#### Abstract

The Yukon River sonar project has provided daily passage estimates for Chinook salmon Oncorhynchus tshawytscha, chum salmon $O$. keta, and coho salmon $O$. kisutch for most years since 1986. Fish passage estimates for each species were generated in 2006 through a 2-component process: (1) estimation of total fish passage with 120 kHz split-beam sonar and a Dual Frequency Identification Sonar (DIDSON ${ }^{1}$ ), and (2) apportionment to species by sampling with a suite of gillnets of various mesh sizes. An estimated 5,850,452 fish passed through the sonar sampling area between June 5 and August $31 ; 22.5 \%$ along the right bank and $77.5 \%$ (season average) along the left bank. Included were $145,553 \pm 21,148$ large Chinook salmon ( $>655 \mathrm{~mm}$ METF); $23,850 \pm 5,480$ small Chinook salmon ( $\leq 655 \mathrm{~mm}$ METF); $3,767,044 \pm 159,234$ summer chum salmon; and $790,563 \pm 62,715$ fall chum salmon.

Key words: Yukon River, Chinook salmon, chum salmon, hydroacoustic, riverine, sonar, abundance estimate, species apportionment, net selectivity, split-beam, DIDSON.

## INTRODUCTION

## BACKGROUND

Within Alaska, 3 species of Pacific salmon (Chinook salmon Oncorhynchus tshawytscha, coho salmon $O$. kisutch, and chum salmon $O$. keta) are managed inseason for harvest by commercial, sport, and subsistence fisheries over $2,200 \mathrm{~km}$ of the Yukon River, as well as to meet treaty commitments made under the U.S. / Canada Yukon River Salmon Agreement. The diversity and number of fish stocks, combined with the geographic range of user groups, adds complexity to management decisions. Escapement estimates and run-strength indices are generated by various projects along the river, providing stock-specific abundance and timing information, however, much of this information is obtained after the fish have become unavailable to the fisheries. Timely indices of run strength are provided by gillnet test fisheries conducted in the lower Yukon River, but the functional relationship between catch per unit effort (CPUE) and actual abundance is confounded by varying migration patterns through the multi-channel environment, gear selectivity, and changes in net site characteristics.

The Yukon River sonar project has provided daily salmon passage estimates, run timing and biological information to fisheries managers for most years since 1986. The estimates from this project complement information obtained from other sources. Located in a single-channel environment at river km 197 near Pilot Station, the project is far enough upriver to avoid the wide, multiple channels of the Yukon River Delta. Because salmon migrate from the river mouth to the sonar site in 2 to 3 days, the project provides timely abundance information to managers of downstream fisheries (Figure 1). The Andreafsky River is the only major salmon spawning tributary downstream of the sonar site (Figure 2), therefore the majority of migrating salmon in the Yukon River pass the sonar project on their way to the spawning grounds.

Alaska Department of Fish and Game's (ADF\&G) primary role is to manage for sustained yield under Article VIII of the Alaska Constitution, but Alaska is also obligated to manage Yukon River salmon stocks according to precautionary, abundance-based harvest-sharing principals set forth in the Yukon River Salmon Agreement. The goal of bi-national, coordinated management of Chinook salmon and chum salmon stocks is to meet escapement requirements that will ensure sufficient fish availability for sustained harvests in both the United States and Canada.

[^0]Furthermore, managers follow management plans specified in state regulations for Yukon River Chinook, summer chum, fall chum, and coho salmon. Accurate daily salmon abundance estimates not only help managers adjust harvest in season for harvest and escapement objectives, they are also used postseason to determine whether treaty obligations were met and to judge effects of management actions.

The project uses a combination of fixed-location split-beam sonar and Dual Frequency Identification Sonar (DIDSON) to estimate the daily upstream passage of fish. A series of gillnets with different mesh sizes are drifted through the acoustic sampling areas to apportion the passage estimates to species. Species apportionment methodology continues to be refined. In 2004 the selectivity curves for salmon species were updated in an attempt to more accurately estimate abundance and proportions (Bromaghin 2004).

Locations in this report are referenced by the proximate bank of the Yukon River, relative to a downstream perspective. At the sonar site the left bank is south of the right bank. Both the City of Pilot Station and the ADF\&G sonar camp are located on the right bank.

The Yukon River, at the sonar site, is approximately 1000 m wide between the left and right bank transducers (Figure 3). The left bank substrate, composed of silt and fine sand, drops off gradually at a vertical angle of approximately $2^{\circ}$ to $4^{\circ}$. The right bank has a stable, rocky bottom that drops off uniformly to the thalweg at a vertical angle of approximately $10^{\circ}$. The thalweg is approximately 25 m deep and is located approximately 200 m offshore of the right bank. Water velocity, as measured with acoustic doppler profiling, ranges up to $2 \mathrm{~m} / \mathrm{sec}$ in offshore portions of the water column. Streamflow typically peaks shortly after the ice goes out at breakup in late May and early June, and then generally declines throughout the summer and fall (Figure 4). River height, as observed from 2001 to 2005 at the United States Geological Survey (USGS) gage station located downstream of the project, ranged from a maximum of 27.4 ft to a minimum of 14.3 ft during the months of June, July, and August (Figure 5).

Prior to 1993, ADF\&G used dual-beam sonar equipment that operated at 420 kHz . In 1993, ADF\&G changed the existing sonar equipment to operate at a frequency of 120 kHz to allow greater ensonification range and to minimize signal loss. The newly configured equipment's performance was verified using standard acoustic targets in the field in 1993. Use of lower frequency equipment increased fish detection at long range.

