PRELAUNCH ABSOLUTE RADIOMETRIC CALIBRATION OF THE
REFLECTIVE BANDS ON THE LANDSAT-4
PROTOFLIGHT THEMATIC MAPPER

ABSTRACT

The results on the absolute radiometric calibration of the Landsat-4 Thematic Mapper (TM), as determined during pre-launch tests with a 122-centimeter Integrating Sphere (IS), are presented. Detailed results for the best calibration of the protoflight TM are presented, as well as summaries of other tests performed on the sensor from June 1981 to March 1983. The dynamic range of the TM is within a few percent of that required in all bands, except bands 1 and 3. Three detectors failed to pass the minimum SNR specified for their respective bands: band 5, channel 3 (dead), and band 2, channels 2 and 4 (noisy or slow response). Estimates of the absolute calibration accuracy for the TM show that the detectors are typically calibrated to 5-percent absolute error for the reflective bands; 10-percent full-scale accuracy was specified. Ten tests performed to transfer the detector absolute calibration to the internal calibrator show a 5-percent range at full scale in the transfer calibration; however, in two cases band 5 showed a 10-percent difference and a 7-percent difference. These errors are given under the assumption of identical operating conditions for all transfer tests; known temperature sensitivities for the TM have not yet been included.

KEYWORDS: absolute radiometric calibration, dynamic range, noise, signal to noise, gain, offset.

INTRODUCTION

Since the 1972 launch of the Landsat-1 satellite, views of natural and manmade features on the surface of the Earth have been routinely provided to data users at a relatively coarse resolution (<150 meters) on a repeating basis (once every 18 days). These images have had a profound effect in many areas, including agricultural production; water resource, rangeland, and forestry management; land use and urban and regional planning; geologic survey and mineral resource management; oceanography; cartography; and disaster warning and relief. Landsat data have been used in many studies involving hydrology, agriculture, geology, forestry, and land resources in addition to urban area delineation.

The latest in the series of Landsat platforms (Landsat-4) was launched from Vandenberg Air Force Base, California, on July 16, 1982. It carried a new sensor, the Thematic Mapper (TM), that will observe the Earth through atmospheric windows in the visible, near-infrared, middle-infrared, and thermal-infrared portions of the electromagnetic spectrum. Although this sensor will return new information to users of Landsat data, its value will depend critically on how well the TM can be calibrated.

Absolute calibration of a satellite instrument (or absolute radiometry) may be defined as the ability to relate the voltage or digital output of the sensor to the input radiance. It includes the determination of the accuracy to which that conversion is made. Absolute calibration demands the use of a carefully controlled and monitored standard source that can be directly related to absolute standards maintained by the National Bureau of Standards (NBS). In a system like Landsat, the calibration must provide the relationship between the digital counts output by the sensor to the radiance input to the detectors in each spectral band. Achieving absolute accuracy to some specified value allows the determination of relative scene spectral radiance. With known solar irradiance at the ground and known atmospheric characteristics, the scene reflectance may be determined. Understanding the sensor characteristics and how they may change with time allows the accurate detection and analysis of temporally varying features and comparison with other sensors such as the Multispectral Scanner (MSS).

This paper discusses the prelaunch absolute calibration of the protoflight TM reflective band detectors and the onboard internal calibrator that will be used to correct observed scene radiance values and to monitor the health of the sensor. The results of the calibration and estimates of its

accuracy are presented. The TM thermal band requires a different approach to calibration and is discussed in Lansing and Barker (1983). The procedures and the standard source used to calibrate the sensor and the internal calibrator are discussed in Barker et al. (1983a). In-orbit characterization of the TM is presented in Barker et al. (1983b). An excellent summary of the TM instrument and its major subsystems is given in Engel (1980).

ABSOLUTE CALIBRATION OF THE REFLECTIVE BANDS

CALIBRATION OF THE DETECTORS

Gain and Offset Determination and Dynamic Range

Six different detector calibration tests were performed on the Thematic Mapper (TM) with the 122-centimeter (diameter) Integrating Sphere [IS(122)] to determine gain, offset, and the resulting measured dynamic range of the instrument. The dates and test designations for the six calibration tests are given in Barker et al. (1983a). Certain key assumptions must be made to interpret the data from the IS(122) calibrations of the TM:

- Radiance output from the IS(122) in each TM band and at each level is known; that is, the sphere has not changed characteristics from the time of its calibration until the TM calibration is performed.
- Due to alignment and TM operating mode, the detectors are seeing the peak output from the IS(122).
- The TM voltage response to radiance is linear and uniform.

Some of these assumptions may not be true for certain calibration tests.

