 0.364 ($p < 0.001$; adjusted for age, gender, alcohol intake and glucose tolerance status). This association was affected by adjustment for fasting insulin but not, or considerably less, by adjustment for markers of inflammation, lipid metabolism, acute phase response / complement or kidney function. These data imply that the relation between insulin and C3 is affected by the presence of fatty liver, or vice versa. However, when the association between C3 and CAD (as shown in model 1) was additionally adjusted for ALT, the association between C3 and CAD was not substantially affected (OR is 3.2 [95% CI: 1.5–6.8], $p < 0.002$).

Conclusion: Both the association between plasma C3 levels and CAD, and the relation between plasma C3 levels and fatty liver (as represented by plasma ALT) were, at least partly, explained by insulin and/or insulin resistance, but adjustment for ALT did not affect the relation between C3 and CAD. The data suggest that hyperinsulinemia and/or insulin resistance, rather than fatty liver by itself, explain part of the CAD risk associated with high levels of plasma C3.

Low-grade inflammation and cardiovascular risk in the metabolic syndrome: the CODAM study

M. Jacobs¹, M. M. J. van Greevenbroek¹, C. J. H. van der Kallen¹, E. H. J. Jansen², E. E. Blaak³, E. J. H. Feskens⁴, C. G. Schalkwijk¹, C. D. A. Stehouwer¹; also on behalf of the CODAM study group,

¹Department of Internal Medicine / CARIM, Maastricht University,

²Laboratory for Toxicology, Pathology and Genetics, National Institute for Public Health and the Environment, Bilthoven, ³Department of Human Biology / NUTRIM, Maastricht University, ⁴Human Nutrition, Wageningen University, The Netherlands.

Background: The Metabolic Syndrome (MetS) is associated with an increased risk for cardiovascular disease and type 2 diabetes (T2DM). Abdominal obesity, dyslipidemia, hypertension and insulin resistance are the main determinants that define the MetS, but low-grade inflammation is also increasingly recognized as an underlying trait in the cardiovascular risk associated with the MetS.

Aim: To identify inflammation markers that are determinants of coronary heart disease (CHD) and to establish their association with the individual criteria of the metabolic syndrome.

Methods: The CODAM (Cohort study Diabetes and Atherosclerosis Maastricht) cohort was used. The cohort includes 574 subjects who were invited from a large population based cohort on basis of an elevated risk for T2DM. As determined by oral glucose tolerance test, 301 subjects were normal glucose tolerant, 127 were impaired glucose tolerant or had impaired fasting glucose levels and 146 had T2DM. Relevant anthropometric and blood parameters were determined. First, inflammation markers were identified that were elevated in subjects with a self-reported history of CHD. Subsequently,

logistic regression analyses was used to determine if the relation between the inflammation markers and CHD was independent of the MetS. Finally, the relations between the inflammation makers and the individual determinants of the MetS were determined in linear regression analyses.

Results: C-reactive protein (CRP), interleukin 6 (IL6) and soluble vascular cell adhesion molecule (VCAM) were elevated in CHD. Logistic regression showed that the MetS was a significant determinant of CHD (odds ratio [OR_{MetS}] is 1.82, P_{MetS} : 0.019 adjusted for age, gender and glucose tolerance status). Addition of IL6 to the above described logistic regression model, reduced the association of MetS with CHD (OR_{MetS}: 1.62, P_{MetS} : 0.064; OR_{IL6}: 3.05, P_{IL6} : 0.005). Analysis with CRP resulted in similar results (OR_{MetS}: 1.64, P_{MetS} : 0.056; OR_{CRP}: 1.78, P_{CRP} : 0.061). On the other hand, addition of VCAM to the model did not affect the association of MetS and CHD (OR_{MetS}: 1.78, P_{MetS} : 0.026; OR_{VCAM}: 43.8, P_{VCAM} : 0.001). Multiple linear regression adjusted for age, gender and glucose tolerance status showed that CRP, IL6 and VCAM were all independently associated with lipids and HOMA-IR (P_{CRP} : 0.039, P_{IL6} : 0.035, P_{VCAM} : <0.001). CRP ($P < 0.001$) and IL6 ($P < 0.001$) were also associated with waist circumference. Only CRP was related to blood pressure.

Conclusion: MetS was a significant determinant of CHD. This relation was reduced if CRP or IL6 were included in the model, and remained unaltered if VCAM was added. CRP and IL6 were mainly associated with waist and lipids, whereas VCAM was associated with insulin resistance and lipids. Our data suggest that low-grade inflammation may be an important pathway linking the MetS to CHD. Furthermore it suggests that the association of CRP and IL6 with CHD may occur via a different mechanism than between VCAM and CHD.

¹Section of Endocrinology, Department of Clinical Pathophysiology,

²Geriatric unit, Department of Critical Care, University of Florence, Italy.

Background and Aims: Metabolic Syndrome (MS) is a cluster of risk factors for CVD. Recently, goals of therapy of blood pressure, glucose, and lipids were defined, categorizing patients with MS in 3 classes of Framingham-based estimates of 10 yr-CVD risk: low-to-moderate risk (<10%), moderately high risk (10–20%), and high CVD risk (>20%). Aim of this study is to verify the achievement of treatment goals in patients with MS.

Materials and Methods: A cohort of 2945 individuals, with no history of diabetes, living in Florence and in the nearby Bagno a Ripoli municipality, enrolled in a screening program for diabetes, were studied. Of these, 672 (aged 60.5±9.7 yrs, BMI 29.5±4.0 kg/m²) were affected by MS according to the revised (2004) National Cholesterol Education Program (NCEP) criteria. Anthropometric measures, smoking habits, glucose tolerance (120 minutes after a 75 g oral glucose load), lipid profile, and blood pressure were assessed. 10 yrs CVD risk was computed by Framingham score model based on sex, age, smoking, systolic and diastolic blood pressure, total HDL cholesterol, and diabetes.

Results: 281 (41.8%) subjects had a low to moderate CVD risk, 187 (27.8%) a moderately high risk, and 204 (30.3%) a high CVD risk; normal weight was observed in 9.4% of subjects of the first class, 11.2% in the second class, and only 7.3% in the high risk class. Coronary heart disease (CHD) at enrolment was observed in 5.6% subjects. Considering LDL cholesterol, levels <130 mg/dl were found in 47.0% and 44.9% subjects with low to moderate and moderately high risk, respectively, while LDL levels <100 mg/dl were found in only 13.7% of high risk patients. CHD patients with LDL <70 mg/dl were 5.4%, and those with non-HDL cholesterol <100 mg/dl were 2.6%. The prevalence of non-HDL cholesterol <160 mg/dl was 46.3% in low risk individuals and 40.6% in subjects with moderately high risk class. Few patients were treated with lipid drugs as statins, fibrates or fish oil: 3.5% in the low risk, 4.3% in the medium risk class, and only 6.4% in the high risk class. Patients with blood pressure <130/80 mm Hg were 44.8% and 24.0% in low and moderately high risk, respectively, while high risk subjects with optimal blood pressure control were 14.7% only. 423 (62.9%) subjects had normal glucose tolerance, 119 (17.7%) impaired glucose tolerance, and 140 (20.8%) type 2 diabetes; fasting plasma glucose >100 mg/dl was found in 24.9% of low risk subjects, 18.2%

of those with moderately high risk, and in 12.2% of high risk individuals. The higher prevalence of smokers was found in moderately high risk patients (24.6%) and in high risk subjects (23.5%), versus 13.2% of individuals with low CVD risk. Antiplatelet drugs were assumed in 4.5% of subjects with MS. **Conclusion:** Despite recommendations from guidelines, lipid lowering therapy is underutilized in subjects with MS, particularly among those at higher CVD risk and with known CHD. Similarly, blood pressure targets are seldom achieved in individuals with MS. Taken together, these data suggest that MS is not considered by many physicians as a condition of elevated CVD risk, requiring a special attention in the management of each individual risk factor.

Diabetic dyslipidaemia: blood lipid profiles in 54,885 type 2 diabetic patients

K. Eeg-Olofsson¹, S. Gudbjornsdottir¹, J. Cederholm², P. M. Nilsson³, B. Eliasson¹, M. Eriksson⁴;

¹Department of Medicine, Goteborg University, ²Department of Public Health and Caring Sciences, Family Medicine and Clinical Epidemiology Section, Uppsala, ³Department of Clinical Sciences Medicine, Division of Medicine, Lund, ⁴Department of Medicine and Molecular Nutrition Unit, Karolinska Institutet at Karolinska University Hospital in Huddinge, Stockholm, Sweden.

Background and Aims: Dyslipidemia is considered an integral part of the insulin resistance syndrome associated with type 2 diabetes and a strong risk factor for cardiovascular morbidity and mortality. The aim of this study was to describe blood lipid profiles in a large cohort of type 2 diabetic patients and to examine the role of gender, age, and association with cardiovascular risk factors such as obesity.

Material and Methods: Blood lipid values from 26413 patients without and from 28472 with lipid lowering agents (LLA) were included in the study based on yearly registrations of clinical data to the Swedish National Diabetes Register (NDR). Around one third of all diabetic patients in Sweden were reported to NDR in 2005.

Results: Patients treated with LLA (48%) had lower total and LDL-cholesterol (4.6 vs. 5.1; 2.5 vs. 3.0 mmol/L, respectively), but slightly higher triglycerides (TG) than the untreated patients (1.7 vs 1.6 mmol/L). HDL levels were similar in the two groups (1.34 vs 1.37 mmol/L) (all differences $p < 0.001$). 56% of the patients treated with LLA reached LDL < 2.5 mmol/L and 28% reached LDL < 2.0 mmol/L.

In patients not treated with LLA, women exhibited higher total, LDL, and HDL cholesterol levels as well as TG than men. Total and LDL cholesterol increased with age in women, and HDL levels were highest in the oldest patients. In men, LDL levels were highest between 40–60 years of age. In men and women, total and LDL cholesterol were highest in patients with BMI 25–39, while TG increased and HDL decreased with higher BMI. Patients with low HDL are obese, smoke, exhibit microalbuminuria and are more often treated with blood pressure lowering agents.

Conclusion: In this large type 2 diabetic population, TG and HDL levels are surprisingly normal, HDL being higher in women than in men at all ages. However, many patients are not treated with LLA and many treated patients do not reach the LDL goal. The results from this study raise questions: how should type 2 diabetic patients be treated adequately; is it justifiable to adopt the current goals that we have for all high risk individuals to patients with type 2 diabetes? Indirectly these results support the importance of glucose control in order to reduce glycosylation of the different lipoprotein fractions.

1220

Characteristics of individuals with dyslipidaemia and hyperglycaemia in Shanghai communities

Y. Bao, W. Jia, J. Lu, J. Zhou, M. Yang, J. Pan, K. Xiang; Shanghai Diabetes Institute, Department of Endocrinology and Metabolism, Shanghai Clinical Center for Diabetes, The Sixth People's Hospital Affiliated to Shanghai Jiao Tong University, Shanghai, China.

Background and Aims: To investigate the distribution of different kinds of dyslipidemia and characteristics among individuals with dyslipidemia and hyperglycemia in Shanghai communities.

Materials and Methods: Totally 5628 individuals aged over 20 years old were enrolled. According to the 1997's Recommendations for Prevention and Treatment of Dyslipidemia in China, the prevalences of different kinds of dyslipidemia were analyzed. The clinical characteristics of subjects with dyslipidemia and hyperglycemia were studied. All the individuals were divided into four groups, normal ones, isolated dyslipidemia (iDYL), iDYL with impaired glucose tolerance (IGR) and iDYL with diabetes mellitus (DM). Subjects with hypertension or overweight/obesity were excluded.

Results: 1. The prevalence of dyslipidemia was 71.78%. The most common kind of dyslipidemia was hypertriglyceridemia with hypercholesterolemia/high-density lipoprotein cholesterol (LDL-C) and isolated hypercholesterolemia/high LDL-C. 2. The frequency of dyslipidemia increased with age in both men and women (P for trend < 0.01). 3. The frequencies of IGR and DM in individuals with dyslipidemia were significantly higher compared with those with normolipidemia ($P < 0.01$). 4. Isolated postprandial hyperglycemia was the most common kind of hyperglycemia in the individuals with dyslipidemia and hyperglycemia. The frequency of dyslipidemia was 74% in IGR and 50% in DM. 5. Body mass index (BMI), waist circumference (W), blood pressure, fasting plasma glucose (FPG), postprandial glucose (2hPG), fasting insulin (FIN), postprandial insulin (2hINS), C-reactive protein (CRP) and HOMA-IR in iDYL group were all higher than normal group ($P < 0.01$). Age, BMI, W, TG, FIN, 2hINS, CRP and HOMA-IR in iDYL with IGR and iDYL with DM were higher than iDYL ($P < 0.01$). HOMA-IR in iDYL with DM further increased compared with iDYL with IGR.

Conclusion: 1. The prevalence of dyslipidemia in community was relatively high. 2. The frequency of hyperglycemia in the individuals with dyslipidemia was higher. The most common kind of hyperglycemia in the individuals with dyslipidemia and hyperglycemia was isolated postprandial hyperglycemia. 3. Total body fat, regional body fat, and CRP in the subjects with dyslipidemia increased independent of hyperglycemia. Total body fat and regional body fat further increased among the subjects with both dyslipidemia and hyperglycemia. 4. Individuals with dyslipidemia had insulin resistance. The extent of insulin resistance further increased in individuals with both dyslipidemia and hyperglycemia.

Increase of gamma-glutamyltransferase as a predictor of established cardiovascular risk factors and diabetes in Japanese adults

S. Jimba¹, T. Nakagami¹, J. Oya¹, T. Wasada², Y. Iwamoto¹;
¹Diabetes Center, Tokyo Women's Medical University, Tokyo,
²Department of Internal Medicine, Saitama-ken Saiseikai Kurihashi Hospital, Saitama-ken, Japan.

Objective: Recently, associations between fatty liver disease and risk of cardiovascular diseases (CVD) have been accumulated. While Nakanishi et al. have reported that gamma-glutamyltransferase (GGT) is an important predictor for CVD and diabetes (DM) in Japanese. However, subjects with fatty liver disease existed in those with normal liver enzymes in our study. Thus, we assess the relation between the changes in GGT over 3-years and the development of DM, impaired fasting glucose (IFG), dyslipidemia and hypertension (HT), in Japanese.

Subjects and Methods: A total of 1,950 subjects were enrolled in a general health examination programme at SSK Hospital from Sep '02 to Feb '03. Among them 784 subjects who had pharmacological treatment for DM, HT or dyslipidemia were excluded. Of the remaining 1,166 subjects at baseline, 1,004 subjects (mean age: 48 ± 7 years old) were followed up until Oct 2006 (follow-up rate: 85.1%). The relation between 3-year change in GGT against baseline and 3-year changes in anthropometric and metabolic variables were examined by Spearman's correlation coefficients. Subjects were classified into three groups according to GGT changes, such as an increased ($> +5$ U/L), unchanged (-5 to $+5$ U/L) or decreased (< -5 U/L) group. The logistic regression model was used to analyse the relation between changes in GGT levels and incident of DM (fasting plasma glucose [FPG] ≥ 7.0 mmol/l), IFG (FPG: 6.1–6.9 mmol/l), HT (systolic [sBP] ≥ 130 mmHg and/or diastolic blood pressure [dBp] ≥ 85 mmHg), hypertriglyceridemia (triglyceride [TG] ≥ 1.69 mmol/L), low HDL-cholesterol (HDL-C < 1.03 mmol/L), and obesity (BMI ≥ 25 kg/m²).