Up until 1995, ADF\&G attempted to identify direction of travel of detected targets by aiming the acoustic beam at an upstream or downstream angle relative to fish travel. This technique was discontinued in 1995. Significant enhancements that year included implementation of an aiming strategy designed to consistently maximize fish detection. Because of this and subsequent changes in counting methodology, data collected from 1995 to 2006 are not directly comparable to previous years. In 2001 the equipment was changed from the dual-beam to the current splitbeam sonar system. This technology allows better testing of assumptions about direction of travel and vertical distribution.

In 2004, the selectivity model used in species apportionment was refined through biometric review and analysis of historical catch data from the project test fishery. The model providing the best overall fit to the data was a Pearson model with a tangle parameter. Species proportions and passage estimates reported here were generated with this apportionment model, and are
comparable with estimates from 1995 to the present, as historical estimates have been regenerated using the most current model and methodology (Hamazaki ${ }^{2}$; Bromaghin 2004).

Early in the 2005 season, the Yukon River experienced high water levels and erosion in the bottom profile that, along with a combination of changes in fish movement and distribution, affected detection of fish with the split beam sonar within 20 m of shore on the left bank. On June 19, 2005 a DIDSON imaging sonar was deployed in this area to verify nearshore fish detection. With its wider beam angle, the DIDSON system was able to detect fish passage within 20 m despite high water levels and problematic erosion nearshore, and was operated for the remainder of the season, supplanting split-beam counts in this section of nearshore region.

In 2006, the DIDSON was integrated into the sampling routine on the left bank for the whole season, operating side-by-side with the split-beam sonar. The DIDSON sampled the first 20 m of the nearshore stratum; the remainder of the 250 m range was sampled by the split-beam.

## Goals and ObJECTIVES

The primary goal of this project is to accurately estimate daily fish passage, by species, during upstream migration past the sonar site. Project objectives were to:

1. Provide managers with timely estimates, and associated confidence intervals, of daily and seasonal passage of adult Chinook, chum and coho salmon;
2. Collect biological data from all fish captured in the test-fishery, including species, sex, length, and scales as appropriate;
3. Assist in the collection of Chinook and chum salmon tissue samples for separate genetic stock identification projects; and
4. Collect hydrological data representative of the ensonified areas of the river.

## METHODS

Estimates of upstream migration of targeted fish species are produced from a combination of independently generated estimates of fish movements past the sonar site using hydroacoustic equipment, and species proportions based upon the results of drift gillnetting in the same area (Figure 6).

## Hydroacoustic Data AcQuisition

## Equipment

Left bank sonar equipment included:

1. A Hydroacoustic Technology Inc (HTI) Model 244 echosounder configured to transmit and receive at 120 kHz , controlled via Digital Echo Processing (DEP) software installed on a laptop P.C.;
2. An HTI 120 kHz split-beam transducer with a $2.8^{\circ} \times 10^{\circ}$ nominal beam width;

[^1]3. Three 250 ft HTI split-beam transducer cables connecting the sounder to the transducer;
4. An HTI Model 405 digital chart recorder coupled with a Panasonic KXP 3624 dot matrix printer; and
5. A Hewlett-Packard (H.P.) Model 54501A digital storage oscilloscope.
6. A DIDSON-LR (Long Range) unit ( $12^{\circ} \times 29^{\circ}$ approximate beam dimension), configured to transmit and receive at 1.2 MHz , and controlled via software installed on a laptop PC; and
7. One 500 ft . DIDSON underwater cable connecting the DIDSON to the "topside breakout box" and laptop PC.
Right bank sonar equipment included:

1. An HTI Model 244 echosounder configured to operate at 120 kHz , controlled via DEP software installed on a laptop P.C.;
2. An HTI split-beam 120 kHz transducer with a $6^{\circ} \times 10^{\circ}$ nominal beam width;
3. Three 250 ft ( 228.6 m combined length) HTI split-beam cables connecting the sounder to the transducer; and
4. An HTI Model 405 digital chart recorder coupled with Panasonic KXP 3624 dot matrix printer.

Each system configuration of sounder, transducer, and cable was calibrated by the manufacturer prior to the field season. Transducers were mounted on metal tripods and remotely aimed with HTI model 662 H dual-axis rotators. Rotator movements were controlled with HTI model 660-2 rotator controllers with position feedback to the nearest $0.1^{\circ}$. Gasoline generators ( 3000 W ) supplied 120 VAC power. The split-beam sonar signal was processed by the digital chart recorders, printed to paper charts, and hand-marked. DIDSON data was saved onto the laptops and processed daily via electronic echograms.

## Equipment Settings, Thresholds, Data Storage

The split-beam echosounders used a $40 \log (\mathrm{R})$ time-varied gain (TVG) and 0.4 ms transmit pulse duration during all sampling activities (Table 1). The receiver bandwidth was automatically determined by the equipment based on the transmit pulse duration. Pulse repetition rates were set below the maximum allowed by range to avoid overloading printer buffers. On the left bank, the nearshore stratum pulse repetition rate was set to 5 pings per second ( pps ), the midshore stratum was set at 4 pps and the offshore stratum was set at 2.5 pps . The pulse repetition rate for the right bank nearshore was set at 5 pps and the offshore stratum was set at 4 pps .