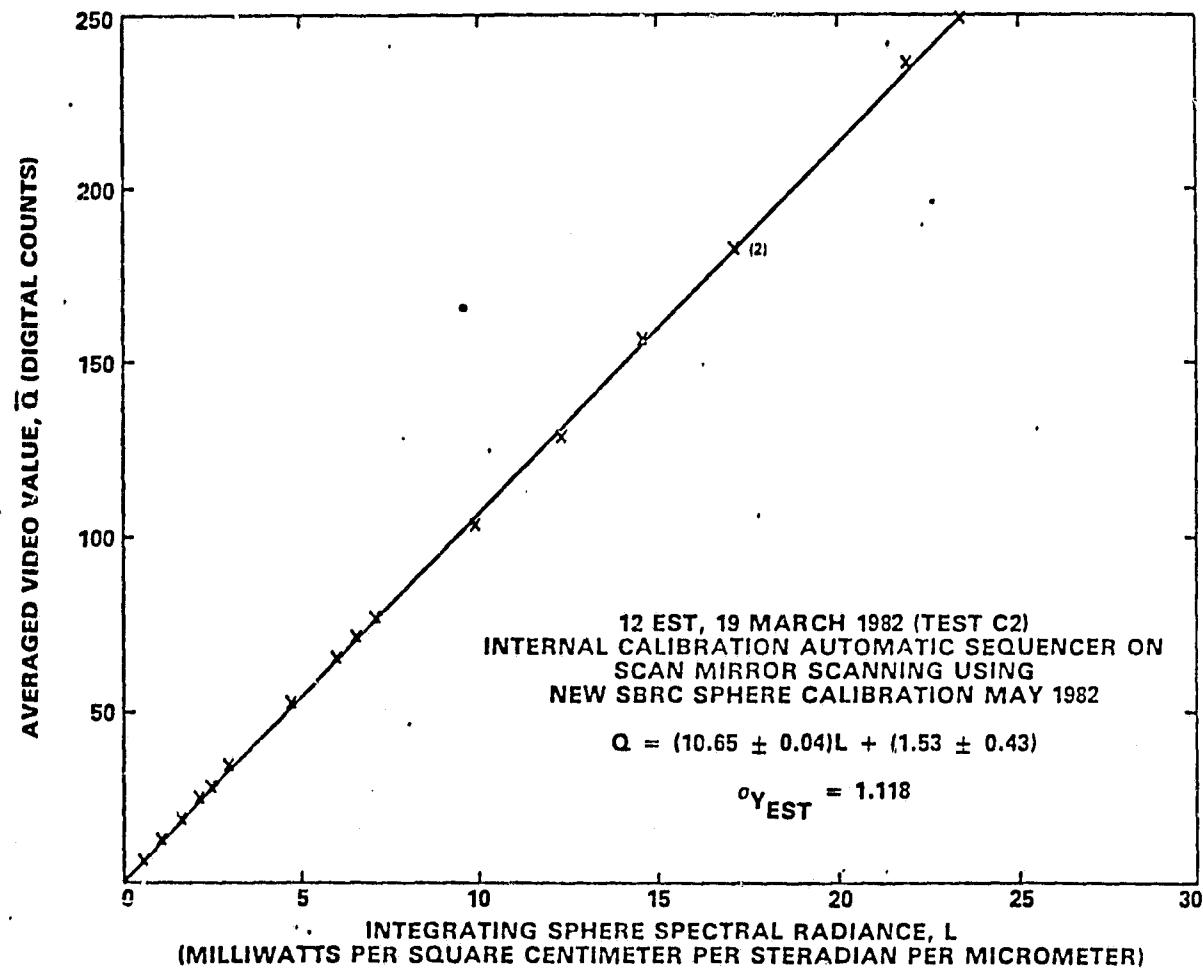

During each test, TM data were acquired as the lamps in the IS(122) were switched off according to the test sequences described in Barker et al. (1983a). The test sequences used in the detector calibration give 20 different radiance levels. These data were analyzed to determine the characteristics of the 96 detectors in the reflective bands. Selection of the proper gain resistors to establish the dynamic range of the individual detectors was performed only once (test A in Barker et al., 1983a).

Sample results for band 3, channel 9, from test C2 are shown in Figure 1; the residuals for that data are shown in Figure 2. Gain, offset, dynamic range, and signal-to-noise

ratio (SNR) for these parameters for test C2 are given in Tables 1 through 7; statistics for these parameters are given in Tables 8 through 13 for the same test. Results for the other tests are given in Barker et al. (1983c). The gain and offset are calculated by a least-squares fit to data, such as shown in Figures 1 and 2. The calibration equation is as follows:

$$\bar{Q}_{ijk} = g_{ik} L_{ijk} + o_{ik}$$

where \bar{Q}_{ijk} is the averaged digital count TM output for detector i (1 to 16) in band k (1 to 5 and 7) and radiance level j (1 to 20), L_{ijk} is the corresponding spectral radiance (milliwatts per square centimeter per steradian per micrometer), and g_{ik} and o_{ik} are the derived gain and offset for the i th detector in band k . The least-squares fit gives values of g_{ik} and o_{ik} as well as their standard errors. The band-averaged gain and offset, the band-averaged SNR, and the derived dynamic range for each band are summarized in Table 14.

The information presented in Tables 1 through 14 should be considered estimates of the best results possible from the TM calibration, not examples of actual calibrations of the TM with the IS(122). A complete set of derived calibration parameters from all six tests has been obtained. A summary of average gains and offsets for three of the tests is given in Table 15. Table 16 shows average gain changes between tests in percent for odd-numbered, even-numbered, and all detectors by band compared to test C2. Although all gains are lower in the March 1982 tests than they were during the initial radiometric calibration, all bands and detectors appear to be within specified values for accuracy and dynamic range. Calculated offset values increased in nearly all bands; values for test C2 are nearly those expected for the background level of two or three digital counts, while those for test A were not.

The apparent systematic nature of the residuals shown in Figure 2 is probably due to the integrating sphere calibration and not to the TM detectors. Other sources of information, such as the sphere calibration of the flight unit TM in July 1982 and the analog-to-digital test measurements on both the protoflight and flight units, show that the TM detectors are extremely linear. Special care was taken in the sphere calibration for the flight unit tests in July 1982, and preliminary results from those tests indicate no such systematic effects.

Table 1

EXPLANATORY INFORMATION FOR DERIVED RADIOMETRIC CALIBRATION PARAMETER TABLES

1. CALIBRATION EQUATION:

$$\text{COUNTS} = \text{GAIN} * \text{RADIANCE} + \text{OFFSET} \quad (\alpha = G*L+O)$$

2. UNITS FOR QUANTITIES:

- A. DIGITAL COUNTS
- B. RADIANCE - MILLIWATTS PER SQUARE CENTIMETER PER STERADIAN PER MICROMETER (i.e., SPECTRAL RADIANCE)
- C. GAIN - DIGITAL COUNTS PER "RADIANCE UNITS"
- D. OFFSET - DIGITAL COUNTS

3. SNR IS SIGNAL TO NOISE RATIO AT:

LSR - LOWER SCENE RADIANCE (SPECIFIED)

MSL - MINIMUM SATURATION LEVEL RADIANCE (SPECIFIED)

4. RADIANCE IS GIVEN AT:

MIN - RADIANCE AT MINIMUM (ZERO COUNTS)

MSL - RADIANCE AT MINIMUM SATURATION LEVEL (243 COUNTS)

MAX - RADIANCE AT MAXIMUM (255 COUNTS)

^aGAIN CHANGE DEFINED AS: VALUE = $100\% \times (\text{CURRENT} - \text{REFERENCE}) / \text{REFERENCE}$.

^bNO BANDS 5 AND 7 DATA TAKEN DURING TEST B.

Our choice of test C2 as the best calibration of the TM for use during postlaunch activities was dictated by several considerations:

- The IS(122) was recalibrated in May 1982; these output radiances were used to obtain the results presented in Tables 2 through 7 and are not affected by any significant use of the IS(122) from March to May 1982. Tests A and B, however, are well removed in time and sphere usage from both May (and February) 1982 and June 1980 sphere calibrations.
- A change in IS(122) output in the blue wavelengths from the June 1980 to the February and May 1982 sphere calibrations (2 to 4 percent or worse at some wavelengths according to Walker (1982a, b)) may in particular affect TM band 1.
- The cooled focal plane assembly (CFPA) (bands 5, 6, and 7) was removed from the TM in August 1981 for repair. This invalidates the band 5 and 7 calibrations during the A tests.
- Alignment of the IS(122) and the TM was questionable during test B; in addition, no CFPA data were taken during that test.
- One 25-watt lamp burned out after the February 1982 sphere calibration check; the new lamp was calibrated during May 1982.

Changes made in the CFPA in August 1981 may explain most of the observed differences in bands 5 and 7 between tests A and C. Changes in sphere output from June 1980 to February and May 1982 should also be considered for bands 5 and 7 as well as band 1. It is not clear, however, that changes in the sphere can account for more than 1 or 2 percent of the observed differences in band 4 (see Table 16).