Results: The median follow-up period was 3 years and the average of 3-year GGT change was -4.56 ± 33.86 IU/L. The 3-year GGT change was

significantly correlated with baseline values for GGT (correlation coefficient: -0.319), AST (-0.250), ALT (-0.272), BMI (-0.148), FPG (-0.078), uric acid (-0.174), triglyceride (-0.121), sBP (-0.097) and dBP (-0.103). Moreover, the 3-year GGT change was positively correlated with the 3-year change in ALT (0.586), BMI (0.388), FPG (0.178), UA (0.241), TG (0.196), sBP (0.110) and dBP (0.132). The proportion of subjects with hypertriglyceremia, low-HDL-cholesterol, obesity, IFG, and HT at baseline was 24.1%, 5.3%, 29.8%, 7.2%, and 24.8%. Whereas the proportions of people who newly developed DM, hypertriglyceremia, low-HDL cholesterol, obesity, IFG and HT were: 1.7% (16/967), 10.0% (74/743), 7.4% (69/929), 6.2% (43/689), 6.3% (57/912) and 29.7% (219/737), respectively. The group of subjects with an increased GGT over 3 years had an increased risk of developing hypertriglyceremia, HT, obesity, IFG and DM, in comparison to those with a decreased GGT, with odds ratio of 5.78 (95% confidence interval: 2.96–11.29), 2.02 (1.23–3.31), 8.81 (2.66–29.22), 5.10 (2.45–10.62) and 5.76 (1.82–18.18), after adjusting for age and sex, respectively. Further additional adjustment for alcohol habits, the 3-year change in BMI, and smoking did not change these associations except HT and obesity.

Conclusions: Increase of GGT over 3 years seems to be an independent predictor of newly developed DM, IFG, and hypertriglyceride in Japanese. It may be important to pay attention to increase of GGT as well as GGT level to prevent future CVD at primary health care settings.

This analysis has been carried out with the support of a grant from the Japan Medical Women's Association for T.N.

Population-based assessment of diabetes and major cardiovascular risk factors among adults in Syria (AleppDiab study)

N. Albache;

Diabetes Research, Aleppo University, Syrian Arab Republic.

Background: The prevalence of Diabetes is increasing in many countries in the world, particularly in some countries like the Arab gulf countries where the prevalence of DM reaches a high level. Syria, a country of Middle East with 18 million inhabitants, was also witness to a lifestyle modification & diet changes, with probably an increase in the prevalence of DM as well other metabolic diseases during the last decades. We still lack population-based standardised prevalence to estimate the prevalence of diabetes and major cardiovascular disease CVD risk factors. We need also to have an accurate and updated idea about the metabolic diseases in general in Syria and to input that data on a regional map.

Objectives: The aim of this study is to estimate the population-based prevalence of diabetes and associated disorders and cardiovascular risk factors including obesity, hypertension and lipid profile abnormalities.

Methods: The first cross-sectional household survey on diabetes mellitus prevalence and associated risk factors among people aged ≥ 25 years residing in Aleppo-Syria. It was carried out in 2006 involving 1168 household representatives (51.1% men, mean age is 44.6 ± 10.7 years). The study included a household interview of administration of computerized questionnaires and physical examinations (blood pressure, height, weight and waist and hip circumferences) and blood examination included fasting blood glucose, HbA1c, lipid profile and CRP. Response rate for completed blood examination was 69.1%. The data was standardised for age and gender.

Results: The prevalence of previously diagnosed diabetes was 8.9 % and undiagnosed diabetes was 5.5 %, so 14.5 % of participants had diabetes. The prevalence of impaired fasting glucose was 25.6%. The prevalence of obesity, central obesity and hypertension was 43.9 %, 72.4%, 46.9% respectively. Serum total cholesterol and triglyceride were high in 22.4%, 42.9% respectively. Mean values (SD) in CRP concentrations were 2.13 (0.87) mg/L for men and 2.20 (1.14) mg/L for women. There was a significant difference in CRP levels between men and women ($t = 1.095$, $p < 0.05$).

Conclusions: AleppDiab, which is the first national study on diabetes prevalence in Syria, demonstrated that Syria has a high prevalence of diabetes (higher than published on Diabetes Atlas 2006) and associated risk factors. This increase could be due to the rapid urbanization and occidentalization of lifestyle. More studies in other urban and rural Syrian regions may be needed to confirm these results.

PS 126 Cardiovascular risk in diabetes: prospective studies

1223

After a high-fat mixed meal, postprandial hyperglycaemia, but not postprandial insulin, impacts postprandial increases in inflammatory markers and nitrosative stress in patients with type 2 diabetes

A. Ceriello¹, W. V. Brown², N. A. Le², R. B. Goldberg³, P. J. Beisswenger⁴, J. Cooke⁵, D. C. Robbins⁶, R. G. Moses⁷, H. B. Yuan⁸, S. Sarwat⁸, C. A. Jones⁸, Z. Milicevic⁸, M. H. Tan⁸;

¹Dept of Clinical Sciences, Warwick Medical School, United Kingdom, ²Dept of Medicine, Emory University, Atlanta, United States, ³School of Medicine, University of Miami, United States, ⁴Section of Endocrinology, Diabetes, and Metabolism, Dartmouth Medical School and Dartmouth-Hitchcock Medical Center, Hanover, United States, ⁵School of Medicine, Stanford University, United States, ⁶Section of Endocrinology, Kansas University Medical School, Kansas City, United States, ⁷Illawarra Diabetes Service, Wollongong Hospital, SESIAHS, Sydney, Australia, ⁸Eli Lilly and Company, Indianapolis, United States.

Background and Aims: In patients with type 2 diabetes (T2D), blood glucose (BG), serum insulin (INS), hs-C reactive protein (hs-CRP), tumour necrosis factor α (TNF- α), interleukin 6 (IL-6) and nitrotyrosine (NT) increase in the postprandial (pp) period after a high-fat mixed meal. We studied the impact of pp BG or pp INS on pp increase in inflammatory markers (pp hs-CRP, pp TNF- α , pp IL-6) and nitrosative stress (pp NT) in T2D patients.

Materials and Methods: A subgroup of T2D patients participating in a prospective, open-label, parallel group study comparing the effects of prandial+basal lispro mix 50 (LM50; 50% lispro/50%insulin lispro protamine suspension) ac tid with basal insulin glargine (G) hs, both plus metformin (Met) participated in the test-meal substudy after 24 weeks of treatment. The night before the test meal, patients (LM50+Met, $n=25$; G+Met, $n=21$) ate their supper, took their assigned insulin, and fasted overnight. Met was taken 30 min and LM50 injected 5 min before a standardized McDonald's® breakfast (fat 39 g, CHO 78 g, protein 24 g) followed by sampling at 0,1,2,3,4,6, 8 hrs. The pp increase was measured as area under the curve (AUC) and AUC excursion above baseline 0–8 hours. Multiple linear regression approach was applied to assess the possible independent effect of pp BG or pp INS (independent variables) on pp hs-CRP, pp TNF- α , pp IL-6 and pp NT (dependent variables) respectively after adjusting for all other covariates (HbA1c, fasting BG/INS, age, gender and BMI). Hs-CRP, TNF- α , IL-6 and NT were measured by ELISA.

Results: The pp BG AUC and AUC excursion were significantly associated with pp hs-CRP, pp TNF- α , pp IL-6 and pp NT AUC and AUC excursion. The strength of the associations was weak for pp INS (see table).

Variable	Pp BG	R square	p-value	pp BG Exc	R square	p-value
pp hs-CRP		0.54	<0.001		0.63	<0.001
pp TNF- α		0.30	0.018		0.41	0.009
pp IL-6		0.57	<0.001		0.31	0.003
pp NT		0.48	<0.001		0.43	<0.001
	pp INS			pp INS Exc		
pp hs-CRP		0.23	0.06		0.27	0.013
pp TNF- α		0.10	0.29		0.23	0.016
pp IL-6		0.18	0.14		0.15	0.14
pp NT		0.13	0.28		0.21	0.016

Conclusion: In T2D patients after a high-fat mixed meal, the pp increases in inflammatory markers (pp hs-CRP, pp TNF- α , pp IL-6) and nitrosative stress (pp NT) were strongly impacted by the increase in pp BG but not by the increase in pp INS. Control of pp BG may be important in decreasing the pp inflammation and nitrosative stress seen in T2D patients.

The Munich Myocardial Infarction Registry: impact of CRP and creatinine on hospital mortalityK. F. Braun¹, E. Standl¹, W. Otter², O. Schnell¹;¹Department for Cardiovascular Disease, Diabetes Research Institute, Munich, Oberschleißheim, ²Department of Cardiology, Center of Internal Medicine, Unterschleißheim, Germany.**Background and Aims:** To study the impact of CRP and creatinine in diabetic (D) and non-diabetic patients (ND) with acute myocardial infarction (AMI) on hospital mortality.**Materials and Methods:** All patients of the Munich Myocardial Infarction Registry (1999 – 2004, n = 2015) were assessed. In both D (38.2%) and ND (61.2%), CRP and creatinine levels on admission were analyzed with regard to hospital outcome.**Results:** In the entire group of patients with AMI, hospital mortality was 15.2% (n= 307). The median CRP level was 7mg/dl. In patients with CRP levels above the median, hospital mortality was higher compared to those with CRP levels equal or below the median (21% vs. 9%; p<0.001). The median CRP level was higher in D than in ND: 9 vs. 6mg/dl (p<0.001). In both D and ND, CRP levels remained a significant predictor for hospital mortality after correction for age, impaired kidney function (IKF = creatinine >1.2mg/dl) and hypertension: OR (95% CI) highest vs. lowest CRP quintile: D 1.9 (1.1 – 3.2) (p<0.05), ND 2.4 (1.4 – 4.3) (p<0.01). In the entire group, 864 patients (66.7%) had normal creatinine levels (≤1.2mg/dl). IKF occurred in 432 patients (33.3%). Hospital mortality was higher in patients with IKF than in those with normal creatinine levels (31.5% vs. 6.9%; p<0.001). Creatinine levels were higher in D than in ND: 1.4 ± 0.9 mg/dl vs. 1.1 ± 0.7 mg/dl (p<0.001). In both, D and ND, creatinine levels remained a significant predictor for hospital mortality after correction for age, CRP levels and hypertension: highest vs. lowest quintile: D 3.6 (2.1 – 6.4) (p<0.001), ND 4.9 (2.8 – 8.7) (p<0.001). In patients with CRP levels equal or below the median, absence of diabetes and IKF, hospital mortality was 4.4% whereas in patients with CRP levels above the median, presence of diabetes and IKF, hospital mortality increased significantly to 37.9% (p<0.001).**Conclusion:** The Munich Myocardial Infarction Registry emphasises the impact of CRP and creatinine levels on the hospital mortality of AMI. It demonstrates that the combined presence of diabetes, elevated CRP and creatinine on admission is associated with a highly increased hospital mortality in AMI. An intensification of early diagnostic and therapeutic approaches is required to potentially overcome the unfavourable prognosis.

1225

Familial predisposition to cardiovascular disease contributes to the prevalence of cardiovascular risk and cardiovascular disease – from baseline features of a diabetic large-scale multicenter-based cohort

H. Yokoyama, K. Kawai, H. Sugimoto, K. Hirao, H. Takeda, M. Oishi, M. Minami, M. Kudo, K. Doi, K. Iwasaki, Y. Fukumoto, H. Sone, M. Matsushima, H. Takagi, M. Kobayashi;

Japan Diabetes Data Management Study Group, Jiyugaoka Clinic, Obihiro, Japan.

Background and Aims: Diabetic population is affected by 2–6 folds higher cardiovascular morbidity and mortality than non-diabetic population. Effects of cardiovascular risk factors cannot fully account for the excess morbidity and effects of genetic predisposition remain elucidated.**Materials and Methods:** A diabetic large-scale (n=3611) multicenter-based (17 medical clinics (i.e. general practitioners) or general/university-affiliated hospitals from different areas in Japan) cohort was recruited. Cardiovascular risk factors, a first-degree family history (FH) of diabetes, hypertension, coronary heart disease (CHD) and stroke, and a previous history of CHD, stroke (ischemic cerebrovascular disease), and peripheral vascular disease (PVD) were investigated. Cross-sectional associations of risk factors with prevalence of cardiovascular disease were explored by multiple logistic regression analysis.**Results:** Among 3611 diabetic patients, 181 (5.0%) had CHD, 118 (3.3%) had stroke, and 37 (1.0%) had PVD; accounting for 315 patients (8.7%) who had at least one of them, i.e. cardiovascular disease. Age, male, hypertension, hyperlipidemia, and smoking were significant determinants of the prevalence of cardiovascular disease. After adjustment for these conventional

cardiovascular risk factors, FH of CHD was independently associated with CHD and FH of stroke was independently associated with stroke. FH of hypertension was significantly associated with presence of hypertension. FH of diabetes, hypertension, CHD and stroke was significantly associated with FH of each disease, indicating clustering of FH.

Conclusion: FH of CHD and stroke is an independent determinant of the prevalence of CHD and stroke, respectively. Clustering of FH of diabetes, hypertension, CHD, and stroke may indicate interrelation of genetic predisposition.

1226

Use of oral contraceptives and coronary artery disease in type 1 diabetes: The Pittsburgh Epidemiology of Diabetes Complications (EDC) Study

T. Costacou, T. J. Orchard;

Epidemiology, University of Pittsburgh, United States.

Background and Aims: Results from the Women's Health Initiative, a large clinical trial, raised concerns that hormone replacement therapy may pose increased health risks, including increased heart disease. Oral contraceptives (OC) may also result in the activation of the renin angiotensin system, increasing renal disease risk. As women with type 1 diabetes are often prescribed OC, there is concern that such use may further increase the already elevated risk of coronary artery disease (CAD) in these women. Thus, we assessed the association between use of OC and CAD incidence in a cohort of women with type 1 diabetes.**Materials and Methods:** Female participants of the Pittsburgh Epidemiology of Diabetes Complications study, a prospective investigation of childhood onset type 1 diabetes, were selected for study (baseline mean age 27 and diabetes duration 18 years). Two hundred ninety-nine women free of CAD (defined as EDC physician diagnosed angina, confirmed myocardial infarction, stenosis ≥50%, ischemic ECG, or revascularization) provided information on OC use throughout 16 years of follow-up. Repeated measures mixed model logistic regression analyses with a binomial error distribution and a logit link function were conducted.**Results:** At baseline, adjusting for age, OC users were more likely to report having ever smoked (p=0.005); no other differences were observed. During follow-up, higher blood pressure (p<0.0001), non-HDL cholesterol (p=0.002), pulse rate (p=0.05), albumin excretion rate (p=0.006), and white blood cell count (p=0.03) but lower HDL (p=0.07) and insulin sensitivity (p<0.0001) were observed in those women who subsequently developed CAD (n=62) compared to non-cases (n=237). Moreover, compared to non-cases, a greater proportion of subsequent CAD cases had overt nephropathy (p=0.02) and proliferative retinopathy (p=0.02). However, the proportion of OC users did not differ by subsequent CAD status (p=0.97) and OC use was not associated with CAD incidence (OR=1.32, 95% CI=0.77–2.25) in multivariable analyses.**Conclusion:** Among women with type 1 diabetes, there was no association between OC use and CAD. However, as length of use was relatively short (mean length of use among users = 4 years, median = 3 years), definitive conclusions on the effects of long term OC use cannot be made.*Sponsored by NIH*

1227

A study of cardiovascular risk management in adult patients with type 1 diabetes mellitus in Birmingham, United KingdomA. A. Syed¹, S. Hussain¹, A. H. Barnett², M. Charlton², P. De³, P. Narendran¹;¹Division of Medical Sciences, University of Birmingham, ²Department of Diabetes, Heart of England NHS Trust, Birmingham, ³Department of Diabetes, City Hospital NHS Trust, Birmingham, United Kingdom.**Background and Aims:** Cardiovascular disease (CVD) is the commonest cause of death in adult patients with type 1 diabetes (T1D). Aggressive management of CVD risk factors is therefore an important aspect of the care we provide for them. We studied the management of cardiovascular risk factors adult T1D patients attending hospital outpatient diabetes clinics in the City of Birmingham, UK.**Materials and Methods:** Data was collected between June 2006 to February 2007 for age, T1D duration, smoking history, BP, BMI, lipids and HbA1c.

CVD risk factor targets were those recommended by Joint British Societies 2005.