For the split-beam system, echoes were digitized by chart recorders, and then printed on wide carriage, continuous-feed paper using dot matrix printers. Four printer thresholds, corresponding to degrees of gray-line, were set for all strata in approximately 3 dB increments. The lowest sampling threshold was set at -43 dB , approximately 13 dB lower than the theoretical on-axis target strength of a chum salmon of minimal length ( 450 mm ) calculated using Love's equation (Love 1977). Lowering the threshold by 15 dB allows for detection across the nominal beam width ( 6 dB ) and variability ( $\sim 7 \mathrm{~dB}$ ) induced by fish aspect and noise corruption. Transmit power was adjusted as necessary to compensate for environmentally induced signal loss. Threshold levels (in mV ) were recorded and converted to target strength, $T S_{d B}$, as follows:

$$
\begin{equation*}
T S_{d B}=20 \cdot \log \left(\frac{T_{m V}}{1000 m V}\right)-\left(S L+G_{S}+G_{R}\right) \tag{1}
\end{equation*}
$$

where $T_{m V}$ is the chart recorder threshold in $\mathrm{mV}, S L$ is the transmitted source level in $\mathrm{dB}, G_{S}$ is the through-system gain, and $G_{R}$ is the receiver gain.
The DIDSON (Table 2) operated at an average rate of 8 frames $/ \mathrm{s}$ with a starting range of 0.83 m and an end range of 20.84 m , in high-frequency mode ( 1.2 MHz ). Files were recorded onto the laptop and were processed using electronic echograms, where operators could change intensity and threshold to increase visibility of targets on screen.

## Aiming

The transducers were always positioned and aimed to maximize fish detection. With the transducer located in the area with the best bottom profile, the beam was oriented approximately perpendicular to the current so that migrating fish would present the largest possible reflective surface. Since many fish travel close to the substrate, the maximum response angle of the beam was oriented along the river bottom through as much of the range as possible.
Fluctuating water levels required repositioning of the transducers, and subsequent re-aiming of the beams. To establish an optimal aim, the transducer was panned horizontally upstream and downstream approximately $15^{\circ}$ off perpendicular in $2^{\circ}$ increments. At each increment, the vertical tilt was adjusted to obtain the best possible bottom picture. The left bank transducers were re-aimed more often to compensate for the dynamic bottom conditions on that side of the river. Once an optimal aim was obtained, the rotator settings were documented and chart printouts of the new aim were posted for visual reference. All operators were trained to first aim to established pan and tilt settings, then to refine that aim to match the substrate pattern on the current chart printout with those of reference chart samples.

## Sampling Procedures

Transducers were deployed on both the left bank and the right bank in an area where the river is approximately $1,000 \mathrm{~m}$ wide. The right bank transducer was positioned approximately 3 m from shore, and the aim was adjusted between 2 strata (S1: $0-50 \mathrm{~m}$ and S2: $50-150 \mathrm{~m}$ ). The left bank split-beam transducer was deployed approximately 5 m from the shoreline and utilized 3 distinct aims to sample a nearshore stratum ( $\mathrm{S} 3,0-50 \mathrm{~m}$ ), a midshore stratum ( $\mathrm{S} 4,50-150 \mathrm{~m}$ ), and an offshore stratum (S5, 150-250 m). The DIDSON unit was deployed next to the split-beam transducer (within 2 m ) and ensonified 2 sectors of the nearshore stratum ( $0-20 \mathrm{~m}$ ) (Figure 7). Because the DIDSON sonar's wider beam angle is ideal for the less linear nature of the eroded left bank nearshore, it is assumed that it will detect fish targets better than the split-beam which is narrower in the extreme nearshore. Therefore, when aiming the split-beam for the nearshore stratum from 0 to 50 m , when necessary for best detection, the aim is optimized for the 20 to 50 $m$ portion of the stratum, which is not ensonified by the DIDSON. In this way, the sonar systems are used in concert to maximize detection for the entire nearshore stratum on left bank. The counts from the 2 systems cannot directly be compared for the 0 to 20 m nearshore, since the aiming strategy optimizes fish detection for DIDSON but not the split-beam within this range.

Throughout the season, strata ranges were adjusted to provide an optimal fit to the bottom profile. The left bank transducers were occasionally relocated either upstream or downstream to compensate for the dynamic bottom profile. Transducers on each bank were repositioned either inshore or offshore as needed to compensate for changing water levels.
Acoustic sampling was conducted simultaneously on both banks during three 3-h periods each day (Table 3). Sample periods were scheduled from 0530 to 0830,1330 to 1630 , and 2130 to 0030 hours, alternating sequentially between strata every 30 minutes. Each sampling stratum was subdivided into 5 equal range sectors, with sonar counts tallied by sector in 15 -minute intervals during daily sampling periods. The DIDSON-generated sonar counts supplanted those of the split-beam for sectors 1 and 2 of the nearshore stratum (S3) if they were higher.
Operators counted fish traces on paper echograms for the split-beam system, and on electronic echograms for the DIDSON system. Echo traces were counted as a single fish if at least 2 pings in the cluster passed the second printer threshold level (see Equipment Settings, Thresholds, Data Storage) and the targets did not resemble inert downstream objects. Groups of fish were distinguishable when the apparent direction of movement of one fish trace differed from that of an adjacent trace.