To further evaluate the accuracy of the calibration of the TM with the IS(122), errors have been computed for detectors 1, 8, 9, and 16 in each band. These are based on computed errors in gain and offset from the least-squares fit and standard deviations for the averaged digital counts from the highest observed sphere radiance level in each band that does not saturate. The errors are part of the transfer error in the calibration from the IS(122) to the TM. These results are listed in Table 17. The error, in percent, in

Table 17

**COMPUTED ERRORS IN SPECTRAL RADIANCE FOR
CALIBRATION OF TM/PF DETECTORS WITH IS (122)**

CHANNEL	BAND					
	1	2	3	4	5	7
1	1.11	0.76	0.68	0.69	0.65	0.81
8	1.06	0.58	0.59	0.70	0.62.	0.70
9	0.95	0.64	0.57	0.70	0.62	0.80
16	1.10	0.70	0.60	0.70	0.66	0.81

VALUE IS FRACTIONAL ERROR IN SPECTRAL RADIANCE AT HIGHEST UN-SATURATED SPHERE BRIGHTNESS LEVEL IN BAND, IN PERCENT:

$$\frac{\Delta L}{L} (\%) = 100 * \sqrt{\frac{(\Delta \bar{Q})^2 + (\Delta O)^2}{(\bar{Q} - O)^2}} + \left(\frac{\Delta G}{G} \right)^2$$

$\bar{Q}, \Delta \bar{Q}$ AVERAGED VIDEO DIGITAL COUNT AND ITS STANDARD DEVIATION
 $O, \Delta O$ OFFSET AND ITS STANDARD DEVIATION
 $G, \Delta G$ GAIN AND ITS STANDARD DEVIATION

radiance for the highest unsaturated sphere level is computed as follows, based on the calibration curve $Q = GL + O$:

$$\frac{\Delta L}{L} (\%) = 100 * \sqrt{\frac{(\Delta Q)^2 + (\Delta O)^2}{(Q - O)^2} + \left(\frac{\Delta G}{G}\right)^2}$$

These values provide a measure of the full-scale precision of the calibration of the TM. Other sources of error in the calibration, such as errors in the radiance output by the IS(122) in a TM band and the relative spectral response in the band, are also contributing to the transfer error from the IS(122) to the TM. The estimated error in the TM calibration is discussed in a later section.

The measured dynamic range, minimum saturation level (MSL), and maximum radiances for each detector were presented in Tables 1 through 13. They are computed from the inverted calibration curve $L = (Q - O)/G$ at digital count values of zero, 243, and 255. The MSL radiance is computed at 95 percent of full scale. This level was chosen by Santa Barbara Research Center (SBRC) as a measure of both full-scale SNR and dynamic range and allowed for possible errors in the calibration as well as in setting the detector gain. The measured dynamic range of the TM is summarized in Table 18 for the full-scale values. The table gives the average MSL radiance, its standard deviation, and the minimum MSL radiance, which is computed as follows:

$$RMIN_i = \text{Minimum } (RMSL}_{ij}$$

where $RMIN_i$ is the minimum MSL in band i and $RMSL_{ij}$ are the MSL radiances for all j detectors in band i . For example, the $RMIN$ value for band 1 occurs in detector 3 (see Table 2). (Similar values are given in Table 14 for the lowest maximum observable radiance and the highest minimum observable radiance in each band.) The minimum MSL values given in Table 18 have also been compared to the specified dynamic range for each TM band. Each band saturates at a higher level than specified, up to 15 percent for band 3. The within-band variability of the measured dynamic range is about 1 percent. Although this would lead to minimal stripping in a TM scene, it should be compared to the specified relative accuracy level of one digital count. The range of variability by bands is from 1.3 to 3.0 digital counts.

Signal-to-Noise Determination

The SNR ratio for each detector was calculated at two standard radiance levels for each test. First, the mean (signal)

Table. 18

**AVERAGE DYNAMIC RANGE OF THE TM FROM COMPUTED
RADIANCE LEVELS**

NOTES:

MSL IS MINIMUM SATURATION LEVEL SPECTRAL RADIANCE ($\text{mWcm}^{-2} \text{sr}^{-1} \mu\text{m}^{-1}$)

COMPARING OBSERVED MSL WITH SPECIFICATION

1. SATURATES AT A HIGHER LEVEL (UP TO 15%) THAN SPECIFICATION.
2. WITHIN-BAND VARIABILITY IS ABOUT 1%.

and standard deviation (noise) for each detector were calculated from a large number of scans at each standard source radiance level. The resulting SNR values at each radiance level were then fit by a linear function of spectral radiance. Finally, the fitted straight lines were evaluated at two reference levels, and the high and low SNRs shown in Tables 1 through 7 resulted. Only three channels do not meet the specifications: 5/3 (dead), 2/4 (slow response), and 2/2 (noisy). When band 2/channel 2 data were examined, it was noticed that the SNR-versus-radiance curve showed a pronounced trend typical of a Schott-noise square root curve (Osgood and Lansing, 1981). Detector 2/4 does not show a significant problem until rapidly changing intensities are presented to it. Thus, the gain/offset determinations from the largely static IS(122) radiance levels show no appreciable difference when compared to other detectors in band 2. The 2/4 detector does, however, have a much slower response time to changing radiance values, particularly those characteristic of the TM internal calibrator (IC) light pulse. Under these conditions, the detector is sluggish but still useful.

CALIBRATION OF THE IC

The purpose of the calibration transference was to determine the radiance value for each detector in each band for each IC lamp configuration. As the TM was viewing the eight radiance levels provided by the IC lamps, its output was monitored. By the procedure outlined in Barker et al. (1983a,b), an average integrated calibration pulse value in digital counts was determined for each lamp configuration for each detector. These values were then converted to spectral radiance using calibration coefficients (gains and offsets) determined during the absolute calibration test with the IS(122). The IC data are nominally taken between the two radiance level series that make up the IS(122) test (Barker et al., 1983a), with the IC automatic sequencer on and the lamps operating in normal mode. Some data have also been collected for the backup mode of IC operation. Because the data collection for the calibration transference is a part of the calibration of the TM with the IS(122), this test is always performed in an ambient environment, not in a vacuum test chamber; the IS(122) is too big to fit inside a vacuum chamber. To obtain data taken during in-orbit-like conditions (in vacuum), it is necessary to transfer the results to a set of data taken in these conditions and as close in time and instrument operating conditions to the absolute calibration test as may be feasible; even so, differences due to so-called vacuum shift may still be noted. Several tests have been performed to transfer the IS(122) calibration of the TM detectors to the IC and are listed in Table 19. Three additional sets of IC data taken in vacuum

Table 19

^aTEST NUMBER 7 IS THE REFERENCE TEST.

^bTESTS 8, 9, AND 10 ARE DATA SETS OBTAINED IN VACUUM AND HAVE BEEN INCLUDED FOR COMPARISON.