Results: 1282 patients were analysed with mean age 46yrs (range 18–95). A minimum dataset, defined as BP, total cholesterol, smoking history and HbA1c, was available in 72 % of patients, of whom only 1.3 % achieved all 4 targets (BP130/80, total cholesterol 4mmol/l, not smoking, HbA1c 6.5%). Using the previously applied criteria of HbA1c 7.5%, BP 140/90, total cholesterol 5mmol/l, 14% of patients achieved all 4 targets. BP, HbA1C, cholesterol, smoking status and BMI was documented in 93%, 95%, 94%, 84% and 74% respectively. Overall 56%, 93%, 63%, 24 % and 60% failed to achieve JBS 2005 targets for BP, HbA1C, total cholesterol, smoking and BMI (<25Kg/m²) respectively. Patients over the age of 40yrs were less likely to achieve target blood pressure than younger patients (64% Vs 41%). Otherwise there was no difference in target attainment. Of those patients over the age of 40, 43% were not on lipid lowering therapy, and 58% were not on aspirin, even though these are now recommended therapies. 19% of patients had microalbuminuria. Of these, 62%, 93%, 66%, 22%, and 57% failed to achieve targets for BP, HbA1C, total cholesterol, smoking and BMI respectively. Of those patients who failed to achieve lipid targets, 59% were not on lipid treatment.

Conclusion: Cardiovascular risk factors are poorly recorded and managed in T1D patients. The low target attainment may be explained by complications of therapy, for example hypoglycaemia preventing attainment of HbA1c of 6.5%; however acquisition and recording of data can and should be improved. We conclude that better data acquisition and treatment of CVD risk factors in T1D patients is required, and suggest in the long term this will reduce their macrovascular complications and mortality rates. Patients over the age of 40, and those with microalbuminuria in particular need to be targeted.

Five-year mortality in congestive heart failure patients with undiagnosed diabetes

J. Flores¹, J. Comin², J. F. Cano¹, D. Benaiges¹, J. J. Chillaron¹, A. Goday¹, J. Bruguera², M. Fernandez¹, J. Puig¹;

¹Endocrinology, Hospital del Mar,

²Cardiology, Hospital del Mar, Barcelona, Spain.

Background and Aims: Little is known about the prevalence and prognostic importance of undiagnosed diabetes mellitus (UDM) among individuals with heart failure (HF). To determine five-year mortality rate in heart failure hospitalized patients suffering UDM. To assess the prevalence of UDM and the relevant clinical parameters of this population. To evaluate the number of hospital re-admissions during a one year period due to cardiovascular and non-cardiovascular events.

Materials and Methods: A prospective study of patients admitted in the Heart Failure Unit of our hospital between January-2000 and December-2002. Patients suffering diagnosed DM at the time of admission were identified as well as those fulfilling the diagnosis criteria for diabetes according to ADA (outside the acute complication episode). A five-year survey was carried out.

Results: During the study period, 410 patients were admitted at the Heart Failure Unit. The prevalence of diagnosed diabetes (DDM) was 36,8% against 16% for UDM.

	Non Diabetic	Undiagnosed diabetes	Diagnosed diabetes	p
N	193	66	151	
Age (years,mean+SD)	71,7 (+–10,9)	72,9 (+–10)	71,5 (+–6,5)	n.s.
Sex (female %)	49,2	54,4	52,5	n.s.
Ever smoker (%)	41	42,7	43,2	n.s.
Hypertension (%)	68,9	72,1	83,3	P<0,05
Dyslipidemia (%)	29,0	19,1	42,2	P<0,01
Chronical renal failure (%)	16,4	29,4	21,6	n.s.
Peripheral arterial disease (%)	8,7	5,9	21	P<0,01
Stroke (%)	10,9	14,7	14,8	n.s.
CAD (%)	34,8	38,2	54,3	P<0,01
Ejection fraction (% ,mean+SD)	46,53(+ 17,6)	47,29(+ 18,3)	45,23(+ 17,8)	n.s.

The proportion of patients treated with ACEi, ARA-II, beta-blockers, spironolactone, diuretics and anti-thrombotic agents was similar across the three groups. Use of statins, however, was more common among patients with DDM. Nevertheless, total cholesterol, LDL and HDL levels were comparable. All patients with DM (diagnosed and undiagnosed) were more likely to be readmitted due to cardiovascular-events during the one year period (43 & 41,8% vs 33,2% p<0,01). No differences were observed for readmissions caused by non-cardiovascular episodes.

One-year mortality rate in DM patients (DDM & UDM) was higher than among non-diabetics (19,3–21,8% vs 13,1%) differences were not, however, statistically significant. During the five-year survey, mortality rates were considerably higher among the UDM group (66,7%) than among non-diabetics (40,7%, p<0,01). The former group also showed a higher rate when compared with DDM patients, although the difference is not statistically significant.

Conclusion: UDM is common (16%) in patients hospitalized as a result of heart failure and entails a five-year mortality rate almost twice as high than in the case of non-diabetics.

Patients with UDM, in spite of having lower rate of comorbidities and cardiovascular risk factors, showed a trend of higher mortality rate than DDM. Further studies are warranted to define this issue.

Are measures of adiposity associated independently with incident cardiovascular disease in individuals with newly diagnosed type 2 diabetes?

R. L. Coleman, R. R. Holman;

Diabetes Trials Unit, OCDEM, University of Oxford, United Kingdom.

Background and Aims: Obesity is associated with an increased risk of cardiovascular disease (CVD) and of type 2 diabetes (T2DM). The prevalence

of obesity has tripled in most European countries in the past twenty years. We investigated whether measures of adiposity are associated with incident CVD in people with newly-diagnosed T2DM.

Materials and Methods: Of the 5102 patients with newly-diagnosed T2DM recruited into the UK Prospective Diabetes Study, 4478 did not have CVD and had the requisite data available for these analyses. Discrete time survival models were used to examine time to the first occurrence of CVD, defined as any of fatal or non-fatal myocardial infarction, ischaemic heart disease, fatal or non-fatal stroke, coronary revascularization or fatal peripheral vascular disease. At diagnosis 59% of patients were male, 82% White caucasian, 30% current smokers and 1.1% had atrial fibrillation (AF). Their mean (SD) age was 52 (9) years, systolic blood pressure 136 (20) mmHg, total cholesterol 5.4 (1.0) mmol/l, HDL-cholesterol 1.11 (0.25) mmol/l, total to HDL ratio (Tot:HDL) 5.1 (1.4) and median (IQR) HbA1c 6.5 (5.8–7.5) %. Measures of adiposity were weight 80.9 (16.4) kg, body mass index (BMI) 28.9 (5.6) kg/m², waist circumference (WC) 94.9 (13.2) cm and hip circumference (HC) 87.0 (17.6) cm.

Results: 787 first CVD events occurred over median (IQR) 10 (8–13) years. All measures of adiposity were associated univariately ($p < 0.001$) with an increased risk of CVD but none remained significant after adjusting for traditional CVD risk factors (weight $p = 0.258$, BMI $p = 0.255$, waist circumference $p = 0.266$, waist:hip $p = 0.850$). Correlations between these measures of adiposity and traditional CVD risk factors were:

	Age	Sex	Ethnicity	Smoker	HbA1c	SBP	Tot:HDL	AF
BMI	-0.065	0.223	-0.054	-0.053	0.023	0.148	0.145	0.022
Weight	-0.117	-0.181	-0.060	-0.003	-0.018	0.144	0.092	0.041
WC	-0.025	-0.117	-0.080	-0.007	0.035	0.123	0.199	0.017
WC:HC	-0.007	0.500	0.039	-0.065	0.028	-0.024	-0.200	0.013

None of these measures of adiposity correlated significantly with any of the traditional CVD risk factors.

Conclusion: The increased risk of CVD seen with increased adiposity in the general population is not evident in individuals with newly-diagnosed T2DM. Although the measures of adiposity examined here are associated individually with future risk of CVD, the survival analysis suggests their effects are absorbed by the combined effects of the traditional CVD risk factors. The correlation patterns between these adiposity measures and the traditional CVD risk factors are, however, not significant. Although increased adiposity at diagnosis does not affect future CVD risk in this cohort, weight reduction after diagnosis may well influence CVD risk and should remain an important focus in the management of diabetes.

1231

Cardiovascular risk and metabolic syndrome in patients with obstructive sleep apnea

R. Tkacova¹, Z. Dorkova¹, A. Molcanyiova², Z. Radikova³, I. Klimes⁴, I. Tkac¹;

¹Dept. for Respiratory Disorders, Medical Faculty, PJ Safarik University, Kosice, ²Dept. of Biochemistry, LABMED, Kosice, ³Laboratory of Human Endocrinology, Institute of Experimental Endocrinology, Bratislava, ⁴Diabetes and Nutrition Research Laboratory, Institute of Experimental Endocrinology, Bratislava, Slovakia.

Background and Aims: Obstructive sleep apnea (OSA) has been linked to the metabolic syndrome, insulin resistance, cardiovascular and cerebrovascular diseases in previous studies. Our aim was to determine whether OSA relates to National Cholesterol Education Program (Adult Treatment Panel III) (NCEP ATP III) cardiovascular risk independently of insulin resistance and other confounders.

Materials and Methods: At the sleep unit in the tertiary referral teaching hospital, a cross-sectional analysis was undertaken on 98 subjects studied by attended polysomnography: 28 without OSA (apnea-hypopnea index, < 5), 39 with mild-moderate (apnea-hypopnea index, ≥ 5 to < 30), and 31 with severe OSA (apnea-hypopnea index, ≥ 30). Insulin resistance index (HOMA-IR) was based on the homeostasis model assessment method. Metabolic syndrome was defined according to the International Diabetes Federation criteria.

Results: From patients without to those with mild-moderate, and to those with severe OSA, significant increases were observed in the NCEP ATP III risk [from 2.0 (1.0, 8.0) to 3.0 (1.0, 12.0) to 16.0 (5.3, 20.0)%, p for trend

< 0.001], in association with increases in HOMA-IR [1.24 (0.69, 2.47) to 1.46 (0.99, 3.06) to 5.02 (2.25, 7.35), $p < 0.001$], mean blood pressure (97.7 \pm 12.4 to 103.2 \pm 12.0 to 107.2 \pm 13.1 mm Hg, $p = 0.039$), apolipoprotein B [0.95 (0.86, 1.07) to 0.91 (0.78, 1.08) to 1.10 (0.91, 1.16) g/l, $p = 0.013$], serum fibrinogen [2.73 (2.28, 3.08) to 2.74 (2.21, 3.12), to 3.28 (2.62, 3.89) g/l, $p = 0.013$], and fasting glucose levels [4.8 (4.4, 5.3) to 5.0 (4.6, 5.4) to 5.8 (5.0, 6.6) mmol/l, $p = 0.002$]. The proportion of patients treated for arterial hypertension increased from subjects without OSA to those with mild-moderate and to those with severe OSA [from 10 (36%) to 18 (46%) to 22 (71%), $p = 0.019$]. Metabolic syndrome was present in 13 (46%) subjects without OSA, in 20 (51%) patients with mild-moderate, and in 24 (77%) patients with severe OSA ($p = 0.029$). Patients with severe OSA had significantly higher odds for the presence of metabolic syndrome compared to those without OSA, after adjustments for age and gender (odds ratio, 3.60; 95% CI, 1.18–11.00; $p = 0.025$). In addition, compared to subjects without sleep apnea, patients with severe OSA had significantly higher odds for the NCEP ATP III risk higher than 10% (moderately high and high cardiovascular risk) both in the unadjusted model (odds ratio, 8.36; 95% confidence interval, 2.48–28.19; $p = 0.001$), and after adjustments for body mass index and insulin resistance (odds ratio, 4.06; 95% confidence interval, 1.02–16.25; $p = 0.048$).

Conclusion: The present findings suggest that severe OSA is related to higher level of several components of the metabolic syndrome. In addition, severe OSA is related to higher global cardiovascular risk, independently of obesity and insulin resistance.

More than 20% of European dyslipidaemic patients have undiagnosed dysglycaemia

M. Baccara-Dinet¹, E. Eschwege², E. Bruckert³;

¹Merck Santé, ²U780, INSERM, ³Service d'Endocrinologie Métabolique, Groupe Hospitalier Pitié-Salpêtrière, Paris, France.

Background: The Pan-European Survey of HDL-cholesterol (HDL-C) collected data on HDL-C and other cardiometabolic parameters from 8545 patients treated for dyslipidaemia in 11 European countries. Patients had a high prevalence of low HDL-C (<1.03 mmol/L in 33% of men and <1.29 mmol/L in 40% of women), type 2 diabetes (45%) and coronary heart disease (45%). Recent guidelines from the European Association for the Study of Diabetes/European Society of Cardiology and the World Health Organisation/International Diabetes Federation (WHO/IDF) recommend screening for undiagnosed dysglycaemia in patients at high cardiovascular risk. We used fasting plasma glucose (FPG) measurements to determine the prevalence of undiagnosed impaired fasting glucose (IFG) or diabetes in the survey population.

Patients and methods: The population included 2327 patients from the Pan-European Survey of HDL-C who had FPG measurement and no prior diagnosis of diabetes. IFG was defined as FPG ≥ 6.1 mmol/L and <7.0 mmol/L (WHO/IDF definition).

Results: Undiagnosed diabetes was found in 159 patients (6.8%) and IFG was found in 361 patients (15.5%). The total prevalence of undiagnosed dysglycaemia (diabetes + IFG) was 22.3%. Patients with previously diagnosed diabetes, undiagnosed diabetes, IFG or normoglycaemia had similar mean age (60–64 years). Overall, patients with previously diagnosed diabetes were obese (BMI ≥ 30); patients with undiagnosed diabetes or IFG had a higher BMI (29 kg/m²) compared to normoglycaemic patients (27 kg/m²). The proportion of men with IFG (71%) was higher than the proportion of men with diagnosed type 2 diabetes (58%), undiagnosed diabetes (62%), or normoglycaemia (64%). Mean waist circumference was higher in patients with a prior type 2 diabetes diagnosis (104 cm), undiagnosed diabetes (102 cm) or IFG (100 cm) than in normoglycaemic patients (96 cm). The prevalence of hypertension was similar in pre-diabetic subjects and patients with diabetes and higher than that in normoglycaemic patients (see table); prevalence rates of myocardial infarction (MI) or coronary heart disease (CHD) were similar between groups. The prevalence rates of low HDL-C and/or high triglycerides (TG), were highest in patients with diagnosed type 2 diabetes, and elevated in patients with IFG or undiagnosed diabetes relative to normoglycaemic patients. Mean values of lipid parameters, and the prevalence of the metabolic syndrome (IDF or US National Cholesterol Education Program [NCEP] criteria), followed a similar pattern.

Conclusions: Undiagnosed dysglycaemia (diabetes or IFG) is common (>20%) among patients under treatment for dyslipidaemia in Europe and these patients display adverse cardiometabolic risk profiles relative to normoglycaemic patients. These data support recent recommendations for screening for undiagnosed dysglycaemia of patients at high cardiovascular risk. (Tab. 1)

Effects of 20 mg rosuvastatin on VLDL1-, VLDL2-, IDL- and LDL-apoB kinetics in type 2 diabetes

B. Vergès¹, L. Duvillard², R. Chadarevian³, S. Baillot-Rudoni¹, J.-M. Petit¹, E. Florentin², L. Princep², P. Gambert²;

¹Endocrinology-Diabetology, Hôpital du Bocage, Dijon, ²CRI 866, INSERM, Dijon, ³Astrazeneca, Laboratoires, Rueil-Malmaison, France.

Background and Aims: Rosuvastatin is a statin which, in addition to its efficacy to reduce LDL-cholesterol, has been shown to decrease significantly plasma triglyceride levels. However, the effects of rosuvastatin on the metabolism of triglyceride-rich lipoproteins remains unknown. This prompted us to perform an in vivo kinetic study of apoB containing lipoproteins with C13 leucine in patients with type 2 diabetes.

Materials and Methods: We performed a randomized double-blind cross-over trial of six-week treatment period with placebo or rosuvastatin 20 mg in 8 patients with type 2 diabetes treated orally by metformin alone or in combination with sulfonylureas. In each patient, a kinetic study was performed at the end of each treatment period.

Results: Mean HbA1c was 6.88 ± 1.6 % and remained stable throughout the study. Rosuvastatin 20 mg significantly reduced LDL cholesterol (60 ± 18 vs. 122 ± 32 mg/dl, $p = 0.012$), plasma triglycerides (170 ± 70 vs. 274 ± 122 mg/dl, $p = 0.012$) and total apoB (67 ± 12 vs. 112 ± 16 mg/dl, $p = 0.012$). Rosuvastatin significantly induced a reduction of VLDL1- ($p = 0.049$), VLDL2- ($p = 0.012$), IDL- ($p = 0.012$) and LDL - ($p = 0.012$) apoB pool sizes. This reduction was associated with a significant increase in the FCR of VLDL1-apoB (6.71 ± 3.24 vs. 4.43 ± 2.34 pool/day, $p = 0.049$), VLDL2-apoB (8.71 ± 3.36 vs. 5.39 ± 2.62 , $p = 0.012$), IDL-apoB (6.97 ± 1.56 vs. 4.21 ± 1.51 , $p = 0.012$) and LDL-apoB (1.02 ± 0.26 vs. 0.58 ± 0.13 , $p = 0.012$). Rosuvastatin did not change the production rates of VLDL2, IDL nor LDL but tended to decrease VLDL1-apoB production rate (12.7 ± 5.3 vs. 19.1 ± 8.5 mg/kg/day, $p = 0.08$).