Fish traces were tallied on field data forms and entered into an Access database. The data were checked daily for data entry or tallying errors, then processed in SAS using statistical routines developed by the regional Biometrician.
All personnel were trained to distinguish between fish tracings and non-target echoes. Chart printouts and echograms were reviewed daily by either the project leader or crew leader to monitor the accuracy of the marked fish tracings and reduce individual biases. Each chart image was checked for indications of signal loss and changes in bottom reverberation markings, which could indicate either movement of the transducer or a change in bottom structure.

## SYSTEM ANALYSES

Performance of the hydroacoustic system was routinely monitored following procedures first established in 1995 (Maxwell et al. 1997). System analyses included equipment performance checks, bottom profiles using down-looking sonar, and hydrologic measurements.

## Bottom Profiles

Bottom profiles were recorded along both banks using a Lowrance LCX15MT recording fathometer with GPS capabilities to locate deployment sites with suitable linear bottom profiles. All bottom profiles were recorded and stored electronically. Inseason, the fathometer was used regularly to monitor changing bottom conditions and to watch for the formation of sandbars capable of re-routing fish to unensonified areas.

## Hydrological Measurements

Water level was measured using a staff gage located slightly offshore on the right bank, near the field camp. To standardize measurements with observations from previous years, water level measurements were adjusted to the USGS Water Resources Division reference located approximately 500 m downstream of Pilot Station. The information collected from the staff gage was used inseason as a relative water height indicator, and to gather information as a backup for times when the USGS water data was unavailable.

## SPECIES APPORTIONMENT

## Equipment and Procedures

To estimate species composition, gillnets were drifted through 3 zones (right bank, left bank nearshore, and left bank offshore) corresponding to sonar sampling strata (Figure 7). A total of 8 different mesh sizes were fished throughout the season to effectively capture all size classes of fish present and detectable by the hydroacoustic equipment (Table 4). All nets were 25 fathoms $(45.7 \mathrm{~m})$ long and approximately 8 m deep. All nets were constructed of Momoi MTC-50 or MT50 , shade 11 , double knot multifilament nylon twine and hung "even" at a $2: 1$ ratio of web to corkline.

Testfishing was conducted twice daily between sonar periods, from 0900 to 1200 hours and 1700 to 2000 hours. During each sampling period, 4 different nets were drifted within each of 3 zones for a total of 24 drifts per day (Table 5). The order of drifts were 1) left bank nearshore zone, 2) right bank zone, and 3) left bank offshore zone, with a minimum of 20 minutes between drifts in the same zone. Each mesh size was fished in all 3 zones before switching to the next mesh size. The shoreward end of the left bank nearshore drift was held approximately 5 to 10 m from shore. The left bank offshore drift was approximately 65 m offshore so as not to overlap with the nearshore drift. Drifts were approximately 8 minutes in duration, but were shortened as necessary to avoid snags or to limit catches during times of high fish passage.
Captured fish were identified to species and measured to the nearest 1 mm length. Salmon species were measured from mid eye to fork of tail (MEFL); non-salmon species were measured from snout to fork of tail (FL). Fish species, length, and sex were recorded onto field data sheets. Each drift record included the date, sampling period, drift start and end times, mesh size, length of net, and captain's initials.
The probability of a fish of a given species and length being captured in a net is dependent on mesh size. To remove the effect of net selectivity, the Pearson T net selectivity model is used with coefficients generated for the following species: Chinook salmon; summer and fall chum salmon; coho salmon; pink salmon O. gorbuscha; cisco Coregonus sardinella, C. laurettae; Humpback whitefish C. pidschian; and Broad whitefish C. nasus. In addition, coefficients have also been generated for a group of other species containing: sheefish Stenodus leucichthys; burbot Lota lota; longnose sucker Catostomus catostomus; Dolly Varden Salvelinus malma; sockeye salmon O. nerka; and northern pike Esox lucius. A detailed description of the apportionment model and the derivation of net selectivity coefficients used (listed in Appendix A) can be found in Bromaghin 2004.

Scale samples were collected from Chinook salmon, mounted on scale cards, and scale and card numbers were recorded on the test-fishing data sheets. Data were transferred from data sheets into a database and processed using SAS software. Age-sex-length (ASL) data were processed, analyzed and reported by ADF\&G staff based in Anchorage (Bales 2008). Handling mortalities among the captured fish were distributed to the local community, with fish dispersal documented daily.
Genetic tissue samples from both Chinook and chum salmon were also collected for several other projects, in conjunction with the Yukon Sonar project testfishing. Age, sex and length data were cross-referenced with each tissue sample. The ADF\&G Gene Conservation Laboratory and
the USFWS Conservation Genetics Laboratory independently processed and analyzed these samples (Bromaghin and Wenburg In prep, Flannery et al. In prep).

Chinook salmon were classified as either 'large' (> 655 MEFL) or 'small' ( $\leq 655$ MEFL), with small Chinook salmon serving as a proxy for one-ocean 'jacks'. Although there is some temporal overlap between the summer and fall runs of chum salmon, for the purposes of estimating passage, all chum salmon encountered through July 18 were designated as summer chum and post July 18 were designated as fall chum.

## Analytical Methods

Daily estimates were produced from a multi-component process involving:
a) Hydroacoustic estimates of all fish targets passing the site, without regard to species.
b) Species composition derived from testfishing results and applied to the undifferentiated hydroacoustic estimates.
c) Traditional CPUE estimates, used as a separate index by the managers and calculated on a subset of the testfishing data.