361-BA/ABI(49)
 JLB/DB2/83

chamber tests have been included. Some comments on these tests are in order.

First, although any set of IC data may potentially be used to establish the calibration transference, data collected as close in time and environmental conditions to the TM detector absolute calibration as possible are to be preferred to minimize effects of environmental changes on the transfer. Although the March 1982 test (test 7 in Table 19) was performed 1 day after the three IS(122) calibrations (tests C), this test has been selected as the reference for intercomparison of transfer test results as well as for postlaunch operations. This is because it is closest to the date of launch, a large volume of IS(122) data is available, and continuity of absolute calibration of the CFPA detectors with postlaunch operational activities exists.

Second, four data sets have been included for comparison purposes: the November 1981 test, which lacks CFPA detector data, and three sets taken from vacuum chamber testing. Tests 9 and 10 were special tests performed in vacuum at General Electric and designed to mimic expected in-orbit operational conditions (E. Beyer, General Electric, private communication, 1982).

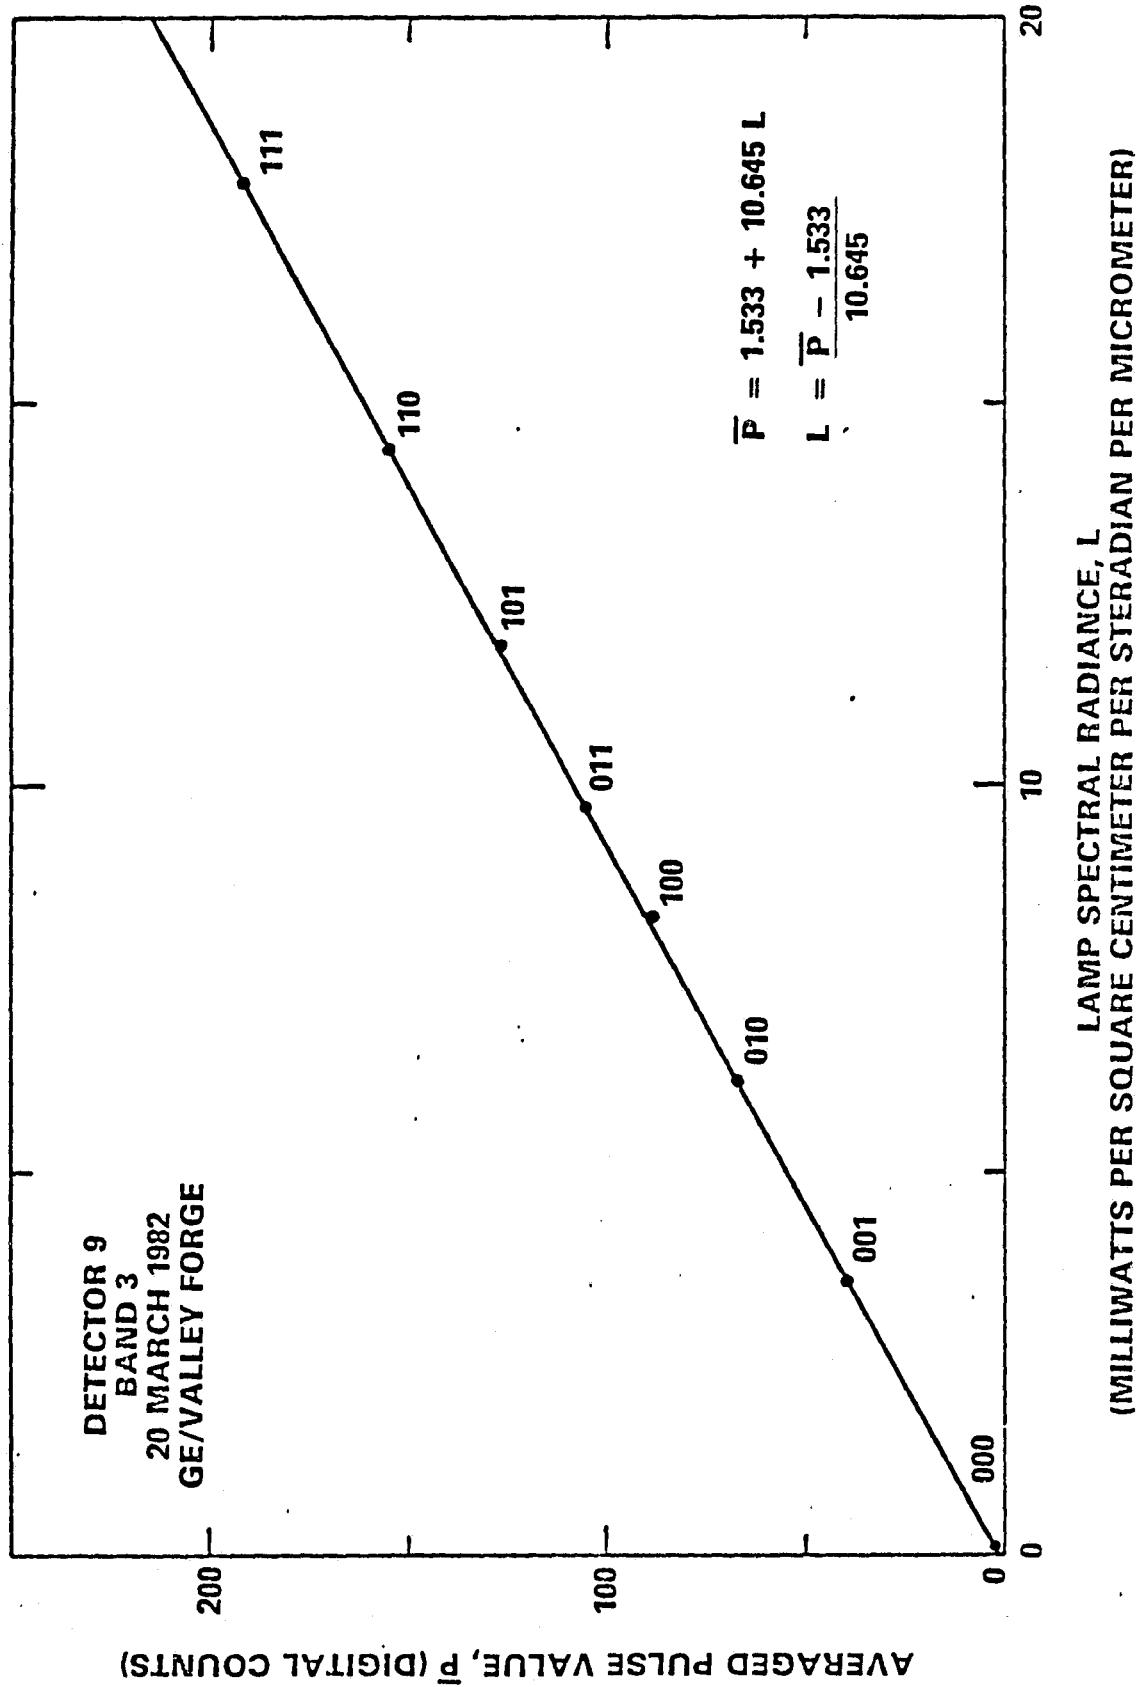

Third, there are only two tests for the backup mode of IC operation; none was performed during the March 1982 test series. If the backup mode is to be used during postlaunch operations, a set of transference data for the backup mode will have to be constructed from other sources. Internal lamp self-consistency problems have been noted with these data sets taken in backup mode.