Conclusion: Treatment with rosuvastatin 20 mg, in type 2 diabetes, induces not only a significant increase of LDL-apoB catabolism (+76%) but also favorable effects on the catabolism of triglyceride-rich lipoproteins such as a significant increase in the catabolism of VLDL1-apoB (+51%), VLDL2-apoB (+61%) and IDL-apoB (+65%) as a borderline significant reduction in the production rate of VLDL1-apoB (-34%). The effects of rosuvastatin on the metabolism of triglyceride-rich lipoproteins may have positive effects on the prevention of atherosclerosis, in type 2 diabetic patients.

1234

Effects of achieving very low LDL-cholesterol concentrations with simvastatin or atorvastatin on steroidogenesis in high-risk diabetic patients

N. Demirag¹, Z. Berberoglu¹, M. Asik¹, N. Bayraktar², A. C. Yazici³, N. Tutuncu¹;

¹Endocrinology, ²Biochemistry, ³Biostatistics, Baskent University, Ankara, Besevler, Turkey.

Background and Aims: The present study had 2 main objectives: (1) to compare the effect of achieving a low-density lipoprotein cholesterol (LDL-

C) < 70 mg/dL vs achieving an LDL-C < 100 mg/dL on adrenal and testicular steroidogenesis in high-risk diabetic patients; and (2) to compare simvastatin with atorvastatin with respect to the abovementioned goal.

Materials and Methods: This was an open-label, randomized, controlled trial. High-risk diabetic males and postmenopausal females were randomly assigned to simvastatin 10 mg or atorvastatin 10 mg. LDL-C was monitored at 30 days intervals. If LDL-C was ≥ 100 mg/dl, the doses of the 2 agents were up-titrated. The study protocol allowed the doses of simvastatin and atorvastatin to be increased up to the maximum dose of 40 mg and 80 mg, respectively. Patients within each treatment group were stratified by achieved LDL-C goals. Thereafter, they were followed up for 12 weeks. Before and after the intervention, lipids and hormones were assessed.

Results: Of the 120 subjects initially enrolled in the study, 114 patients completed all treatment and testing. After simvastatin therapy, mean LDL-C levels were 60.8 mg/dl in the subgroup with achieved LDL-C < 70 mg/dL ($n = 29$) compared to 87.8 mg/dl in the subgroup with achieved LDL-C < 100 mg/dL ($n = 28$) ($P = 0.000$). After atorvastatin therapy, mean LDL-C levels were 55.6 mg/dl in the subgroup with achieved LDL-C < 70 mg/dL ($n = 30$) compared to 88.8 mg/dl in the subgroup with achieved LDL-C < 100 mg/dL ($n = 27$) ($P = 0.000$). At 12 weeks, there were no statistically significant differences among the four groups nor any statistically significant within-group changes from baseline in cortisol, androstenedione and total testosterone. Significant reduction in DHEA-S was observed in subjects with an LDL-C < 70 mg/dL in both simvastatin and atorvastatin groups at 12 weeks compared with baseline ($P < 0.05$ and $P < 0.01$, respectively). DHEA-S fell by 17% and by 21% after simvastatin and atorvastatin administration, respectively. On the other hand, no significant effect was observed in the other two groups. The differences in the changes in this parameter between the LDL-C < 70 mg/dL groups and LDL-C < 100 mg/dL groups were significant ($P < 0.01$ for both simvastatin and atorvastatin groups, respectively).

Conclusion: These results indicate that achieving an LDL-C < 70 mg/dL with simvastatin or atorvastatin have no considerable negative impact on adrenocortical and testicular steroidogenesis in diabetic patients. Whereas, the decrease in secretion of DHEA-S might reflect a decrease in substrate concentration causing compensatory alteration in the activity of DHEA sulphotransferase and steroid sulphatase in the adrenal cortex and an increased ratio of DHEA activation to inactivation. Additional data are required to determine whether there is a level of LDL-C beyond which downstream conversion of DHEA to sex steroids is affected.

1235

Triglycerides and glycaemic control have influence on the small artery elasticity in diabetic patients

S. Redondo, O. Sánchez, R. Fabregate, M. Fabregate, E. Marin, G. Nuñez de Arenas, J. Sabán-Ruiz; Endothelial Pathology Unit, Ramon y Cajal Hospital, Madrid, Spain.

Introduction: The HDI/PulseWave CR-2000 obtains upper-arm blood pressure values and waveform data by non-invasive methods.

Aims: 1- To determine the prevalence of abnormal elasticity index in a type 2 DM. 2- To determine its correlation with hemodynamic evaluation and glycaemic control.

Methods: N=106, 22–81yrs; M/F ratio: 57/49, Group A: N=50 (non-diabetic); group B: N=56 (diabetic); Glyc, creat, HDL, LDL, total chol, trig, HbA1c. Hemodynamic evaluation: HDI/PulseWave. Statistical: t-Student, Chi-Square, Pearson correlation and Multivariate Linear Regression.

Results: 1- The prevalence of abnormal large artery elasticity (C1) was 37,7% in groups A+B; 28,0% in A and 46,4% in B ($p < 0,05$). Abnormal subjects were older ($p = 0,001$) and had higher values of SBP ($p < 0,001$), DBP ($p = 0,004$), MBP ($p < 0,001$) and PP ($p < 0,001$) than those with normal elasticity. 2- In relation to C1, significant differences in SVR ($p < 0,001$), TVI ($p < 0,001$), CO ($p < 0,001$), CO Index ($p = 0,003$), SV ($p < 0,001$) and SVI ($p = 0,001$). 3- The prevalence of abnormal small artery elasticity (C2) was 43,4% in groups A+B; 40,0% in A and 46,4% in B. 4- Abnormal subjects were older ($p < 0,001$), and had higher SBP ($p = 0,02$), DBP ($p = 0,014$), MBP ($p < 0,001$), and PP ($p = 0,010$). 5- In relation to C2, significant differences in the determination of SV Resistance ($p < 0,001$), TV Impedance ($p = 0,007$), C Output ($p = 0,001$), CO Index ($p < 0,001$), Stroke V ($p = 0,004$) and SVIndex ($p = 0,002$). 6- There is a correlation between small artery elasticity and triglyceride levels ($p = 0,007$). 7- We found an age-independent linear correlation between C2 and metabolic control in the diabetic population [$p = 0,013$], in the multivariate analysis.

Conclusion: 1- The prevalence of stiff large and small arteries was of 38,3% and 43,4%. 2- Age is more important than the diabetic status in vascular elasticity. 3- Both phenomena present with changes in other cardiovascular parameters. 4- The stiffness of small arteries is related to levels of triglycerides in all subjects and to glycaemic control in diabetic patients.

1236

Free fatty acid changes with insulin glargine vs thiazolidinediones according to baseline HbA_{1c} in type 2 diabetes mellitus

N. Rosenberg¹, S. Schwartz², A. Cohen³, L. Traylor¹; J. Rosenstock⁴
¹sanofi-aventis US, Bridgewater, ²dgd Research Inc, San Antonio,
³Endocrinology, Endocrine Clinic, Memphis,
⁴Dallas Diabetes and Endocrine Center, United States.

Background and Aims: Dyslipidemia, including elevated free fatty acids (FFAs), triglycerides (TGs), and low-density lipoprotein and reduced high-density lipoprotein, greatly increases the cardiovascular risk associated with diabetes. Elevated FFA has a confirmed role in insulin resistance while thiazolidinediones (TZDs) have demonstrated effects on reducing lipotoxicity and FFA levels, resulting in improved insulin sensitivity. Additionally, insulin has well known effects on reducing hyperglycemia-associated lipolysis. This analysis examined the relationship between glycaemic control and lipid variables.

Material and Methods: Two randomized, open label, parallel group studies comparing the effects of insulin glargine (GLAR) vs a TZD on glycaemic control as add-on therapy in patients inadequately controlled on a sulfonylurea and/or metformin were conducted. We assessed FFA and TG changes according to baseline HbA_{1c} in this post-hoc analysis. Study 1: GLAR ($n = 165$) vs pioglitazone (PIO; $n = 182$). Baseline and Wk 24 lipid values were available for 121 and 128 patients, respectively. Patients were separated into 2 groups based upon baseline HbA_{1c} values: $\leq 8.5\%$ and $> 8.5\%$. Study 2: GLAR ($n = 105$) versus rosiglitazone (RSG; $n = 112$). Baseline and Wk 24 lipid values were available for 87 and 83 patients, respectively, who were likewise separated into two groups based upon baseline HbA_{1c} values. Safety assessments, including hypoglycemia and adverse events, were monitored throughout the study.

Results: In study 1, decreases in mean \pm SE FFA were significantly greater with GLAR vs PIO in the patient group with baseline HbA_{1c} values $> 8.5\%$ (-0.21 ± 0.02 vs -0.12 ± 0.02 mmol/L, $P = 0.006$). In study 2, FFA decreases were similar with GLAR and RSG. Decreases in TGs were similar for GLAR and PIO in study 1 and significantly greater with GLAR versus RSG in the patient group baseline HbA_{1c} values $\leq 8.5\%$ (-0.34 ± 0.11 vs 0.20 ± 0.13 , $P = 0.002$) in study 2. All 3 therapeutic agents were safe and tolerable. There were no statistically significant differences in treatment-emergent adverse events between the GLAR and PIO groups in study 1 or the GLAR and RSG groups in study 2.

Conclusion: Overall, the baseline HbA_{1c}-dependent effect on FFA and TG appears to be more pronounced with GLAR, possibly reflecting greater HbA_{1c} reductions in patients with higher baseline HbA_{1c}. The data discovered in this post-hoc analysis suggest that insulin glargine exhibits greater FFA-lowering effects than TZDs when baseline HbA_{1c} is $> 8.5\%$ and exhibits reductions similar to those observed with TZDs at lower baseline HbA_{1c} levels. Since elevated FFA levels contribute to glucose metabolism dysregulation and have detrimental effects on cytokines and adiponectin, the FFA-lowering effect of

GLAR at elevated HbA_{1c} values may be beneficial in type 2 diabetes mellitus patients.

Supported by sanofi-aventis U.S.

1237

Change in lipid variables with insulin glargine versus pioglitazone in T2DM patients inadequately controlled on a sulfonylurea or metformin

J. B. McGill¹, L. Traylor², A. Dwarakanathan³;

¹Division of Endocrinology, Metabolism and Lipid Research, Washington University School of Medicine, St. Louis, ²sanofi-aventis U.S., Bridgewater, ³Diabetes Center, St James Diabetes Center, Chicago Heights, United States.

Background and Aims: The progressive nature of type 2 diabetes mellitus (T2DM) often requires increasingly aggressive therapy over time in order to maintain adequate glycemic control. Pharmacologic treatment is typically introduced with a sulfonylurea or metformin, with thiazolidinediones or insulin added for persistent hyperglycemia. The aim of this study was to examine the impact of pioglitazone versus insulin glargine when added to sulfonylurea or metformin monotherapy. This analysis focused on the change in lipid profiles.

Material and Methods: This randomized, multicenter, 48-week, parallel-group, open-label study compared glargine (GLAR) (n=129) versus pioglitazone (PIO) (n=130) as add-on therapy in T2DM patients inadequately controlled with $\geq 50\%$ of the maximum labeled dose of a sulfonylurea (SU) or ≥ 1000 mg metformin (MET). We compared lipid variables by strata (SU vs MET) over 48 weeks focusing on free fatty acid (FFA), triglyceride (TG), and high-density lipoprotein (HDL) changes. Safety assessments including hypoglycemia and adverse events were monitored throughout the study.

Results: A1C decrease from baseline was significantly greater in the SU strata of the GLAR versus the PIO at 48 weeks ($P=0.035$). FFA decrease from baseline with GLAR was significantly greater than PIO at 24 weeks in the MET strata (-0.19 ± 0.03 mmol/L, $P=0.002$) and 48 weeks in the SU strata (-0.29 ± 0.04 mmol/L, $P=0.026$). While TG reduction was substantial (ranging from -0.49 to -0.59 mmol/L at 24 weeks and -0.42 to -0.67 mmol/L at 48 weeks) with GLAR and PIO, differences in the MET and SU strata were not significant. GLAR and PIO increased HDL in both strata but the increase

was significantly higher with PIO relative to GLAR in both strata at 24 and 48 weeks ($P < 0.01$ in both strata with GLAR and PIO). Changes from baseline to week 24 and week 48 were statistically significant ($P < 0.05$) for all variables except for week 48 HDL in the GLAR + SU strata ($p=0.09$). Both treatments were safe and tolerable, with no statistically significant differences in adverse events between GLAR and PIO groups. Hypoglycemia ($BG < 70$ mg/dL) occurred more frequently in patients treated with GLAR (45.7%) relative to patients treated with PIO (19.9%) ($P < 0.001$). Conclusions: This study shows that both GLAR and PIO lower TGs when used as add-on therapy to SU or MET, however PIO raised HDL to a greater extent in both groups. At week 48, GLAR had a significantly greater A1C-lowering effect than PIO when used in combination with SU. Additionally, the FFA-lowering benefit of GLAR is greater than PIO when used in combination with MET (24 weeks) or SU (48 weeks). The FFA-lowering effect of GLAR may be an important contributor to its metabolic benefit in patients failing single, oral agent therapy. (Fig. 1)

Circulating interleukin-8 levels are selectively determined by plasma non-esterified myristate, oleate, and $\omega 3$ -polyunsaturated fatty acids

H. Staiger, F. Machicao, A. Fritsche, N. Stefan, H.-U. Häring; Internal Medicine IV, Medical Clinic, Eberhard-Karls-University Tübingen, Germany.

Background and Aims: Elevated plasma levels of non-esterified fatty acids (NEFA), due to high fat intake and/or dysregulated adipose tissue lipolysis, are a hallmark of the metabolic syndrome and play a role in the pathogenesis of atherosclerosis. In this study, we assessed whether certain plasma NEFA species contribute to the chronic low-grade inflammatory state seen in the metabolic syndrome.

Materials and Methods: We determined the individual fasting plasma NEFA patterns of 75 overweight non-diabetic subjects and analysed the relationship of single NEFA species with plasma inflammatory parameters.

Results: After adjustment for gender, age, body fat, and waist-hip ratio, no strong correlations of single NEFA species with plasma leukocyte number, C-reactive protein, interleukin (IL)-6, tumour necrosis factor (TNF)- α , or

monocyte chemoattractant protein-1 were detected. However, oleate was negatively ($r=-0.36$, $p=0.0015$) and myristate ($r=0.41$, $p=0.0003$) as well as the ω 3-polyunsaturated NEFA (PUFA) α -linolenate ($r=0.37$, $p=0.0011$), eicosapentaenoate ($r=0.40$, $p=0.0003$), and docosahexaenoate ($r=0.40$, $p=0.0004$) were positively associated with plasma IL-8 levels. The other NEFA species as well as the total plasma NEFA concentration did not correlate with plasma IL-8. The correlations of myristate, oleate, and the sum of all ω 3-PUFA with plasma IL-8 levels were independent of plasma TNF- α concentration and overall adiposity.

Conclusion: Our data do not provide evidence for an association of single plasma fasting NEFA species with overall inflammatory state, but demonstrate close and selective associations of oleate, myristate, and ω 3-PUFA with plasma levels of the pro-inflammatory chemokine IL-8. Thus, these NEFA species may represent specific determinants of plasma IL-8.

New capillary electrophoresis method for the analysis of glycated triacylglycerol-rich lipoproteins in diabetics

S. Sharma;

Dept of Diabetes, UHI Millennium Institute, Inverness, United Kingdom.