## Sparse and Missing Data

Testfishing was not conducted during commercial fishery openings and occasionally, during periods of low salmon passage, catches were too sparse to accurately estimate species proportions and associated error bounds. When sufficient gillnet samples were not available for a given day and zone, the data were pooled with data from one or more adjacent days by assigning the same report unit $u$.

Traditional CPUE estimates were calculated on a daily basis irrespective of catch size. In contrast, sonar passage, species composition, and species passage estimates were first calculated on the basis of report units (encompassing one or more full days of sampling in a zone), and then apportioned to daily estimates. For any testfish variable $x$ the report unit $u$ encompasses day $d$, testfish period $p$, and zone $z$ such that:

$$
\begin{equation*}
x_{u}=\sum_{d, p, z}^{u} x_{d p z} \tag{2}
\end{equation*}
$$

The report unit was then also appended to the corresponding days and zones of sonar passage estimates. In effect, any unique combination of day and zone having sufficient testfish catch was also assigned a unique report unit $u$, while combinations not having sufficient catch were pooled by assigning the same report unit either across zones or days.

## Sonar Passage Estimates

Total fish passage was estimated separately for each of 3 zones. Zone 1 consisted of the entire counting range on the right bank, corresponding to strata 1 and 2 (approximately $0-150 \mathrm{~m}$ ). Zone 2 consisted of the counting range corresponding to stratum 3 (approximately $0-50 \mathrm{~m}$ on the left bank). Zone 3 consisted of the counting range corresponding to stratum 4 and stratum 5 (approximately $50-150 \mathrm{~m}$ and $150-250 \mathrm{~m}$ on the left bank, respectively).

Within zone 2, passage was simultaneously estimated in sectors 1 and 2 (representing approximately the first 20 m of stratum 3) using both the DIDSON and the HTI sonar. Although the DIDSON was the primary system used to generate estimates in those 2 sectors, the HTI system was also tallied since operating it in sectors 3,4 , and 5 also entailed operating in sectors 1 and 2 . The counts generated by the HTI in those 2 sectors essentially served as a backup to the DIDSON in the event of a system failure or a loss of data. Since the ranges of the 2 systems didn't always precisely overlap, a passage rate for the DIDSON (targets per meter-hour) was first calculated, and then expanded by the sector width and count time of the corresponding HTI sample to provide consistent width and count time for all sectors 1 through 5 . This was done primarily as a matter of calculation convenience.
First, for sectors 1 and 2 of stratum 3, the sector widths $w$ in meters were calculated for all samples $q$ on day $d$, period $p$ for both the DIDSON and HTI. The DIDSON unit counts over a single continuous range while the HTI subdivides this range into equal width sectors $(k) 1$ and 2 of stratum $(s) 3$. Sector widths for both systems are based on the start and end points of the range sampled, such that:

$$
\begin{equation*}
w_{d p s k q}=E n d_{d p s k q}-\text { Start }_{\text {dpskq }} \tag{3}
\end{equation*}
$$

The mean width of sectors 1 and 2 of the HTI:

$$
w_{H T I}=\frac{\sum \sum \sum_{d=3 q} w_{d p k q}}{n}
$$

and the width of the DIDSON:

$$
w_{D I D}=\frac{\sum w_{d p q}}{n}
$$

samples were calculated, where $n$ is the number of samples. The total hours $h$ sampled with the HTI system:

$$
\begin{equation*}
h_{H T I}=\sum_{q} h_{d p k q} \tag{6}
\end{equation*}
$$

and the DIDSON:

$$
\begin{equation*}
h_{D I D}=\sum_{q} h_{d p q} \tag{7}
\end{equation*}
$$

were summed, as were the total upstream counts $y$ :

$$
\begin{gather*}
y_{\text {HTI }}=\sum_{q} y_{d p k q}  \tag{8}\\
y_{D I D}=\sum_{q} y_{d p q}
\end{gather*}
$$

Passage rates $r$ were then calculated for both the DIDSON and the HTI systems:

$$
\begin{align*}
& r_{D I D}=\frac{y_{D I D}}{w_{D I D} \cdot h_{D I D}}  \tag{10}\\
& r_{H T I}=\frac{y_{H T I}}{w_{H T I} \cdot h_{H T I}} . \tag{11}
\end{align*}
$$

Due to better detection capabilities at close range, and the aiming protocol described above, it was typical that the DIDSON passage rate would exceed the HTI passage rate in both sectors 1 and 2. In this case a passage estimate was generated for the time sampled by expanding the DIDSON using the HTI sector width and hours:

$$
\begin{equation*}
y_{d p k}=r_{D I D} \cdot w_{H T I} \cdot h_{H T I} \tag{12}
\end{equation*}
$$

However, in the event of a system failure or data loss using the DIDSON, the HTI estimate for those 2 sectors would be retained and used in subsequent calculations. In this case, the estimates for this time period would be considered conservative.
Total upstream fish passage $y$ on day $d$ during sonar period $p$ in zone $z$ and stratum $s$ was then calculated by summing net upstream targets over all sectors $k$ and samples $q$ :

$$
\begin{equation*}
y_{d p z s}=\sum_{q k} \sum_{k} y_{d p z s q k} \tag{13}
\end{equation*}
$$

and the duration, in hours $h$, of the time sampled as:

$$
\begin{equation*}
h_{d p z s}=\sum_{q k} \sum_{k} h_{d p z s q k} \tag{14}
\end{equation*}
$$

The hourly passage rate $r$ for day $d$, sonar period $p$, and zone $z$ was computed as ratio of the sum of the estimated upstream passage in strata $s$ to the duration (in hours) of the sample:

$$
r_{d p z}=\frac{\sum y_{d p z s}}{\sum h_{d p z s}}
$$

Total passage of fish in report unit $u$ was estimated as the product of the average hourly passage rate and the total hours encompassed by the report unit:

$$
\begin{equation*}
\hat{y}_{u}=\left(d_{2}-d_{1}+1\right)_{u} \cdot 24 \cdot\left(\frac{\sum r_{d p z}}{d_{u}, p, z \in u} 口\right) \tag{16}
\end{equation*}
$$

where $d_{1}$ is the first day, $d_{2}$ is the last day, and $n_{u}$ is the number of sonar sampling periods in report unit $u$.