The results of the calibration transference for test 7 of Table 19, which was selected as the reference transference data set for the TM, are presented in the appendix along with the results of test 9. For each IC lamp configuration and each detector, the averaged observed digital count output obtained with the Hughes pulse integration scheme and the corresponding spectral radiance are given. The spectral radiances were computed using the observed digital counts and gains and offsets given in Tables 2 through 7 for tests 7 and 9. An illustrative plot of average calibration pulse value against lamp radiance is shown in Figure 3 for the reference test (test 7).

To evaluate the repeatability of the calibration transfer from the IS(122) to the IC lamps, a straight-line, least-squares fit was performed for each detector using all eight IC lamp levels between a given test and the reference test. An example of one such comparison is shown in Figure 4. The

361-BA/AB(97)83
JLB/D82/83

fit was computed two ways, one using radiance value comparisons and one with digital counts. The result of these comparisons is given in detail elsewhere (Barker et al., 1983d) and will only be briefly summarized here. For each test comparison, a slope and intercept and their respective standard deviations and a figure of merit for the overall fit were computed by the method of least squares for each detector. For the data shown in Figure 4, the results are summarized in Table 20. The figure of merit used is the standard error of the estimate. For either radiance or digital count comparison, the figure of merit is less than 0.45 percent of full-scale IC lamp output (lamp configuration III). These values are typical, not best estimates.

To evaluate the error involved in the transfer of the absolute calibration to the IC, the error in the calibration of the detectors must be determined, as shown in Table 17. Because the detectors are calibrated first and the calibration is then transferred to the IC, this error is twice that given in Table 17. Thus, the error in the transfer is typically 1 to 2 percent, depending on the band. This estimate is included in the error propagation analysis discussed in the next section.

ESTIMATED ERRORS IN THE TM/PF CALIBRATION

It was noted in Barker et al. (1983a) that the IS(122) is calibrated against a secondary standard that is related to standards set by the National Bureau of Standards (NBS). The overall sequence of calibrations is shown in Figure 5. Each standard lamp has a rated lifetime during which its output will not change. For example, the Optronics Laboratories, Inc., standard (NBS) used by SERC has a rating of 50 hours of use with the calibration holding to within 1 percent for that period. The IS(122) is used for long periods of time in calibrating the TM and, if the sphere were calibrated directly against the SBRC standard, the standard calibration would quickly degrade. Thus, the SBRC standard is used to calibrate secondary standards similar in design and characteristics to the SBRC standard (for example, see Campbell, 1980 and Walker, 1982c). In Figure 5, the lamp filament symbol labeled "PRI" on the upper left represents an Optronics standard quartz-halogen 1000-watt lamp that has been calibrated against an NBS standard lamp. The vendor-stated uncertainty in the transfer of calibration from the NBS lamp to the Optronics standard (SBRC lamp S466) is 1.3 percent at a wavelength of 450 nanometers, 0.9 percent at 1600 nanometers, and 3.1 percent for 1600 to 2500 nanometers. These errors are mainly due to uncertainty

in the NBS scale of irradiance. The cumulative root sum of square error at each step in the calibration is then given by

$$\sigma_{\text{cum}} = \left(\sigma_{\text{cal}}^2 + \sigma_{\text{trans}}^2 \right)^{1/2}$$