In addition to hyperglycaemia and hyperinsulinaemia, diabetic subjects often present with hypertriacylglycerolaemia, which is associated with an increased risk of atherosclerosis and coronary heart disease (CHD). The combination of high plasma glucose and triacylglycerol (TAG)-rich lipoproteins increases the risk of lipoprotein modification (including glycation). This modification (glycation) has been hypothesised to increase the risk of CHD. To investigate the association and extent of TAG-rich lipoprotein modification, suitable routine assays are required. Conventional electrophoresis and immunochemical methods, which have been used for the analysis of glycated lipoproteins, are often inaccurate, time consuming and semi-quantitative.

Aim: The aim of this study was to develop new, robust and rapid capillary electrophoresis (CE) methods for the separation of TAG-rich lipoproteins and their modified forms. A procedure has been developed that uses high performance CE to monitor the electrophoretic mobility of native chylomicrons (CMs), very low density lipoproteins (VLDL1 and VLDL2) isolated by ultracentrifugation and their modified forms *in-vitro* and *in-vivo*. For *in-vitro* modifications, native lipoproteins were incubated with sugar concentrations corresponding to the levels in normal and diabetic state. Separation of native lipoproteins and modified lipoproteins was successfully achieved within 10 min by this method called Micellar Electrokinetic Chromatography (MEKC). Changes in peak profile (shape, width, height) and emergence of new peaks during the incubation of these lipoproteins reflects the progressive change in mass, associated with the slight increase in electronegativity of these compounds due to modifications. For *in-vivo* study lipoproteins from 6 diabetic and 6 non diabetic volunteers were isolated and analysed by newly developed MEKC method. As expected from the *in-vitro* study and because diabetic subjects possess higher postprandial levels of TRLs (triglyceride rich lipoproteins), in MEKC the total peak area readily discriminated between lipoprotein samples from the diabetic and control groups. Gel electrophoresis data support the differences observed by MEKC. This new procedure has the ability to discriminate between TRLs from diabetic and control subjects, as well as TRLs modified by sugars *in-vitro*. This novel MEKC method will further facilitate the quantification of modified lipoproteins and aid in the research of factors influencing modification and glycation of lipoproteins *in-vitro* and *in-vivo*.

PS 128 Biomarkers for cardiovascular disease

1240

Novel risk factors for atherosclerosis and silent myocardial ischaemia in diabetic patients: osteoprotegerin a useful marker to select patients who should benefit from screening?

A. Avignon¹, A. Sultan¹, C. Piot², D. Marino-Goulart³, J. Thuan dit Dieudonné¹, A. Dupuy⁴, J. Cristol⁴;

¹Metabolic Disease, ²Cardiology, ³Nuclear Medicine, ⁴Biochemistry, University Hospital, Montpellier, France.

Background and Aims: Silent myocardial ischemia (SMI) is frequent in diabetic patients and is associated with a worse outcome, supporting efforts to identify and intervene in the preclinical phase of coronary artery disease. A process whereby the patients at highest risk could be selected for screening would optimize the cost effectiveness of the screening strategy. The aim of the present study was to evaluate osteoprotegerin, an inhibitor of osteoclastogenesis involved in atherosclerosis and additional novel risk factors for the prediction of SMI.

Materials and Methods: 465 consecutive diabetic patients with ≥ 1 additional risk factor were evaluated for SMI using stress myocardial perfusion imaging. Association of SMI (positive stress-ECG and/or abnormal scintigraphic image) with 1) osteoprotegerin, 2) other novel risk factors (lipoprotein(a), homocystein, adiponectin, C-reactive protein and fibrinogen) and 3) conventional risk factors (total cholesterol, LDL-cholesterol, HDL-cholesterol, triglycerides) was evaluated.

Results: 92/465 patients were diagnosed with SMI. Of the 6 novel markers measured, OPG was the only one to be associated with SMI; the relative risk of SMI for patients above the 75th percentile for that marker was 3.19 (95% CI, 1.99 to 5.18) in comparison to those who were below that percentile. In univariate analyses, the other plasma markers significantly associated with SMI were higher triglyceride levels ($p=0.04$) and lower levels of HDL-C ($p=0.02$). The association of OPG with SMI remained significant after correcting for other variables associated with SMI at $p<0.15$ in univariate analysis (RR 3.59; 95% CI 1.95–6.60; $p<0.0001$). The association of OPG with SMI was observed in males ($p<0.0001$), in females ($p=0.03$), in type 1 (0.002) and type 2 (0.0004) diabetic patients, in patients with (0.0004) or without (0.03) nephropathy and in patients without ($p<0.0001$) but not in those with ($p=0.2$) peripheral arterial disease.

Conclusion: Addition of the measurement of OPG to other factors may provide an improved method of identifying diabetic patients susceptible to benefit from SMI screening.

1241

Suboptimal glycaemic control, plasma osteoprotegerin and interleukin 6 predict progression of coronary artery calcification in asymptomatic type 2 diabetic subjects

D. F. C. Hopkins¹, D. V. Anand², E. Lim³, D. Lipkin³, D. Darko³, R. Corder⁴, A. Lahiri²;

¹Diabetic Medicine, King's College Hospital, London,

²Cardiac Imaging and Research Centre, Wellington Hospital, London,

³Jeffrey Kelson Centre, Central Middlesex Hospital, London,

⁴William Harvey Research Institute, Barts and The London,

Queen Mary's School of Medicine & Dentistry, London, United Kingdom.

Background and Aims: Coronary artery calcification (CAC) imaging enables non-invasive detection of coronary atherosclerosis and quantification of the extent of calcified atherosclerotic plaque. We have previously demonstrated that there is a high prevalence of CAC in type 2 diabetic subjects with no symptoms or history of coronary artery disease and that CAC predicts both abnormal myocardial perfusion and incident cardiovascular disease. In the present study we have followed a prospective cohort of subjects with type 2 diabetes to determine the progression of CAC and the factors that influence progression.

Materials and Methods: 398 asymptomatic patients (mean age 52 \pm 8 years, HbA_{1c} 8.0 \pm 1.5%) were evaluated by serial CAC imaging (mean follow-up 2.5 \pm 0.4 years). Progression/regression of CAC was defined using previously published criteria. Demographic data, anthropometric measurements,

medical and treatment history were recorded at baseline and follow up together with determination of biochemical parameters including HbA_{1c}, microalbuminuria status, lipids, serum hs-CRP, IL-6 and plasma osteoprotegerin (OPG) levels.

Results: At baseline, CAC was present in 211 patients (53%). Progression occurred in 118 (29.6%) and regression in 3 (0.8%). Age, male gender, hypertension, baseline HbA_{1c}, baseline CAC score, IL-6 and OPG were univariate predictors of progression. In a multivariate logistic regression model adjusted for baseline CAC, serum HbA_{1c} (Odds ratio [OR] = 10.5 [95% CI: 2.04, 53.9], $p = 0.02$), plasma OPG (OR = 2.50 [1.19, 5.22], $p = 0.02$) and IL-6 (OR = 2.06 [1.13, 3.75], $p = 0.05$) were independent predictors of progression.

Conclusions: Suboptimal glycaemic control is a risk factor for progression of atherosclerosis in type 2 diabetes as are elevated concentrations of the cytokines IL-6 and OPG. Uniquely, OPG predicted both the extent of CAC at baseline and its subsequent progression and may prove useful as a biomarker for atherosclerosis in diabetes.

Lipoprotein-associated phospholipase (Lp-PLA₂), C-reactive protein (CRP) and coronary artery disease (CAD) among persons with type 1 diabetes

T. J. Orchard, R. G. Miller, T. Costacou, R. W. Evans;
Epidemiology, University of Pittsburgh, United States.

Background and Aims: The enzyme Lp-PLA₂ may be implicated in processes leading to vascular inflammation. CRP, an acute phase protein, is elevated during inflammatory states. Recent evidence suggests that both Lp-PLA₂ and CRP independently predict future cardiovascular events and together may be particularly effective. However, little is known about their effect on CAD risk in type 1 diabetes. We thus assessed the association between Lp-PLA₂ (activity and mass) and CRP with CAD among individuals with type 1 diabetes who are at particularly high risk for cardiovascular events by also having overt nephropathy.

Materials and Methods: Participants of the Pittsburgh Epidemiology of Diabetes Complications (EDC) study, a prospective investigation of childhood onset type 1 diabetes (baseline mean age was 28 and diabetes duration 19 years), with overt nephropathy (confirmed albumin excretion rate >200 µg/min) were selected for study (n=96). CAD was defined as EDC physician diagnosed angina, confirmed myocardial infarction, stenosis >50%, ischemic ECG, or revascularization. CRP was measured using a high sensitivity turbidimetric method utilizing reagents developed by Carolina Liquid Chemicals (Brea, CA). Samples were assayed for Lp-PLA₂ mass using a microplate-based ELISA (PLAC™ assay, diaDexus, Inc., South San Francisco, CA) whereas for levels of Lp-PLA₂ activity, samples were assayed using a colorimetric assay (diaDexus, Inc., South San Francisco, CA). Cox proportional hazards models were constructed.

Results: No correlations between CRP and Lp-PLA₂ activity and mass were observed (Pearson's $r=0.03$, $p=0.76$ and $r=0.09$, $p=0.34$, respectively). During 16 years of follow-up, 38 incident CAD cases developed. In univariate analyses, Lp-PLA₂ activity ($p=0.007$), but neither mass ($p=0.38$) nor CRP ($p=0.60$), was increased among subsequent CAD cases compared to non-cases. Multivariable models allowed for duration, gender, blood pressure and blood pressure medication, smoking status, waist-hip ratio, and lipid levels. While neither Lp-PLA₂ activity nor mass was independently associated with CAD incidence, a significant interaction between Lp-PLA₂ mass and CRP levels was noted ($p=0.002$), with Lp-PLA₂ risk increasing with elevated CRP levels. No interactions were observed with gender or LDL cholesterol.

Conclusion: In this cohort of type 1 diabetes persons at high risk for CAD, the predictive role of Lp-PLA₂ appears conditional on elevated CRP despite their concentrations not being correlated.

Platelet-activating factor acetylhydrolase activity in patients with type 1 diabetes mellitus

M. B. Gomes¹, E. Nunes², H. C. C. Faria Neto², M. F. Bevilacqua¹, M. N. Silva¹;

¹Diabetes, State University of Rio de Janeiro, ²Immunopharmacology, Laboratory of Immunopharmacology, FIOCRUZ, Rio de Janeiro, Brazil.

Background and Aims: Platelet-activating factor acetylhydrolase (PAF-AH) is a Ca²⁺ independent phospholipase A₂ that catalyses the conversion of platelet-activating factor (PAF) to lyso-PAF inactivating it. Plasma PAF-AH binds to lipoproteins mainly with LDL-cholesterol and HDL-cholesterol. The relationship between PAF-AH and atherosclerosis is currently controversial. Considering that PAF is a lipid mediator involved in inflammatory disease as well in atherogenesis, its inactivation by PAF-AH would result in an anti-inflammatory effect. On the other hand, PAF-AH may also generate bioactive oxidized free fatty acids and lysophosphatidylcholine that have deleterious effect on the arterial wall, thus having a proinflammatory and proatherogenic action. The aims of the present study were to evaluate if type 1 diabetic patients with and without clinical microvascular complications matched to subjects without diabetes have altered levels of PAF-AH activity and whether its level is related to clinical and metabolic variables.

Materials and Methods: We studied cross-sectionally 118 type 1 diabetic outpatients (54 males) aged 27.1±11.3 years with a duration of diabetes of 12.3±8.4 years, with ($n=38$) and without ($n=80$) clinical chronic complications and 94 non-diabetic subjects (48 males) aged 25.8±7.2 years. PAF-AH activity was measured with PAF-AH assay kit (Cayman Chemical, Ann Arbor, MI, USA). Human PAF-AH standard or human serum and 2-thio PAF, substrate for PAF-AH (Aarsman *et al.*, 1991), were added to the wells, followed by DTNB ((5,5'-dithiobis (2-nitrobenzoic acid)). One unit of enzyme hydrolyzes one µmol of 2-thio-PAF per minute at 25°C. Absorbance was read over a period of time (0, 1, 2, 3, 4, 5, 10, 15, 20, 30 minutes) using a plate reader. A minimum of two time points was used to determine enzyme activity. The reaction was determined using the DTNB extinction coefficient and results were represented as µmol/min/ml.

Results: Diabetic patients had higher PAF-AH [(0.016 ± 0.004) vs (0.014 ± 0.005-µmol/min/ml $p<0.05$) levels than nondiabetic subjects. No difference was noted between patients with and without microvascular complications. In diabetic patients PAF-AH was correlated with age, HbA_{1c}, uric acid and HDL-cholesterol. No correlation was found with LDL-Cholesterol. Stepwise multiple regression with PAF-AH as the dependent variable showed that HbA_{1c} was the only significant independent variable.

Conclusion: According to our results, PAF-AH, a lipid mediator involved in inflammatory diseases and atherogenesis, are increased in patients with type 1 diabetes probably independently of the presence of clinical microvascular disease. PAF-AH could be another inflammatory marker in patients with diabetes. Considering the importance of cardiovascular disease in patients with type 1 diabetes the influence of PAF-AH on the development of this complication in these patients must be addressed in prospective studies.

Implications of lipocalin-2 and visfatin levels in patients with coronary artery disease

K. Lee¹, K. Choi¹, T. Kim¹, H. Yoo¹, S. Park², H. Kim², J.-A. Seo³, N. Kim³, Y. Kim⁴, D. Choi², C. Park⁵, S. Baik¹;

¹Endocrinology, Korea University Guro Hospital, Seoul, ²Endocrinology, Korea University Anam Hospital, Seoul, ³Endocrinology, Korea University Ansan Hospital, Seoul, ⁴Endocrinology, Jae Saeng Hospital, Seung Nam, ⁵Cardiology, Korea University Guro Hospital, Seoul, Republic of Korea.

Background and Aims: Visfatin and lipocalin-2 have been implicated in insulin resistance and obesity-associated metabolic disorders.

The aim of this study was to examine lipocalin-2 and visfatin concentrations in patients with coronary artery disease (CAD) compared with those of control subjects, and evaluated their association with cardiovascular risk factors for atherosclerosis.

Materials and Methods: We examined visfatin, lipocalin-2 levels and cardiovascular risk factors in 91 subjects (49 patients with angiographically

confirmed CAD vs. 42 age- and gender-matched control participants). Cross-sectional study.

Results: Circulating lipocalin-2 levels were significantly higher in patients with CAD compared to the control subjects (82.6 ± 38.7 ng/ml vs. 43.8 ± 27.8 ng/ml; $P < 0.001$). However, visfatin levels were not significantly different between patients with CAD and control subjects. Serum lipocalin-2 levels were positively associated with weight ($r = 0.22$; $P = 0.036$), fasting insulin ($r = 0.42$; $P < 0.001$) and insulin resistance ($r = 0.44$; $P < 0.001$), whereas these levels showed a negative correlation with HDL cholesterol ($r = -0.30$; $P = 0.005$). The multiple regression analysis showed that lipocalin-2 levels were independently associated with HDL cholesterol and insulin resistance ($R^2 = 0.199$). In addition, the multiple logistic regression analysis showed that systolic blood pressure, insulin resistance and lipocalin-2 levels were independently associated with CAD.

Conclusion: Serum lipocalin-2 levels were significantly elevated in patients with CAD and were independently associated with CAD. The present findings suggest that measurement of serum lipocalin-2 levels may be useful for assessing CAD risk.

1245

Visceral fat thickness measured by ultrasonography is associated with metabolic risk factors of cardiovascular disease in Korean type 2 diabetic patients

D.-H. Cho, G.-H. Jeong, J.-O. Chung, D.-J. Chung, M.-Y. Chung;
Department of Internal Medicine, Chonnam National University Medical School, Gwang-Ju, Republic of Korea.

Background and Aims: It was already demonstrated that visceral fat accumulation is a major contributor for multiple risk factors clustering in patients with type 2 diabetes mellitus. Several studies demonstrated stronger positive relationships between the amount of visceral abdominal fat and insulin resistance and several cardiovascular risk factors than that of total body fat in patients with type 2 diabetes. Evaluation of visceral fat has been conducted using waist circumference and several imagings using computed tomography, magnetic resonance imaging, or ultrasonography (US). Ultrasound measurements have been recently shown to correlate better with cardiovascular risk factors than those derived from anthropometric measures. The aim of our study was to compare visceral fat thickness measured by ultrasonography with other anthropometric indices in order to assess the relationship between these indices and cardiovascular risk factors in type 2 diabetic subjects.