Sonar sampling periods, each 3 hours in duration, were spaced at regular (systematic) intervals of 8 hours. Treating the systematically sampled sonar counts as a simple random sample would yield an over-estimate of the variance of the total, since sonar counts are highly auto correlated (Wolter 1985). To accommodate these data characteristics, a variance estimator based on the squared differences of successive observations, recommended by Brannian (1986) and modified from Wolter (1985), was employed;

$$
\begin{equation*}
\hat{\operatorname{Var}}\left(\hat{y}_{u}\right)=\left[\left(d_{2}-d_{1}+1\right)_{u} \cdot 24\right]^{2} \cdot\left[1-\frac{h_{u}}{\left(d_{2}-d_{1}+1\right)_{u} \cdot 24}\right] \cdot \frac{\sum_{p=3}^{n_{u}}\left(\hat{r}_{u p}-\hat{r}_{u, p-1}\right)^{2}}{2 n_{u}\left(n_{u}-1\right)} \tag{17}
\end{equation*}
$$

Where:

$$
\begin{equation*}
1-\frac{h_{u}}{\left(d_{2}-d_{1}+1\right)_{u} \cdot 24} \tag{18}
\end{equation*}
$$

is the finite population correction factor.

## CPUE

Traditional CPUE measures were calculated for each day $d$ and bank $b$ using 2 gillnet suites $g$ of specific size mesh $m$. Chinook salmon CPUE was calculated on the pooled catch $c$ and effort $f$ of the large mesh gillnets ( 7.5 " and 8.5 "); chum and coho salmon CPUE was calculated on the pooled catch and effort of the small mesh gillnets ( $5.25^{\prime \prime}, 5.75$ " and $6.5^{\prime \prime}$ ).
The duration of the $j^{\text {th }}$ test-fish drift in minutes $t$ was calculated as:

$$
\begin{equation*}
t_{j}=\left(S I j-F O_{j}\right)+\frac{\left(F O_{j}-S O_{j}\right)}{2}+\frac{\left(F I j-S I_{j}\right)}{2} \tag{19}
\end{equation*}
$$

where $S O$ is the time the net is initially set out, $F O$ is the time the net is fully set out, SI is the time the net starts back in, and FI is the time the net is fully retrieved in.

The total fishing effort (in fathom-hours) for each day, bank, and gillnet suite was calculated as:

$$
\begin{equation*}
f_{d b g}=\sum_{g} \frac{25 \cdot t_{d b g}}{60} \tag{20}
\end{equation*}
$$

since all nets were 25 fathoms ( 45.7 m ) in length. CPUE estimates (in catch per fathom-hour) for each species $i$ were made daily for the right and left banks as:

$$
\begin{align*}
& \\
& C P U E_{d b i}=\frac{\sum c_{d b i g}}{f_{d b g}} . \tag{21}
\end{align*}
$$

## Species Composition

Testfishing drifts were made at stations in each of the same 3 zones ( 1,2 , and 3 ) used in the sonar passage estimates. The results of the testfishing were used to generate species proportions for each zone, which were then applied to the corresponding sonar passage estimate in that zone.
To estimate species proportions, first the total effort $f$ (in fathom-hours) of drift $j$ with mesh size $m$ during report unit $u$ was calculated as in Equations (19) and (20), where each gillnet suite $g$ consisted of a single mesh size, rather than the pooled sizes used in CPUE reporting. Total effort for each mesh size fished was then summed over each report unit:

$$
\begin{equation*}
f_{u m}=\sum_{j} f_{u m j} \tag{22}
\end{equation*}
$$

and the catch of species $i$ of length $l$ in each report period was summed across all mesh sizes:

$$
\begin{equation*}
c_{u i l}=\sum_{m} c_{u i l m} \tag{23}
\end{equation*}
$$

for the catch of each species $i$ of length $l$, the associated effort was adjusted by applying a lengthbased selectivity parameter $S$ derived from the Pearson T net selectivity model:

$$
\begin{equation*}
f_{u i l}^{\prime}=\sum\left(S_{i l m} \cdot f_{u m}\right) \tag{24}
\end{equation*}
$$

and the CPUE of the catch of each species $i$ of length $l$ was calculated as:

$$
\begin{equation*}
C P U E_{u i l}^{\prime}=\frac{c_{u i l}}{f_{u i l}^{\prime}} \tag{25}
\end{equation*}
$$

The proportion $p$ of species $i$ during report unit $u$ was estimated as the ratio of the CPUE for species $i$ to the CPUE of all species combined:

$$
\hat{p}_{u i}=\frac{\sum_{l} C P U E_{u i l}^{\prime}}{\sum_{i, l} C P U E_{u i l}^{\prime}}
$$

and the variance was estimated from the squared differences between the proportion for each testfish period $x$ within the report unit, and the proportion for the report unit as a whole:

$$
\begin{equation*}
\hat{\operatorname{Var}}\left(\hat{p}_{u i}\right)=\frac{\sum\left(\hat{p}_{u i}-\hat{p}_{u d x i}\right)^{2}}{n_{u} \cdot\left(n_{u}-1\right)} \tag{27}
\end{equation*}
$$

where $n_{u}=$ number of testfish sampling periods within the report unit.