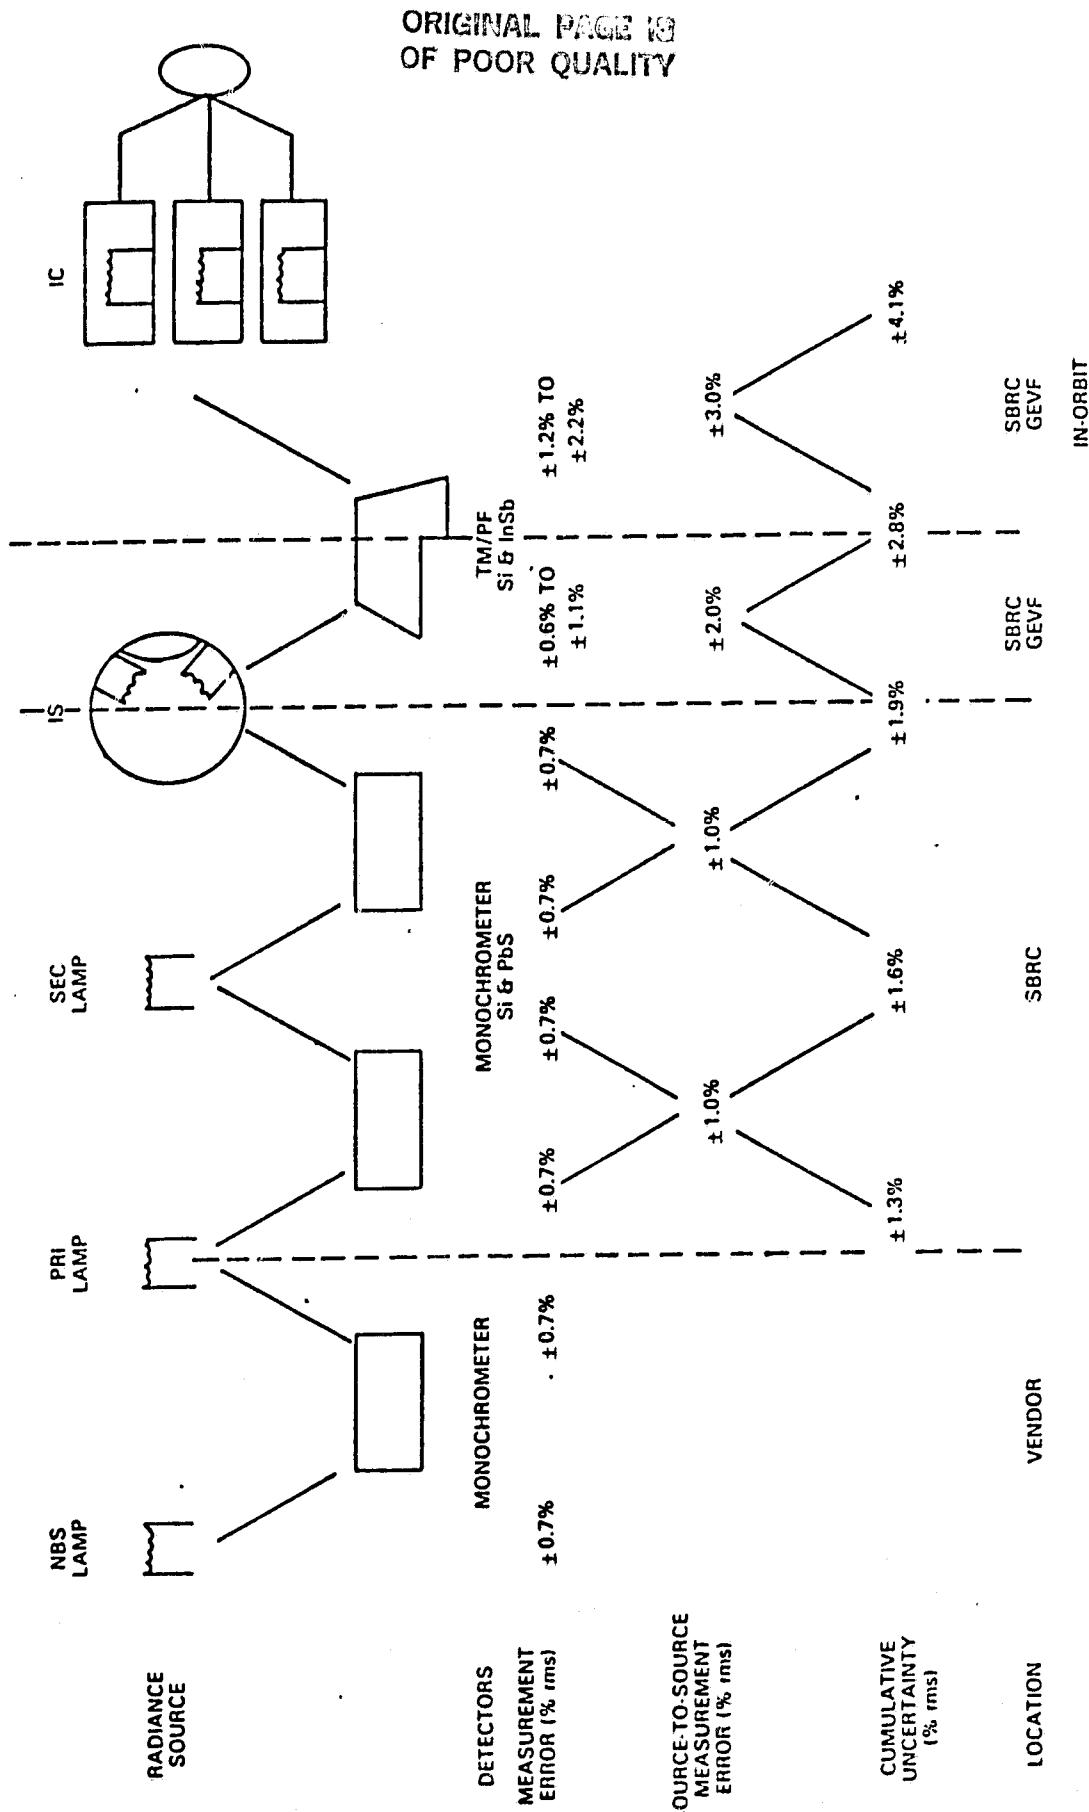

where σ_{cum} is the cumulative standard error, σ_{cal} is the source calibration error at the previous step, and σ_{trans} is the transfer error or source-to-source measurement error. Thus, at 450 nanometers, the known error in the calibration of the IS(122) is 1.9 percent. The IS(122) must be recalibrated periodically to ensure that the output of the sphere has not changed significantly due to lamp aging or spectral changes in the surface of the sphere. For example, study of data from June 1980, February 1982, and May 1982 (Walker, 1982b) has shown a decreased output from the IS(122) in the blue wavelengths. The overall change is a net decrease by 2 to 4 percent for the brighter radiance levels.

The transfer error associated with the spectral calibration of the IS(122) by the secondary standards has been specified to be less than or equal to 2.0 percent. This error is the standard deviation obtained when comparing spectral radiance values at 50-nanometer intervals between 450 and 2500 nanometers for two separate measurements at each lamp level setting. Values are typically between 1 and 2 percent. These are higher than those for the transfer from the standard lamp S466 to the secondary standards, primarily because the signal levels differ more in the IS(122) calibration. This standard deviation is an indicator of the consistency and precision of the IS(122) calibration. The absolute accuracy of the calibration is not so clearly defined. Campbell (1980) points out that two different measurement techniques used at SBRC gave results that differed by as much as 7 to 8 percent at some wavelengths; typical values are 2 to 3 percent. There is presently no known reason why either of the two methods should give results that are any more, or less, correct than the other. The method selected is the one that provides a higher signal level and, therefore, a better SNR. The other method provides a good SNR at certain wavelength and lamp level combinations, but still gives different results.

Thus, the precision of measurement of the transfer of the NBS calibration to the IS(122) calibration is typically 2 percent but depends on wavelength (5 percent in the infrared). Due to the differences noted above between methods of calibrating the IS(122) with the secondary standards and uncertainties in the NBS scale of irradiance, the absolute accuracy of the calibration of the IS(122) is no better than 5 percent. In Figure 5, the cumulative errors are given for

**ESTIMATED ABSOLUTE RADIOMETRIC CALIBRATION ACCURACY
FOR THE LANDSAT THEMATIC MAPPER SENSOR**

Figure 5

a wavelength of 450 nanometers; these are typical values and are higher in the infrared and lower in the red. The precision of calibration of the TM with the IS(122) is 2.8 percent (at 450 nanometers). The absolute accuracy based on the above discussion is then no better than 5 percent, due to a typical difference of 2 to 3 percent between IS(122) calibration methods and to uncertainties in the NBS scale of irradiance. The transfer of the detector calibration to the IC is then no better than 6 percent.

To summarize, the absolute calibration of the TM reflective band detectors is affected by

- Uncertainty in the NBS irradiance scale (typically 1.2 percent)
- Transfer errors between lamp standards (typically 1.0 percent)
- Differences between methods used to calibrate the IS(122) with a secondary standard (typically 2 to 3 percent)
- Changes in IS(122) lamps and interior surface between calibrations of the IS(122) with the secondary standard (2 to 4 percent between June 1980 and May 1982)

In Figure 5, the cumulative percent error given for the calibration of the protoflight (PF) TM and the IC are for the March TM calibration and the May IS calibration. Due to other uncertainties mentioned earlier, these are lower than the estimated absolute accuracy quoted.

DISCUSSION OF RESULTS

RADIOMETRIC PERFORMANCE REQUIREMENTS

The prelaunch radiometric calibration procedures are designed to ensure that the TM meets its performance requirements. The radiometric specifications can be divided into three groups: dynamic range, sensitivity, and accuracy. The requirements are listed in Table 21.