Materials and Methods: 217 type 2 diabetic patients participated in the study: 108 men (mean age 62.4 ± 9.6 years) and 109 women (mean age 62.0 ± 10.1 years). Anthropometric, clinical, and laboratory data including body mass index (BMI; kg/m^2), waist circumference (WC), systolic and diastolic blood pressure (SBP and DBP; mmHg), lipid profiles [total cholesterol (TC), fractions, and triglycerides (TG)] were measured. Insulin resistance was calculated by using HOMA-IR [fasting plasma insulin (mU/ml) X fasting plasma glucose (mmol/L)/22.5]. All ultrasonographic procedures were performed by the same examiner using a 3.5-MHz probe located 1 cm from umbilicus. Two US measurements of visceral (VFT) and subcutaneous fat (SFT) were taken. US-determined VFT was defined as the distance between the internal face of the rectus abdominis muscle and the anterior wall of the aorta.

Results: VFT was positively correlated with body mass index ($r=0.457$, $p<0.001$), waist circumference ($r=0.516$, $p<0.001$), HOMA-IR ($r=0.391$, $p<0.05$), and triglycerides ($r=0.328$, $p<0.05$), whereas it was negatively correlated with HDL-cholesterol ($r=-0.342$, $p<0.05$). The intraobservational reproducibility of the ultrasonographic estimations was 1.8–2.4% for the VFT. The patients were classified by the tertile on the basis of their VFT; the low tertile (< 42.6 mm in men and < 40.7 mm in women), the middle tertile (42.6–60.3 mm in men and 36.0–57.9 mm in women), and the high tertile (> 60.3 mm in men and > 57.9 mm in women). Men in the middle and high tertiles had a greater prevalence of coronary heart disease, low-HDL cholesterol, and metabolic syndrome than those in the low tertile. In women, the prevalence of coronary heart disease and metabolic syndrome was higher in the middle and high tertiles than in the low tertile. The high tertile of VFT had higher odd ratio of hypertension (OR=4.34, 95% CI 1.23–12.87), dyslipidemia (OR=9.51, 95% CI 1.38–62.12), and metabolic syndrome (OR=15.29, 95% CI 2.52–69.16) than did those in the low tertile, after adjustment for age, sex, and body mass index.

Conclusion: This study suggested that visceral fat thickness measured by ultrasonography may be the reliable and simple index for quantifying metabolic risk factors of cardiovascular disease in Korean type 2 diabetic patients.

1246

Association of subclinical carotid atherosclerosis with ultrasonographic non-alcoholic liver steatosis in diabetic and non-diabetic subjects

D. Torres, G. Parrinello, S. Paterna, G. Licata;
Internal Medicine, University of Palermo, Italy.

Background and Aims: Non-alcoholic fatty liver disease (NAFLD) is the most common cause of elevated liver enzymes in adults. Ultrasonography of the liver is able to identify it with high sensitivity and specificity. NAFLD is frequently associated with type 2 diabetes (DM) and metabolic syndrome. In this study we investigate the relations of ultrasonographic NAFLD with carotid artery intima-media thickness (IMT, a powerful predictor of cardiovascular (CV) and cerebrovascular complications defined by a thickness ≥ 0.9 mm and ≤ 1.5 mm) and plaques (defined by a thickness > 1.6 mm) and C-reactive protein (CRP) levels.

Materials and Methods: We studied a cohort of 54 patients (pts) (32 M, mean age 54 ± 11 years) referred to ultrasound laboratory with diagnosis of NAFLD (defined by presence of bright liver echo pattern according to Saverymuttu criteria and by absence of alcohol abuse and other liver diseases) and subgrouped them in two sex- age-matched groups on the basis of presence ($n=27$) or absence ($n=27$) of DM and compared with 25 sex- age-matched diabetic pts (C) without ultrasonographic NAFLD. There were not significant differences in hypertension, central obesity and dyslipidemia prevalence between groups. Pts with inflammatory, infective, neoplastic, kidney and CV diseases or events were excluded.

Results: A positive correlation between IMT and CRP levels ($p<0.01$) only in all the patients with NAFLD and DM was found. When compared with C, all the enrolled patients with NAFLD had higher levels of CRP (0.64 ± 0.36 mg/dl vs. 0.28 ± 0.27 mg/dl, $p<0.01$), a greater IMT (1.1 ± 0.3 mm vs. 0.98 ± 0.24 mm, $p<0.01$) and also greater prevalence of ACP (54% vs. 33%, $p<0.01$). This association was more relevant in the subgroup with DM ($p<0.01$). IMT was associated with degree of hepatic steatosis defined ultrasonographically ($p<0.05$). If we considered all the diabetic and non-diabetic pts after multiple regression analysis NAFLD and its severity, adjusted for all confounders factors, are predictors of higher carotid IMT ($p<0.01$). Carotid IMT was significantly higher in NAFLD pts when associated with hypertension ($p<0.05$). Diabetes, central obesity and hypotriglyceridaemia were the most predictive factors of NAFLD in all the pts.

Conclusion: Our results suggest that NAFLD and its severity are significantly associated with early asymptomatic carotid atherosclerosis and CRP serum levels, independently by the presence of DM. These data indicate that NAFLD, per se, may contribute to higher risk of CV disease suggesting a potential inflammatory pathogenic loop. This clinical-ultrasonographic condition must be considered, in our opinion, an additional criterium to classical CV risk factors for an early metabolic and CV stratification.

Insulin inhibits tissue factor expression in monocytes

J. Gerrits, J. W. Akkerman;
Department of Clinical Chemistry and Haematology,
University Medical Center Utrecht, The Netherlands.

Background and Aims: Patients with diabetes mellitus (DM) have a 2–4 fold increased risk of coronary artery disease. They suffer from both microvascular and macrovascular complications. DM2 patients have hyperactive platelets in the circulation and elevated plasma levels of many clotting factors leading to augmented activity of the coagulation system. We demonstrated previously in healthy individuals that insulin inhibits platelets through inactivation of the inhibitory G-protein of adenyl cyclase G_i , thereby interfering with P2Y₁₂-mediated suppression of cAMP formation. Platelets from DM2 patients have lost insulin signaling to cAMP, which explains the hyperaggregability in this disease. In the present study we investigated whether insulin also interferes with tissue factor (TF) expression in monocytes, since TF is the key initiator of the blood coagulation cascade.

Materials and Methods: Human monocytes were stimulated with 1 µg/ml lipopolysaccharide (LPS) for 2–5 hours at 37°C and expression of TF-mRNA (Taqman PCR), -protein (western blotting) and -activity (coagulation factor X activation) were analyzed. TF expression was measured in the soluble and membrane compartments. Insulin signaling through the receptor, IRS-1 / IRS-2 and Gi was measured by western blotting. Monocytic THP-1 cells were incubated with the fluorescent dye Fura-2/AM and after stimulation with 10 µM ATP and 10 ng/mL monocyte chemoattractant protein-1 (MCP-1) Ca²⁺ mobilization and influx were measured.

Results: LPS induced a 3–4 fold increase of TF activity in soluble and membrane compartments, which was set at 100%. Preincubation for 15 minutes with insulin (0.1–100 nM) dose-dependently inhibited TF upregulation (mRNA, protein) leading to a 34.4 ± 3.1% (means ± SEM, n=4) reduction of TF activity at 100 nM insulin. Inhibition was accompanied by Tyr phosphorylation of the insulin receptor, IRS-1, Gi and formation of an IRS-1–Gi complex, suggesting that insulin signaling leads to an increase in cAMP formation by interfering with the action of Gi. Indeed, increased cAMP levels induced by incubation with iloprost (a stable PGI₂ analog), forskolin (an adenylyl cyclase activator), IBMX (an inhibitor of phosphodiesterases) and membrane permeable dibutyl cAMP inhibited TF upregulation. For incubation with iloprost this inhibition was 75.7 ± 5.0 % (means ± SEM, n=4). Although LPS-induced TF upregulation occurred without an increase in cytosolic Ca²⁺ {[Ca²⁺]_{in}}, it was inhibited by 80.5 ± 4.5% (means ± SEM, n=4) by Ca²⁺ sequestration (BAPTA-AM), indicating that TF upregulation is Ca²⁺ dependent. Activation of the P2X7 channel with ATP and addition of ionophore A23187 (1 mM [Ca²⁺]_{out}) increased [Ca²⁺]_{in} to 500 nM and 1 mM respectively and enhanced TF expression respectively by 143.9 ± 58.7% n=4 and 231.8 ± 15.7% n=3 (means ± SEM). Insulin neither changed these Ca²⁺ increases nor TF expression. Stimulation with MCP-1 increased [Ca²⁺]_{in}, which was inhibited by preincubation with iloprost and insulin. Monocytes from a limited number of DM2 patients failed to show suppression of TF upregulation by insulin.

Conclusion: These results show that in monocytes from normal subjects insulin suppresses the upregulation of TF expression by LPS, possibly by interfering with the regulation of cAMP and cytosolic Ca²⁺. Preliminary data suggest that this suppression is absent in patients with DM2.

PS 129 Genetic determinants of dyslipidaemia and cardiovascular disease

1248

AHSG tagSNPs associate with type 2 diabetes and dyslipidaemia in a large-scale population-based sample of 7,683 Danish whites

G. Andersen¹, K. S. Burgdorf¹, T. Sparso¹, K. Borch-Johnsen^{1,2}, T. Jørgensen², T. Hansen¹, O. Pedersen¹;

¹Steno Diabetes Center, Gentofte, Denmark, ²Glostrup University Hospital, Research Centre for Prevention and Health, Glostrup, Denmark.

Background and Aims: The gene encoding the α2 Heremans-Schmid glycoprotein (*AHSG*) is a credible biological and positional candidate for type 2 diabetes and the metabolic syndrome, and previous attempts to relate *AHSG* variation with type 2 diabetes, obesity and correlated phenotypes in Swedish and French Caucasians have been largely successful. We sought to investigate seven frequent *AHSG* tagSNPs in relation to a range of metabolic traits including type 2 diabetes, obesity, dyslipidaemia, and hypertension.

Materials and Methods: The polymorphisms were genotyped in 7,683 Danish whites, providing a statistical power of more than 99 % to replicate previous findings. Genotyping was performed using Taqman allelic discrimination or matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry of PCR-generated primer extensions. All subjects underwent a standard 75g oral glucose tolerance test.

Results: The rs2077119 and rs2518136 polymorphisms were associated with type 2 diabetes, and in a combined analysis of the present and a previous study the rs2077119 remained significant (odds ratio 0.90 [0.84–0.97], *p* = 0.007). Furthermore, two *AHSG* haplotypes were associated with dyslipidaemia (*p* = 0.003). rs4917 was associated with lower fasting and postprandial serum insulin secretion and improved insulin sensitivity estimated by the homeostasis model assessment of insulin resistance. Indications of epistatic effects of *AHSG* variants with the *IRS1* Gly971Arg polymorphism were observed for fasting serum triglyceride concentrations.

Conclusion: Common variation in *AHSG* may contribute to the inter-individual variation in metabolic phenotypes, specifically type 2 diabetes and dyslipidaemia.

1249

A common variant (T94A) of L-FABP is associated with fasting triglycerides and LDL-cholesterol in women

E. Fisher¹, C. Weikert¹, I. Lindner², M. Klapper², M. Möhlig³, J. Spranger³, A. Pfeiffer³, H. Boeing¹, F. Döring²;

¹Epidemiology, German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, ²Molecular Nutrition, Institute of Human Nutrition and Food Science, Kiel, ³Clinical Nutrition, German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, Germany.

Background and Aims: A common variant (c.340A>G) of the human liver fatty acid binding protein (*FABP1*) gene, that alters a threonine (T) to alanine (A) at position 94 (T94A), had previously been shown to be associated with altered triglyceride levels after treatment with fenofibrate. Carriers of the A94 allele also had higher baseline plasma-free fatty acid levels, lower body mass index (BMI), and lower waist circumference than T94 homozygotes. To determine the possible role of the *FABP1* T94A polymorphism in modulating susceptibility to traits of the metabolic syndrome and accomplished diseases, we genotyped the polymorphism in the EPIC-Potsdam type 2 diabetes (T2D) case-control study and the EPIC-Potsdam cardiovascular disease (CVD) case-cohort study.

Methods: Genotyping of the c.340A>G polymorphism (rs2241883) was performed with the TaqMan system (ABI, Foster City, CA, USA), and fluorescence was measured with ABI Prism 7900 HT sequence detection system. Analysis of covariance (ANCOVA) was used to assess the association between genotypes and quantitative traits of the metabolic syndrome in men and women from the EPIC-Potsdam-CVD subcohort (N=826). Cox proportional hazard regression analysis was used for the examination of the relationship between *FABP1* T94A and risk of CVD in 220 incident cases of myocardial infarction and ischemic stroke and 820 non-cases. To estimate the risk of T2D associated

with *FABP1* T94A, logistic regression analysis was applied in a study sample of 192 incident cases and 384 sex- and age-matched controls. All analysis were conducted with multivariate adjustments. Power calculation revealed a possible risk determination for T2D of OR 1.7/1.9 (males/females) and for CVD of RR 1.5/1.7 (males/females) in additive inheritance models.

Results: The overall frequency of the minor allele was 0.373 in EPIC-Potsdam study subjects. In women, a significant trend of higher plasma triglyceride ($P=0.01$) and LDL-cholesterol ($P=0.02$) concentrations were seen for A-allele carriers after adjustment for age, menopausal status, hormone intake and Apo E genotype. BMI, waist circumference, HDL-cholesterol, fasting glucose levels, and blood pressure measurements showed no association with *FABP1* T94A genotypes. Also, no significant association with disease risk could be attained in both EPIC-Potsdam studies.

Conclusion: The study provides first evidence for an association of the *FABP1* T94A polymorphism and fasting plasma triglycerides and LDL-cholesterol concentration in females. These results support previous findings about the functional role of the L-FABP protein in fatty acid metabolism in the liver.

Association of variants in upstream transcription factor 1 (USF1) with type 2 diabetes in the Dutch population

S. J. R. Meex¹, J. V. van Vliet-Ostapchouk^{2,3}, C. J. H. van der Kallen¹, M. M. J. van Greevenbroek¹, C. G. Schalkwijk¹, E. J. M. Feskens⁴, E. E. Blaak⁵, T. W. van Haften⁶, T. W. A. de Bruin^{1,7}, C. Wijmenga^{8,9}, M. H. Hofker^{2,3}, C. D. A. Stehouwer¹;

¹Department of Internal Medicine, Maastricht University, The Netherlands, ²Department of Molecular Genetics, Maastricht University, The Netherlands, ³Department of Pathology and Laboratory Medicine, University Medical Center Groningen and University of Groningen, The Netherlands, ⁴Human Nutrition, Wageningen University, The Netherlands, ⁵Human Biology, Maastricht University, The Netherlands, ⁶Department of Internal Medicine, University Medical Center Utrecht, The Netherlands, ⁷GlaxoSmithKline, Research Triangle Park, United States, ⁸DBG-Dept. of Medical Genetics, University Medical Center Utrecht, The Netherlands, ⁹Department of Genetics, University Medical Center Groningen and University of Groningen, The Netherlands.

Background and Aims: Type 2 diabetes shares substantial genetic and phenotypic overlap with Familial Combined Hyperlipidemia. Upstream stimulatory factor 1 (USF1), a basic helix-loop-helix leucine zipper transcription factor which regulates expression of genes involved in lipid- and glucose metabolism is postulated to be such a shared genetic determinant. Although two common polymorphisms in USF1 are consistently associated with Familial Combined Hyperlipidemia and lipid traits, their impact on type 2 diabetes susceptibility is less well established. Replication studies in large cohorts are required to provide conclusive evidence concerning the true contribution of USF1 to type 2 diabetes susceptibility, and allow robust assessment of effect size. We evaluated these variants for association with type 2 diabetes in 2003 Dutch Caucasians comprising 700 patients with type 2 diabetes and 1300 healthy controls from two independent cohorts.