## Fish Passage by Species

The passage of species $i$ was first estimated for each report unit $u$ as the product of the species proportion $p$ (Equation 10) and sonar passage $y$ (Equation 25):

$$
\begin{equation*}
\hat{y}_{u i}=\hat{y}_{u} \cdot \hat{p}_{u i} \tag{28}
\end{equation*}
$$

and the variance as:

$$
\begin{equation*}
\hat{\operatorname{Var}}\left(\hat{y}_{u i}\right)=\hat{y}_{u}^{2} \cdot \hat{\operatorname{Var}}\left(\hat{p}_{u i}\right)+\hat{p}_{u i}^{2} \cdot \hat{\operatorname{Var}}\left(\hat{y}_{u}\right)-\hat{\operatorname{Var}}\left(\hat{y}_{u}\right) \cdot \hat{\operatorname{Var}}\left(\hat{p}_{u i}\right) . \tag{29}
\end{equation*}
$$

Daily species passage by zone was estimated by calculating the proportion of the hourly passage rate for the day and zone to the hourly passage rate for the report unit:

$$
\begin{equation*}
\hat{p}_{d z}=\frac{r_{u d z}}{r_{u}} \tag{30}
\end{equation*}
$$

and then applying the passage proportion $p$ to the report unit estimate $y$ :

$$
\begin{equation*}
\hat{y}_{d z i}=\hat{y}_{u i} \cdot \hat{p}_{d z} . \tag{31}
\end{equation*}
$$

Except for the timing of sonar and gillnet sampling periods, sonar-derived estimates of total fish passage were independent of gillnet-derived estimates of species proportions. Therefore, the variance of their product (daily species passage estimates $y_{d z}$ ) was estimated as the variance of the product of 2 independent random variables (Goodman 1960):

$$
\begin{equation*}
\hat{\operatorname{Var}}\left(\hat{y}_{d z i}\right)=\hat{\operatorname{Var}}\left(\hat{y}_{u z i}\right) \cdot \hat{p}_{d z} . \tag{32}
\end{equation*}
$$

Total daily passage by species was estimated by summing over all zones:

$$
\begin{equation*}
\hat{y}_{d i}=\sum_{z} \hat{y}_{d z i} \tag{33}
\end{equation*}
$$

and passage estimates were summed over all zones and all days to obtain a seasonal estimate for species $y_{i,}$ :

$$
\begin{equation*}
\hat{y}_{i}=\sum_{d z} \sum_{d z i} \hat{y}_{d z} \tag{34}
\end{equation*}
$$

Finally, passage estimates are assumed independent between zones and among days, so the variance of their sum was estimated by the sum of their variances:

$$
\begin{equation*}
\hat{\operatorname{Var}}\left(\hat{y}_{i}\right)=\sum_{d} \hat{\operatorname{Varar}}_{d z i}\left(\hat{y}_{d z}\right) \tag{35}
\end{equation*}
$$

and, assuming normally distributed errors, $90 \%$ confidence intervals were calculated as:

$$
\begin{equation*}
\hat{y}_{i} \pm 1.645 \sqrt{\hat{\operatorname{Var}}\left(\hat{y}_{i}\right)} \tag{36}
\end{equation*}
$$

SAS ${ }^{\circledR}$ program code (Hamazaki ${ }^{3}$ ) was used to calculate CPUE, passage estimates, and estimates of variance.

[^2]
## RESULTS

Testfishing began on June 3, with the sonar transducers deployed on the right bank on June 4. The split-beam sonar was deployed on the left bank on June 8, and the DIDSON unit was deployed on June 9 . Sonar counts began on the right bank on June 5 and the project was fully operational from June 9 through August 31. Passage estimates were transmitted to fishery managers in Emmonak daily.

## Environmental Conditions

Ice break-up on the Yukon River was late this season, delaying project start-up and sonar deployment by 4 days. Recorded gage heights exceeded mean levels in early June, fell below minimum values in late June, and exceeded maximum values in late July based on historical water levels for 2001 to 2005 (Figure 8).

## Test-Fishing

Drift gillnetting resulted in the capture of 10,977 fish during 2,062 drifts, including 557 Chinook salmon, 5,403 summer chum salmon, 2,559 fall chum salmon, 658 coho salmon, and 1,766 fish of other species. Of the captured fish, $29.5 \%$ were retained as mortalities and delivered to local users to help meet subsistence needs within the nearby community (Table 6).
Daily CPUE data is reported in Appendices B1 and B2. Correlations between daily passage estimates and testfishery CPUE for Chinook salmon, summer and fall chum salmon, and coho salmon were all significant (Figure 9). The correlation coefficient for Chinook salmon was $r=0.974(P<0.001)$, summer chum salmon was $r=0.914(P<0.001)$, fall chum salmon was $r=0.920(P<0.001)$, and coho salmon was $r=0.658(P<0.001)$.