The TM is designed for land observations; the reflective bands are therefore designed for maximum dynamic range for the expected land radiance levels (Fraser, 1975; Duck, 1977). This range can be tested using a well-calibrated external source. The radiometric sensitivity is expressed in terms of SNR for reflective bands. The relative accuracy requirements are quite stringent: about 1 quantum level for

between-detector accuracy and 2 percent for between-band accuracy. The overall absolute accuracy specified for the TM is 10 percent.

While in orbit, the TM must rely on its IC to convert individual channel voltages into correct scene radiance values and to monitor the health of the individual detectors, because there are no provisions for performing an external calibration with the Sun or other extraterrestrial body. It is thus very important that the prelaunch absolute calibration of the detectors be accurately transferred to the IC lamps. The absolute accuracy actually attained during the calibration of the TM was stated earlier to be no better than 5 percent for the detectors and 6 percent for the IC. This requirement has thus been met. The relative band-to-band accuracy of the IC is discussed in Barker et al. (1983b).

CALIBRATION OF THE DETECTORS

Gain and Offset Variability

Long-Term Gain Stability

The long-term stability of TM radiometry is quite good. Measurements of its absolute calibration over 9 months (from June 1981 to March 1982) showed that the variations are between 3 and 5 percent (Table 16), well within the required 10-percent accuracy. Variability of individual channels is also within specification.

The within-band variability is quite good. Table 22 summarizes the within-band standard deviations of all the tests. While the band-averaged gain values change by 3 to 5 percent, there is no appreciable change in the within-band spread of individual channel gain values. This indicates that the observed absolute calibration variations are due to changes affecting the whole system, and that the relative accuracy within a single TM band has not deteriorated. The small within-band variability implies that there will be very little striping in an image, even if no calibration by the IC is performed.

Short-Term Reproducibility of Channel Gain

The short-term reproducibility can be established by repeated measurements. The three sets of tests performed in March 1982 were used to obtain an estimate. Although they were different because of mirror scanning mode and IC sequencing mode, they were still the best and most complete set of repeated measurements available. Table 23 shows the

JLB/DB2/83

mean and standard deviations for the three band-averaged gain values. The short-term reproducibility is excellent, indicating the TM to be a very good instrument. However, noticing the small standard deviations of all the band-averaged gain values, it is obvious that the short-term reproducibility of individual channels is also very good. As an example, Table 24 shows the short-term reproducibility of channel 16. This channel was selected because of the somewhat large coherent noise component observed (Barker et al., 1983b). The reproducibility is good. Good within-band variability and stable short-term performance guarantee that the raw image of the TM will show little stripping and that neighboring scenes will show similar radiance levels. Post-launch observations lead to similar conclusions (Barker et al., 1983b).

Offset Stability

The value of individual channel offsets is closely tied to the corresponding gain value. They are obtained through a least-squares linear fit to the IS(122) radiance measurements. Because of this, change in gain and offset values cannot be totally separated. However, some interesting conclusions can still be drawn:

- Channel 1 offset values for all reflective bands are high. Table 25 gives a comparison of the channel 1 offset and the mean offset for the same band. In most cases, these channel 1 values are the largest positive numbers for that band. No corresponding trend in the gain values is observed.
- There was a very strong odd-even effect for the cooled focal plane bands for test A. After the assembly was repaired, this effect disappeared.
- The offset values for all channels within a single TM band are close to one another. From Table 25, it can be seen that the standard deviations for all bands for both tests A1 and C2 are small, on the order of 0.25 digital count. These numbers can be further reduced if channel 1 is removed from the computation of the mean. This improvement will not affect the data analysis, because the offset values are treated individually in the radiometric correction algorithm. The smallness of the standard deviations does, however, indicate that the channels are well balanced within a band.
- The offset values are quite stable for all the absolute calibration tests. Table 26 shows the mean offset values for all bands and all tests. All mean offset values are positive.

JLB/D62/83

Signal-to-Noise Ratio

The computed SNRs for all bands for test C2 are presented in Tables 2 through 7. All but five detectors satisfied the specifications by significant amounts; two of the five passed, but barely (1/4 and 7/7). Channel 3 of band 5 is dead, and channels 2 and 4 of band 2 are bad, one due to noise (2/2) and the other due to slow response (2/4). The 5/3 detector is the only one for which no usable data are obtainable, and this should be treated as dead in the post-launch data processing. Most TM detectors satisfied the specifications although the error in the computed SNR values is somewhat high (typically 4 to 5 for all bands) due to the large scatter.

Dynamic Range

Table 18 gives the ratio of the specified to the average MSL radiance by band, the minimum observed MSL radiance, and the ratio of the standard deviation of the average to the average value. All detectors are within 1 percent of the average, except in band 4 (1.2 percent). The larger standard deviation there is due largely to detector 10, which is an outlier and is less sensitive than the other band 4 detectors. All bands have somewhat poorer dynamic range than specified; band 3 is the worst case, with band 1 next. Bands 2, 4, 5, and 7 are only slightly different from the required values. Whether this will adversely affect TM image data for these bands is not presently known.

A stated requirement for the archived radiometrically corrected data produced by the Landsat-4 Scrounge data processing system for the TM has been that the original raw data must be retrievable. To guarantee this, the radiometric lookup tables used to generate the corrected data should expand or leave the same any raw digital count value. For example, if the original value is 100, the specified dynamic range for the corrected data may give a value slightly greater than 100 by some fraction. The minimum saturation level radiance given in Table 21 for each band is thus appropriate for this requirement because the TM gains have already been set to give a saturation value 5 percent higher than the MSL. However, the postlaunch performance of the TM must also be considered. Data presented in Barker et al. (1983b) show that the gains determined with IC data have shown an exponential-like decline for bands 1 through 4 and have stabilized at approximately 3 to 6 percent below pre-launch values presented here. Bands 5 and 7, however, have shown an oscillatory behavior. Band 7 seems to show no change overall, except for the 2-month oscillation. Band 5 has shown an increase after launch and then the oscillation

and possibly some decrease. The largest change was an increase of 8 percent in band 5. If we recommended using the prelaunch MSL radiances as the upper limit to the dynamic range for the data processing corrections, we would risk loss of some image data in bands 5 and 7. Hence, for bands 5 and 7, we recommend using radiance values 10 percent lower than the maximum possible values for RMAX. Table 27 gives the upper and lower radiance limits for each band that we recommend for use in the postlaunch data processing systems.

CALIBRATION OF THE IC

The two most important parameters derived from these test comparisons are the slope, which measures the relative change between tests, and the standard error of the estimates, which is a measure of the goodness of fit. The major contributor to the latter is noise due to the IC pulse integration and averaging procedure.