Materials and Methods: The first case-control sample comprised 502 subjects with type 2 diabetes from the Breda cohort and 920 healthy blood bank donors of Dutch Caucasian origin. The second case-control sample included 211 subjects with type 2 diabetes ($N=211$), and 379 normoglycaemic control subjects. These subjects were selected from a group of 2700 Caucasian subjects with one or more cardiovascular risk factors, which were screened for type 2 diabetes.

Results: SNP rs2073658 and SNP rs3737787 were in complete LD ($D'=1$, $r=1$). In the first case-control sample, prevalence of the major allele was higher in patients than in controls (75% versus 71%, OR 1.25, $p=0.015$). In the second case control sample, a similar frequency difference and concomitant odds ratio was observed: 76% in patients versus 72% in control subjects, (OR=1.22). Insufficient power of the second case control sample prevented this frequency difference to meet the threshold for statistical significance ($p=0.15$). The effect-size and -direction were identical in both case-control samples and a combined analysis strengthened the evidence for association (OR=1.24, $p=0.005$). Importantly, the increased risk for type 2 diabetes susceptibility could be ascribed to the major allele, and its high frequency translated in a substantial population attributable risk of 14.5%.

Conclusion: These data suggest that the major allele of rs2073658 is associated with a modestly increased risk for developing type 2 diabetes in Dutch Caucasians, with considerable impact at the population level.

Lipoprotein lipase *HindIII* polymorphism influences HDL-cholesterol in statin-treated patients with coronary artery disease

M. Javorsky¹, D. Gašperíková², J. Ukropec², B. Sedláková³, I. Riečanský⁴, O. Križanová³, E. Šeboková², M. Dobříková¹, I. Klimeš², I. Tkáč¹, ¹4th Department of Medicine, Medical School PJ Safarik University, Kosice, ²Diabetes Research Laboratory and DIABGENE, Institute of Experimental Endocrinology, Bratislava, ³Institute of Molecular Physiology and Genetics, Slovak Academy of Sciences, Bratislava, ⁴Department of Cardiology, National Institute of Cardiovascular Diseases, Bratislava, Slovakia.

Background and Aims: HDL-cholesterol (HDL-C) is a recognized athero-protective factor and low HDL-C levels occur frequently in patients with coronary artery disease (CAD). Regulation of HDL-C level most likely results from the interaction of genes involved in the lipoprotein metabolism and nongenetic factors. We studied associations and interactions among *HindIII* polymorphism of the lipoprotein lipase gene (*LPL*) and selected non-genetic factors with respect to HDL-C levels in patients with CAD.

Materials and Methods: 288 Slovak (Caucasian) patients (35% women, mean±SEM age 60±1 years, BMI 29±0.3 kg/m², 25% with type 2 diabetes) with documented coronary artery disease were examined and genotyped for *LPL HindIII* (rs320) by PCR/RFLP method. HDL-C was determined by a direct enzymatic method.

Results: In the total sample, there were no significant differences across the *LPL* genotypes in the adjusted HDL-C levels or other lipids, although a trend toward higher HDL-C and lower triglycerides in H-H- homozygotes was observed. Multiple linear regression identified a significant interaction between *LPL HindIII* and statin treatment, which together with gender and diabetes explained 12.1% of HDL-C variance. Accordingly, in statin treated patients we observed a significant stepwise increments of the HDL-C level related to the increasing number of H-alleles ($p=0.04$ for linear trend), whereas no such association was observed in patients without hypolipidemic treatment. Within the group of statin-treated patients, H-H- homozygotes had the level of HDL-C by 16% (0.19mmol/l) higher when compared with the H+H+ homozygotes ($p=0.06$).

Conclusion: HDL-C may be influenced by an interaction between statin treatment and *LPL HindIII* genotype. However, effect of this interaction appears to be small when compared with the effect of non-genetic factors. Our findings require replication in a pharmacogenetic study.

Galectin 2 but not Lymphotoxin- α polymorphisms predicts cardiovascular mortality in families with type 2 diabetes

A. Jonsson¹, M. Sjögren¹, M. Svensson¹, P. Almgren¹, B. Isomaa², L. Groop^{1,3}, M. Orho-Melander¹;

¹Department of Clinical Sciences, Diabetes & Endocrinology, Lund University, Malmö, Sweden, ²Folkhälsan Research Center, Biomedicum, Folkhälsan Genetic Institute, Helsinki, Finland,

³Department of Medicine, Helsinki University Central Hospital, Finland.

Background and Aims: A single nucleotide polymorphism (SNP) in the gene coding for the inflammatory cytokine lymphotoxin- α (*LTA*, rs1041981, AA-genotype) has been shown to be associated with myocardial infarction (MI) in some but not all previous studies. One reason for this controversy could be that *LTA* is located in the *HLA* gene cluster on chromosome 6p21 making it difficult to determine if the association is due to *LTA* itself or other members of the cluster. Galectin 2, the principal ligand of *LTA* up-regulates the secretion of *LTA* and a polymorphism in intron 1 of the *galectin 2* gene on chromosome 22q13 (*LGALS2*; rs7291467, C3279T) has been associated with 50% reduced transcriptional activity of *LGALS2* and protection from MI. Our aim was to investigate if the two polymorphisms in *LTA* and *LGALS2* are associated with cardiovascular or total mortality in type 2 diabetes (T2D) families.

Materials and Methods: The SNPs rs1041981 and rs7291467 were genotyped using Sequenom iPLEX™ in 4658 subjects above the age of 35 years (2144 males, 2514 females, aged 58.2 ± 13.8 years) from the Botnia T2D family study, followed for a mean time of 11 years. Cause of mortality was divided into cardiovascular (predominantly coronary) or other causes. Survival analyses were performed using Cox regression analyses, stratified by sex and T2D and adjusted for family correlations.

Results: During the follow-up time 1091 subjects died (23.4%; 528 males, 563 females) of which 337 due to cardiovascular events (7.2%; 183 males, 154 females). The frequency of the *LGALS2* rs7291476 CC-genotype was higher among individuals who died due to cardiovascular disease compared to those who remained alive or died due to other causes (20.0 vs. 15.4%, $p=0.028$) while the frequency of the *LTA* rs1041981 AA-genotype did not differ between the groups (15.9 vs. 16.2%, $p=0.87$). In line with this, the *LGALS2* rs7291467 CC-genotype but not the *LTA* rs1041981 AA-genotype predicted cardiovascular mortality (HR 1.38 [1.02–1.85] $p=0.035$ and 0.98 [0.71–1.35] $p=0.89$, respectively). None of the two SNPs predicted other than cardiovascular mortality nor were they associated with total mortality ($p=0.94$ and $p=0.69$).

Conclusion: Our data provide strong support for the earlier described association between *LGALS2* rs7291467 by for the first time demonstrating that it also influences cardiovascular mortality. This could be explained by up-regulation of the inflammatory pathway mediated by *LTA* in carriers of the CC-genotype of *LGALS2*.

1253

Reduced risk of coronary artery disease in type 2 diabetic men associated with the A-allele of the -866G>A variant in the promoter of UCP2 gene: the DIABHYCAR prospective study

G. Velho¹, N. Cheurfa¹, D. A. F. Ferrarezi¹, G. M. Brenner¹, F. Fumeron^{1,2}, M. Marre^{1,2};

¹Unité 695, INSERM, ²Faculté de Médecine Xavier Bichat, Université Paris 7 – Denis Diderot, Paris, France.

Background and Aims: Uncoupling protein 2 (UCP2) inhibits insulin secretion, decreases lipogenesis and increases adiponectin gene expression in adipocytes, decreases the production of reactive oxygen species, notably in macrophages, and is associated with protection against atherosclerosis. A common G/A variant at position -866 in the UCP2 promoter region (SNP rs659366) was shown to modulate mRNA expression, with increased expression associated with the A-allele in adipocytes and pancreatic beta-cells. Allelic associations with several phenotypes related to obesity, glucose homeostasis and dyslipidemia were observed. In the present study, we investigated the association of the -866G>A SNP with coronary artery disease (CAD) in a cohort of subjects with type 2 diabetes (T2DM) followed prospectively for cardiovascular and renal events.

Materials and Methods: We studied 3122 unrelated French type 2 diabetic subjects with high cardiovascular risk from the 6 year prospective DIABHYCAR study. The total prevalence of myocardial infarction at the latest follow-up of DIABHYCAR was 8.6%, comprising 267 cases (172 baseline and 95 incident cases) in 257 subjects. When considering the 295 subjects who underwent coronary artery bypass graft (CABG) and 137 cases of sudden death, the prevalence of CAD was 18.5%, (577 subjects). The variant was genotyped using an Assay by Design kit from Applied Biosystems. Genotype associations with CAD were assessed by logistic regression analyses and odds ratios (OR) were computed.

Results: We observed an inverse association of the A-allele with incident cases of CAD in a dominant model (OR=0.74, 95% C.I. 0.61–0.91, $p=0.0036$) as well as in a codominant model (OR=0.63, 95% C.I. 0.47–0.85, $p=0.0027$). The association persisted after adjustment for age, BMI, smoking, total cholesterol, HDL-cholesterol, triglycerides, urinary albumin excretion, creatinine clearance, HbA1c, duration of diabetes and arterial hypertension. Similar results were observed when we considered the total prevalence of CAD. A significant interaction between genotype and sex was observed in these associations. Stratification by sex showed the allelic associations with CAD to be stronger in men, while only a trend towards an association in a recessive model was observed in women. To assess which CAD phenotypes contributed to these associations we compared genotype frequencies of cases of myocardial infarction, CABG or sudden death to that of subjects with no CAD. Odds ratio for the A-allele in a dominant model was 0.72 (95% C.I. 0.55–0.93, $p=0.01$) for myocardial infarction, 0.76 (95% C.I. 0.60–0.97,

$p=0.03$) for CABG, and 0.81 (95% C.I. 0.57–1.14, $p=0.22$) for sudden death. These associations were stronger in men: 0.64 (95% C.I. 0.48–0.85, $p=0.002$) for myocardial infarction, 0.73 (95% C.I. 0.56–0.96, $p=0.024$) for CABG, and 0.64 (95% C.I. 0.43–0.95, $p=0.03$) for sudden death. No associations were observed in women and similar results were observed with a codominant model.

Conclusion: The A-allele of the -866G>A variant of UCP2 was associated with reduced risk of CAD in men with T2DM. Decreased risk of myocardial infarction, CABG and sudden death contributed individually and significantly to the reduction of CAD risk. This association was independent from other common CAD risk factors.

1254

A polymorphism at the protein tyrosine phosphatase receptor type F (PTPRF) locus is associated with increased risk of coronary artery disease in type 2 diabetes

C. Menzaghi¹, G. Paroni¹, C. De Bonis¹, A. Cocco¹, S. Mastroianno¹, G. Miscio¹, V. Tassi¹, S. Bacci¹, V. Trischitta^{1,2};

¹Research Unit of Diabetology and Endocrinology, IRCCS, San Giovanni Rotondo, ²Clinical Sciences, Sapienza University, Rome, Italy.

Background and Aims: PTPRF is known to down regulate insulin receptor signalling and downstream insulin action. PTPRF is overexpressed in insulin-responsive tissues of obese, insulin-resistant individuals, and may contribute to the pathogenesis of insulin resistance. A polymorphism in the PTPRF gene has been previously associated with insulin resistance, implicating variability at this locus as a possible etiologic factor in the development of insulin resistance-related abnormalities, including coronary artery disease (CAD). The aim of our study was to comprehensively evaluate the role of PTPRF polymorphisms in determining CAD risk.

Materials and Methods: *In silico analysis* using genotyping data downloaded from the HapMap database (Data Release 21/June 06) of the chromosomal region evenly spanning the PTPRF gene (93 kb), revealed three linkage disequilibrium blocks that could be tagged by four SNPs (htSNPs) which account for 87% of all possible haplotypes. The four htSNPs (rs11590627 for the first block, rs2782641 and rs10890257 for the second block, and rs516790 for the third block) were typed in a sample of 592 type 2 diabetic patients comprising 248 CAD cases (by stenosis > 50% at coronary angiography and/or previous myocardial infarction) and 344 CAD controls (i.e. asymptomatic patients with no signs of myocardial ischemia at resting and at stress ECG or with stenosis < 50% at coronary angiography).

Results: A significant association was observed between CAD and rs2782641 (minor allele frequency = 0.202 in CAD-positive vs. 0.137 in CAD-negative, $p=0.035$). Minor allele homozygous had significantly increased CAD risk (OR = 1.70, 95% C.I. = 1.03–2.74, $p=0.037$ after adjusting for age, gender and smoking status). The association was still significant also after adjusting for other known risk factors such as adiposity measures, hypertension and dyslipidemia (data not shown).

Conclusion: In conclusion, these findings point to PTPRF gene as a modulator of CAD risk in type 2 diabetes.

EuroAction: the achievement of lifestyle, risk factor and therapeutic targets at one year in coronary patients and their partners

S. B. Connolly¹, K. Kotseva², C. Jennings³, A. Mead², J. Jones², A. Holden², T. Collier³, D. De Bacquer⁴, G. De Backer⁴, D. Wood²;

¹Cardiovascular Medicine, Imperial College, London, United Kingdom, ²Cardiovascular medicine, Imperial College, London, United Kingdom, ³Epidemiology and Public Health, London School of Hygiene and Tropical Medicine, London, United Kingdom, ⁴Public Health, University of Ghent, Belgium.

Background and Aims: EUROACTION is a cluster randomised controlled trial of a nurse-led multi-disciplinary preventive cardiology programme which aims to manage coronary patients and their families to the European lifestyle, risk factor and therapeutic targets for cardiovascular disease prevention.

Materials and Methods: In each of 6 European countries, a pair of matched general hospitals was randomised to receive the Euroaction intervention programme (INT) or to be monitored for usual care (UC). Consecutive coronary patients were proactively identified by the study nurse and invited with their partners to attend the 16 week EUROACTION programme with a repeat assessment at one year. Using random effects meta-analysis (REML estimation) differences in proportions achieving goal were compared.

Results: 946 patients in INT (60% of all eligible) and 994 patients in UC (66% of all eligible) attended the one year assessment. 401 partners (57% of those identified) in INT and 335 partners in UC (45% of all identified) attended the one year assessment. Table 1 shows the proportions of patients and their partners achieving the European risk factor and therapeutic targets. Despite proactive screening for diabetes in INT, there was no significant difference in the prevalence of diabetes between INT and UC (18.4% INT, 17.7% UC) at one year. More patients in INT were diagnosed with impaired glucose tolerance (8.9% INT, 2.3% UC, $p=0.25$) although not significantly so. However, there was a trend for improved glycaemic control in INT with more patients achieving HbA1c <7.0% compared with UC, (61% INT, 50% UC, $p=0.29$). Moreover, patients with diabetes in INT were significantly more likely to have a lower fasting glucose at one year compared with UC (OR 0.43, $p<0.05$).

Conclusion: The EUROACTION programme helped coronary patients and their families to reduce abdominal obesity and become more physically active. In addition, there was an improvement in blood pressure and lipid control although significant for blood pressure only. In those with diabetes, there was evidence for improved glycaemic control. There was also more use of statins in the intervention arm. These changes should help coronary patients and their families reduce their cardiovascular risk in the longer term.

Proportions of patients and partners achieving European targets at one year

Proportions achieving target (%)	Patients		Partners

Addition of pioglitazone to atorvastatin exerts pleiotropic and anti-inflammatory effects in non-diabetic patients at cardiovascular risk – the PIOVASC study

T. Forst¹, M. Hanefeld², W. Fuchs³, B. Wilhelm¹, C. Köhler⁴, U. Lehmann³, J. Müller⁵, A. Pfützner¹;

¹Medical Dept., Institute for Clinical Research and Development, Mainz,

²Medical Dept., GWT, Dresden, ³Takeda-Pharma GmbH, Aachen,

⁴Laboratory Dept., GWT, Dresden, ⁵Acromion GmbH, Frechen, Germany.

Background and Aims: Insulin resistance and low-grade inflammation are important risk factors for atherosclerosis and the development of cardiovascular disease. We investigated the effect of pioglitazone in addition to atorvastatin compared to single treatment with atorvastatin on several established laboratory risk markers for cardiovascular disease, in a non-diabetic cardiovascular risk population.