To determine to what extent the IC lamp levels may vary due to differences in environment or operating conditions, other IC lamp data are presently being studied. The standard deviation of the average calibration pulse for a lamp state is typically 0.5 digital count. The average difference between forward and reverse mirror sweep scans is typically 0.5 digital count; both values are band dependent. The forward-reverse differences are uncorrected for dark background. These problems are related to overall IC stability under a variety of operating and environmental conditions and are discussed in more detail by Barker et al. (1983b). Present estimates of repeatability with the transfer data indicate that the IC gives calibration radiances repeatable to the 5-percent level or better, except for band 5; band 5 is better than 7 percent. Table 28 shows figure-of-merit values for the comparisons between transfer tests 1 and 7 and between tests 9 and 7. The latter is a comparison of ambient to vacuum calibration transfer. Table 29 shows results for the derived slope for the same test comparisons. Differences noted particularly in band 5 may be attributed to slight differences in operating conditions. The other bands typically show changes of 5 percent or less. The differences between tests 1 and 7 for bands 5 and 7 should be ignored due to changes made in the CFPA in September 1981; these changes introduced a discontinuity between previous calibrations and those performed in March 1982.

Typically, the radiance comparisons between tests have shown more variability than the digital count comparisons (see Table 20). This may be understood by noting that there are slight differences in environment or operating conditions

between the different transfer tests that have not been accounted for. In particular, Clemann et al. (1982) has noted a linear correlation between various temperature parameters, particularly the calibration shutter flag temperature, and the digital output of the TM. Thus, the sensitivity of the TM (gain and offset) changes slightly with these internal temperatures; we are presently studying these effects with these and other TM IC data to firmly establish the correlation and the overall degree of stability of the IC (Barker et al., 1983d). Even so, the results of the transfer test comparisons show good repeatability (5 percent or better for all bands except band 5) without including operational differences; when they are included in the analysis, we can expect to see a significant improvement. The results for tests 1, 3, and 4 that were taken during the June 1981 absolute calibration show that the above considerations are valid. The variation in slope values among these three tests is less than 0.7 percent in all bands.

RECOMMENDATIONS

Our study of the prelaunch absolute radiometric calibration of the protoflight TM reflective bands has shown several areas where improvements in the calibration can be realized, particularly when applied to the flight unit TM. Accordingly, we have separated our recommendations into two categories: protoflight and flight.

PROTOFLIGHT TM

The best calibration of the protoflight TM reflective bands prior to launch was performed in March 1982. The test designated C2 in this paper is to be preferred due to the operating configuration and the state of calibration of the IS(122) afterwards. Tables 1 through 13 summarize the important parameters for this test for all detectors. Additional evaluation of the TM absolute detector calibration is still in progress and is concentrating on the areas of temperature dependence and the effect of nonuniform analog-to-digital conversions on the calibration of the TM. In addition, the raw data from the IS(122) calibration is being examined to ensure that the peak output of the IS(122) was seen by all TM detectors and to evaluate the impact of a non-flat (IS(122) output (if any) on the detector calibration. We are also evaluating the feasibility of recollecting prelaunch calibration data to study the effect of a drifting background (DC restore of offset voltage to a nominal reference corresponding to 2 or 3 digital counts) during an image scan. In-orbit data are also being obtained to study this effect.

The calibrations of the IC that best characterize the transfer from the IS(122) to the IC are the March 20 transfer (test 7 in this paper) for determining the ambient characteristics of the IC and the March 9 transfer (test 9 in this paper) for referencing the vacuum characteristics and transferring the calibration from ambient to vacuum (by comparison with test 7). The use of these data sets as a reference for in-orbit data is discussed in Barker et al. (1983c). Additional studies of protoflight TM data, both prelaunch and in-orbit, to study temperature dependencies of the IC (particularly due to the calibration shutter flag) are needed. (See Cleemann et al., 1982). The dependence of the IC calibration on such parameters as the number of minor frames centered on the pulse to average, number of scans to average, etc., are discussed in Barker et al. (1983b).

FLIGHT UNIT TM

Recommendations for the calibration of the flight unit TM have been developed through experience with the protoflight calibration and application of the calibration while radiometrically correcting in-orbit protoflight data. Changes to the calibration procedures and to the type and quantity of data collected should be made as follows:

- Cross-calibration of all Landsat integrating spheres (one for TM and two for MSS) directly at NBS rather than more than one step (lamp source) removed from NBS as is presently the case; include the thermal band in the calibration if possible
- Operation of the IS(122) in scanning mode for all tests (already done; see Lansing 1981) and, increase the size of the video data window collected in each scan
- Use of multiple IC data collects during sphere calibration to improve statistics of the calibration transfer to the IC and to allow for correction of temperature dependencies
- Use of a linear ramp for system-level measurement of analog-to-digital conversion and inclusion of these measurements in the IS(122) calibration
- Calibration of a lamp source small enough to use during thermal vacuum chamber testing to measure change in TM detectors and IC due to so-called "vacuum shift" (compared to the ambient IS(122) calibration)
- Collection and study of sufficient background data to characterize changes in reference level during an image scan

APPENDIX - SPECTRAL RADIANCES FOR THE IC

The averaged digital counts and their corresponding spectral radiance values for each lamp configuration of the TM IC calibration transfer are given in the following tables. Two reference sets are given, March 20, 1982 (test 7 in Table 22) and March 9, 1982 (test 9), representative of ambient and vacuum conditions, respectively. Tables A-1 through A-16 pertain to test 7, Tables A-17 through A-32 pertain to test 9. Tables A-1 through A-8 and A-17 through A-24 give the averaged digital counts, Q, determined by the Hughes averaging procedure (Barker et al., 1983b) for the eight lamp configurations (100, 110, 010, 011, 111, 101, 001, and 000, where 1 indicates lamp on, and 0, lamp off). Using the gains and offsets for each detector given in Tables 2 through 7. The corresponding radiance values are computed as follows:

$$L = \frac{\bar{Q} - O}{G}$$

where L is the resulting radiance, \bar{Q} is the averaged digital count, G the gain, and O is the offset. These values are presented in Tables A-9 through A-16 and A-25 through A-32. Each table gives mean values (MEAN), standard deviations (SDEV), standard deviations of the mean (SMEN), and coefficients of variation (CVAR) for odd-numbered, even-numbered, and all detectors in a band. Values for detector 4, band 2, are not given in Tables A-1 through A-16 because the Hughes computer program treated it as a dead detector (like band 5, channel 3). Values for this detector are presented in the other tables, derived directly from raw data taken in thermal vacuum testing.

Finally, Tables A-33 through A-40 give the ratio of digital counts for test 7 to test 9 for all eight lamp configurations. These tables are presented to aid in evaluating the so-called "vacuum shift" generally noted in the response of a satellite sensor between ambient and vacuum operating conditions. The mean values and standard deviations given have the same meaning as before (e.g., Tables A-1 through A-8).