Materials and Methods: 148 non-diabetic patients with increased cardiovascular risk, defined as hypertension and/or a previous cardiovascular event (76 male, 72 female; age 61.4 ± 6.5 years; BMI 29.2 ± 4.1 kg/m²; mean \pm SD) were included in our double blinded, placebo controlled parallel study. Patients were randomised to 40 mg atorvastatin and placebo or 40 mg atorvastatin and 45mg pioglitazone. At baseline and after 6 months, fasting blood samples were taken for the measurement of Intact Proinsulin, Adiponectin, IL-6, MCP-1, MMP-9, sCD40L, P-Selectin and t-PA. In addition, the HOMAs Score was calculated from the measurement of fasting glucose and insulin plasma levels.

Results: In association with an improvement in HOMAs Score, combined treatment with atorvastatin and pioglitazone resulted in a reduction in Intact Proinsulin, MCP-1, P-Selectin, and t-PA levels, and an increase in Adiponectin levels (table 1). No significant effect of the combined treatment could be observed on IL-6, MMP-9, or sCD40L plasma levels. Single atorvastatin treatment did not effect any of the above mentioned laboratory parameters in our study.

Conclusion: The addition of pioglitazone to atorvastatin treatment exerts multiple pleiotropic effects in non-diabetic patients with increased cardiovascular risk. Further investigations have to clarify if this kind of combination therapy might be able to improve the clinical outcome in this special risk population.

Risk of stroke and myocardial infarction is reduced in patients with type 2 diabetes treated with pioglitazone: results of a retrospective, claims-based study

Y. Xu¹, C. Vallarino¹, R. W. Baran¹, R. Spanheimer¹;

¹Takeda Pharmaceuticals North America, Inc., Deerfield, United States.

Background and Aims: Patients with type 2 diabetes mellitus (T2DM) have a two- to four-fold increased risk of having a macrovascular event compared to age-matched individuals without T2DM. A recent controlled, randomized

study suggested that the antidiabetes treatment pioglitazone HCl (PIO) may decrease the risk for such events, including stroke and myocardial infarction (MI). The aim of this retrospective, claims-based study was to determine whether the event-reducing treatment effects of PIO observed in the clinical trial setting are observed in clinical practice.

Materials and Methods: This analysis included data from patients enrolled in US healthcare plans affiliated with i3 Innovus. The i3 Innovus database includes eligibility, pharmacy, and medical claims data from more than 24 million patients. Using data from a 3 1/2 year period (1 January 2003 to 30 June 2006), we extracted information for patients with a diagnosis of T2DM (ICD-9 codes 250.x0 and 250.x2). Two treatment groups were defined: (1) a group consisting of patients receiving the thiazolidinedione (TZD) PIO, with or without any other antidiabetes treatment (excluding the other clinically available TZD, rosiglitazone) and (2) a non-TZD-treated group consisting of patients receiving any antidiabetes treatments (excluding any TZD use). The index date was defined as the start date for the initial antidiabetes medication. Patients were included for analysis if they were 45 years of age or older at the index date, had continuous enrollment data available for at least 6 months before and 1 month after the index date, and did not have a record of stroke or MI in the 6 months before the index date. The definition of stroke included the following events (ICD-9 code): occlusion and stenosis of precerebral arteries (433.xx), occlusion of cerebral arteries (434.xx), transient cerebral ischemia (435.x), and acute cerebrovascular disease (436). MI was defined as an event of acute myocardial infarction (410.xx). The study endpoints were the first recorded occurrences of stroke or MI or last date of enrollment, whichever came first.

Results: The adjusted relative risk of stroke was 0.800 (95% CI: 0.716 – 0.893) for PIO (N=11,433) versus the non-TZD group (N=55,273) after controlling for age; gender; the status of hypertension, hyperlipidemia, heart failure, and edema; and use of other concurrent antidiabetic agents, clopidogrel, warfarin, aspirin, and statin. The adjusted relative risk of MI was 0.621 (95% CI: 0.503 – 0.766) for PIO (N=11,917) versus the non-TZD group (N=57,956) using identical controls.

Conclusion: We conclude that, in a clinical practice setting in patients with T2DM, therapies that include PIO are associated with significant reductions in the risk for stroke or MI compared to non-TZD therapies.

Effect of pramlintide treatment on markers of cardiovascular risk in patients with type 2 diabetes using basal insulin

C. Lush, B. Zhang, D. Maggs, T. Darsow, O. Kolterman;
Amylin Pharmaceuticals, Inc., San Diego, United States.

Background and Aims: Cardiovascular disease (CVD) is a major cause of morbidity and mortality in patients with type 2 diabetes (T2DM). Pramlintide, an analog of the beta-cell hormone amylin, improves glycemic control and reduces body weight in patients with diabetes using mealtime insulin. A recent study examined the effects of pramlintide in patients with T2DM using basal insulin ± oral agents (no mealtime insulin). This post-hoc analysis assessed the effects of pramlintide treatment on various cardiovascular (CV) risk factors in these patients.

Materials and Methods: In this 16-week, double-blind study, 211 patients with T2DM using insulin glargine ± oral agents were randomized to treatment with pramlintide or placebo with major meals. Baseline demographics (n = 211, age 55 ± 9 y, diabetes duration 11 ± 6 y, HbA_{1c} 8.5 ± 0.9%, weight 103 ± 18 kg, BMI 35 ± 5 kg/m²; mean ± SD) were well-balanced between the two treatment groups. After optimization of pramlintide dosage (60 or 120 µg), insulin was titrated weekly, targeting a fasting plasma glucose concentration of <100 mg/dl.

Results: At Week 16, HbA_{1c}, mean postprandial glucose (PPG) increments and body weight were significantly reduced in pramlintide- vs. placebo-treated patients (HbA_{1c}: -0.7 ± 0.1% vs. -0.4 ± 0.1%, P<0.05; mean PPG excursions: -24.4 ± 3.6 mg/dL vs. -0.4 ± 3.0 mg/dL, P<0.0001; weight: -1.6 ± 0.3 kg vs. +0.7 ± 0.3 kg, P<0.0001; mean ± SE).

After 16 weeks of pramlintide treatment, hsCRP concentrations were also significantly reduced when compared to placebo (pramlintide -0.85±0.21 mg/L vs. placebo 0.12±0.20 mg/L; P<0.01; mean ± SE). The reduction in hsCRP was most pronounced in patients who were at high CV risk (≥3 mg/dl) at baseline (pramlintide -1.57±0.35 mg/L (-24%) vs. placebo -0.55±0.37 mg/L (-9%); P<0.05). Multiple regression analysis revealed that baseline hsCRP, BMI, and change from baseline in body weight were each

significantly associated with changes in hsCRP. Positive trends were also noted in pramlintide-treated patients who had high risk lipid profiles or blood pressure at baseline. Pramlintide was generally well-tolerated, with the most frequent adverse events being mild-to-moderate hypoglycemia (pramlintide 44%; placebo 47%) and nausea (pramlintide 31%; placebo 10%). There was no treatment-related severe hypoglycemia.

Conclusion: Pramlintide, as an adjunct to basal insulin, improved glycemic control and reduced body weight in patients with type 2 diabetes. Pramlintide-induced weight loss was associated with a significant reduction in hsCRP levels, with the greatest decrease occurring in patients at high risk for CV disease at baseline. While long-term studies are needed, these results suggest that pramlintide treatment may have beneficial effects on CV risk factors, particularly in patients at high risk.

1259

South Danish Diabetes Study: Effect of antidiabetic treatment on cardiovascular risk factors

J. Gram¹, J. Henriksen¹, H. Beck-Nielsen², T. SDDS Study Group²;
¹Department of Endocrinology, University of Southern Denmark, Esbjerg,
²Department of Endocrinology, University of Southern Denmark, Odense, Denmark.

Type 2 diabetes is associated with an increased risk of cardiovascular disease. Intensive anti hyperglycaemic treatment may reduce macrovascular disease but is only proven for metformin. Postprandial hyperglycaemia as well as hyper-cholesterolemia, hypertension and microalbuminuria are well known cardiovascular risk factors. The effects of different antidiabetic treatments on these risk factors were studied in an investigator driven, 2 year randomised, intention to treat (ITT), and treat to target study, comparing the effect of NHP insulin given at bedtime with insulin aspart given at the 3 main meals. Beside insulin all patients received blinded treatment with metformin or placebo and rosiglitazone or placebo giving a total of 8 subgroups (factorial design). All participants received antihypertensive and cholesterol lowering treatment according to international guidelines. In total 371 patients with type 2 diabetes for at least 2 years and not sufficiently controlled on at least one antidiabetic treatment, were included in the study. Age 56.3 ± 8.4 yr (mean ± SD), BMI 33.9 ± 5.7 kg/m², HbA_{1c} 8.6 ± 1.2 %, blood pressure 143 ± 18 / 84 ± 9. 311 patients completed the study but data analysis is based on 369 ITT subjects. Overall, following 2 years treatment, HbA_{1c} was significantly lower in patients treated with aspart as compared to NPH insulin (-0.41%, p<0.001). Moreover, the add on treatment with metformin was associated with a further decrease in HbA_{1c} as compared to placebo (-0.60%, p<0.001) as was rosiglitazone (-0.55%, p<0.001). Blood pressure was similar in insulin aspart, NPH insulin and metformin treated groups. However, rosiglitazone treatment reduced systolic blood pressure by -3.7 mmHg (p<0.001) and diastolic blood pressure by -2.9 mmHg (p<0.001) as compared to the non-rosiglitazone treatment group. Total cholesterol (T-CHOL) decreased in the metformin treated group (-0.21 mmol/l, p<0.012), and increased in the rosiglitazone group (0.33 mmol/l, p<0.001). HDL cholesterol increased in the insulin aspart treated group (0.05 mmol/l, p<0.012) as well as in the rosiglitazone group (0.11 mmol/l, p<0.001). LDL cholesterol decreased in the aspart group (-0.18 mmol/l, p<0.02) and the metformin group (-0.17 mmol/l, p<0.035) but increased in the rosiglitazone group (0.30 mmol/l, p<0.001). There were no differences in the effect on microalbuminuria between treatments.

In conclusion, intensive anti hyperglycaemic treatment regimes were followed by a significant reduction in blood pressure if rosiglitazone treatment was included. There were significant effects on lipid variables in treatment regimes including insulin aspart, metformin and rosiglitazone.

1260

Use of alpha-lipoic acid in patients with type 1 diabetes mellitus

D. Najmutdinova, N. Sadikova;
Endocrinology, the Tashkent Medical Academy, Tashkent, Uzbekistan.

Background and Aims: The aim of the research was to study the effect of alpha-lipoic acid on structural-functional remodeling of the left ventricle in patients with type I diabetes mellitus.

Materials and Methods: The study enrolled 30 patients with type 1 DM complicated by the cardiovascular form of diabetic autonomic neuropathy. Twenty patients took alpha lipoic acid at a dose of 600 mg a day against the background of conventional therapy (group I). The second group (10 patients) received only conventional treatment including individually dosed insulin and inhibitors of angiotensin converting enzyme, enalapril. Before and in 3 months after treatment all the patients underwent cardiovascular tests, subjective and objective assessment of peripheral innervation, echocardiography and ECG with determination of heart rate variability and dispersion of QT-interval.

Results: Significant positive changes of parasympathetic cardiovascular tests were revealed in both therapeutic groups: inhalation/exhalation by 120.46% and 109.20%, Valsalva test – 7.26% and 1.76%), 30/15 test – 4.85% and 2.13%, respectively in groups I and II ($p < 0.05$). Differences of dynamics between groups were significant for Valsalva and 30/15 tests ($p < 0.05$). Cardiovascular tests with isometric load did not change in both groups. Scores characterizing the condition of peripheral innervation did not change in group II and significantly decreased in group I – neuropathic symptomatic count (NSC) by 22.35% and neuropathic dysfunctional count (NDC) by 17.52% ($p < 0.05$). Dynamics of parameters of the structure, systolic and diastolic functions of the left ventricle did not significantly differ in both groups. The diameter of the left atrium reduced by 2.82% and 1.80%, respectively, end-diastolic volume of the left ventricle by 2.56% and 2.22%, the thickness of the interventricular septum by 1.41% and 2.82%, the thickness of the posterior wall of the left ventricle by 3.16% and 4.36%, relative thickness of the walls by 1.28% and 2.66% in groups I and II respectively. Decrease of the wall thickness and internal volume of the left ventricle resulted in significant decrease of the left ventricle myocardium weight index by 5.28% and 6.75%, respectively ($p < 0.05$).

Study of the diastolic function of the left ventricle demonstrated significant increase of PE by 12.06% and 8.32% and decrease of PA by 7.83% and 4.26%, respectively. The phase of isometric relaxation was decreased by 6.59% and 4.75%, DT by 4.77% and 4.29%, respectively. The positive dynamics of parameters of active and passive diastolic relaxation of the left ventricle myocardium resulted in increasing integral parameters of diastolic function – filling spectrum by 21.89% and 13.98% and phase of early filling by 9.39% and 4.80% respectively.

Variability of RR interval on ECG significantly increased in both groups but more in the group on alpha lipoic acid (90.81% against 32.79%) ($p < 0.05$). QT interval dispersion decreased by 45.12% and 15.39% ($p < 0.05$).

Conclusion: Use of alpha lipoic acid in addition to conventional therapy in patients with type I diabetes mellitus positively influenced results of parasympathetic cardiovascular tests, functional condition of peripheral innervation and electrophysiologic properties of the myocardium. The effect of the preparation on the diastolic function of the left ventricle was comparable in both groups.

immunoglobulin k chain promoter were used for this experiment. Cells were incubated 24 hours with 50mM glucose. Also was assayed LPS, which is known to induce NFkB activity. Lutein was added to the medium solved in DMSO 0,1%. In vivo study: Rats were induced diabetic by streptozotocin injection and divided into subgroups: control, diabetic, d+lutein and d+insulin. Treatments (lutein 0.5mg/kg body weight and insulin 50 mUI/g body weight s.c.) were administered daily since day 4 after streptozotocin injection, until the end of the experiment, 1 month after diabetes induction. Lymphocytes were separated from normal whole blood by Ficoll density gradient separation. Malondialdehyde (MDA), a lipid peroxidation product, and glutathione (GSH), were measured by HPLC. NFkB activity was determined by adding luciferin to the medium and measuring the light generated at 530nm with an optical system.

Results: In vitro study: MDA increased significantly after incubation with glucose, LPS, and both together, while GSH concentration was decreased. LPS induced NFkB activity in U937 cells. This activity was even higher when incubated together with glucose, being this increase statistically significant when compared to control or LPS treated cells. Lutein treatment was able to prevent all of these alterations. In vivo study: MDA concentration increased significantly in lymphocytes of diabetic rats when compared to controls, while GSH decreased. Again, lutein prevented these alterations.

Conclusion: This study confirms that oxidative stress is involved in the impairment observed in diabetic immune system and that a treatment with lutein, which has been suggested to regulate NFkB activity, and it is known to stimulate both cell-mediated and humoral immune responses, could be an appropriate treatment for the impairments observed in the study.

In vivo and in vitro study of the effect of high glucose levels on immune system cells: treatment with lutein

M. Muriach¹, E. Arnal¹, M. Miranda¹, R. Blomhoff², D. Silvestre³, F. Bosch-Morell¹, J. Romero¹;

¹Physiology, Universidad Cardenal Herrera-CEU, Valencia, Spain,

²Institute for nutrition research, University of Oslo, Norway,

³Food Technology, Universidad Cardenal Herrera-CEU, Valencia, Spain.

Background and Aims: Diabetic patients present an increased susceptibility to frequent and protracted infections. Several in vitro functional defects of the immune system have been correlated with the metabolic control of diabetic patients, and the recognition of an impaired immune system has implications for the diagnosis, treatment and outcome of infections. Hyperglycaemia induces an oxidative stress situation in diabetic condition which is involved in the pathogenesis of late diabetes complications. NFkB is a redox sensitive transcription factor involved in immune response, cell proliferation and apoptosis that has been associated to development of diabetic complications. The aim of this study was to study the effect of high glucose levels on oxidative stress parameters and NFkB activity, in vitro in U937 cells, and in vivo in T cells of diabetic rats in an experimental model of diabetes. We also assay a treatment with lutein, a natural antioxidant without hypoglycemic properties.

Materials and Methods: In vitro study: Human promonocytic cells (U937) transfected with luciferase reporter gene with NF-kB sites from