## Hydroacoustic Estimates

An estimated 5,850,452 fish passed through the sonar sampling areas between June 5 and August $31 ; 1,317,455(22.5 \%)$ along the right bank, 3,484,223 (59.6\%) along the left bank nearshore, and $1,048,774(17.9 \%)$ along the left bank offshore (Table 7). Daily total passage estimates by zone, with their associated errors, are provided in Appendix C.
On the left bank the summer season fish passage was highest in nearshore strata ( $95 \%$ of total fish passage occurred within 100 m from the transducer), but in fall, fish were more evenly distributed across the strata and distribution occurred further offshore ( $95 \%$ of passage occurred within 160 m ). On the right bank the majority of fish were distributed in the nearshore stratum with $95 \%$ of total fish passage occurring within 75 m in both summer and fall seasons (Figure 10).

Passage estimates based on 24 h sampling periods were not generated this season due to scheduling and budget constraints, therefore no results are reported for 2006.

## SPECIES ESTIMATES

Summer chum and Chinook salmon were first present in the river June 7, two days after sonar estimation began. Daily passage estimates by species for the summer and fall seasons are listed in Appendix D. Chum salmon were the most abundant species during both summer and fall seasons. Cumulative passage estimates for the season totaled 5,850,452 fish (Table 7), comprised of $3,767,044 \pm 159,234$ ( $90 \%$ C.I.) summer chum salmon passing the sonar site from June 5
through July 18 and 790,563 $\pm 62,715$ fall chum salmon passing from July 19 through August 31. Chinook salmon passage estimates were comprised of $145,553 \pm 21,148$ fish $>655 \mathrm{~mm}$ MEFL and $23,850 \pm 5,480 \leq 655 \mathrm{~mm}$ MEFL. Coho salmon passage estimates were $131,919 \pm$ 19,538 as of August 31, with the project ceasing operations before the conclusion of the entire run. The estimate of pink salmon was $115,624 \pm 17,418$. Other species, totaling 875,899 fish, include whitefish, cisco, sheefish, burbot, longnose sucker, Dolly Varden, sockeye salmon, and northern pike.

Of the total passage, $28 \%$ of Chinook, $27 \%$ of summer chum, and $16 \%$ of fall chum passed in the 0 to 20 m region of the left bank nearshore (sectors 1 and 2 of stratum 3), where the DIDSON is the primary sonar used for generating passage estimates. The daily estimates of fish passing through this region of left bank and the associated proportion, (also referred to as the DIDSON contribution), of the total passage are detailed in Appendices E1 and E2.

The first major pulse of both summer chum and Chinook salmon began June 16 (Figure 11). The midpoints of the runs occurred on June 27 for Chinook salmon and June 26 for summer chum. Due to the late start of the Chinook run, and relatively early start of the summer chum run, timing of Chinook in relation to summer chum differed from previous years, with $25 \%, 50 \%$ and $75 \%$ of the Chinook run occurring temporally close to the same points in the summer chum run (Figure 12, Appendices F1 and F2).
Fall chum salmon enumeration began July 19, with passage estimates continuing through August 31, when project operations ended. The first major pulse occurred July 19 (Figure 13) with the midpoint of the run on August 1 (Figure 14 and Appendices F1 and F2). Coho salmon were first detected July 20, with 2 large pulses on August 19 and 23 (Figure 13), comprising approximately $18 \%$ of the total coho passage estimated through August 31. While the fall chum run has largely concluded by the end of August, actual timing of the coho run is unknown since this project historically ends operations before the coho run has concluded.

## Missing Data

Sonar data were unobtainable on the left bank for 1 period each day on June 14, 15 and 16 due to wave action, which caused the sonar charts to be unreadable for those single periods.
During the 2006 season, 6 commercial fishing openings occurred in District 2 during testfishing period 2, and 10 commercial openings occurred in District 2 during testfishing period 1. There were 7 days during the 2006 season when insufficient numbers of fish were captured, therefore variance could not be generated accurately on those days without pooling them with adjacent zones. Zones that were pooled for variance estimation and the associated reason for pooling are listed with their corresponding reporting units in Table 8.

Conductivity, turbidity, water temperature and settleable solids were not measured or recorded on a daily basis this season, and therefore no results for these are being presented in 2006.

## DISCUSSION

This season the Yukon River broke up on May 25 (7 days later than the historical average) and ice flowing into the Andreafsky River delayed boat deployment and camp start-up for 5 days. Good profiles on the right bank allowed sonar to be deployed on June 4, but the left bank was not fully operational with both sonar systems running until June 9. Despite the high water, late
break-up, and deployment issues on left bank, sonar was fully operational early enough to fully assess both the summer chum and Chinook runs. This was verified with the testfishery, which started on June 3.

Scouring and erosion on the left bank continues to cause challenges with finding optimal transducer deployment. In previous seasons, transducer deployment sites were forced farther downriver from the sonar tent to the limits of the sonar cabling. To alleviate this problem in 2006, the left bank sonar site was relocated approximately 200 m downstream where acceptable profiles were found and deployment options were increased within the range of the sonar cabling. However, water levels were very high during the first week of the project, which created further challenges in finding a suitable deployment site on left bank. Daily underwater profiling was conducted on left bank and the split-beam and DIDSON equipment were deployed and tested several times before finding the best location. Though there was scouring and visible erosion continuing on the left bank, the reverberation band, which has been problematic in past seasons, was not encountered this season.
The 2006 season saw record numbers of summer chum salmon passing the sonar site, and a strong run of Chinook. The sonar equipment ran smoothly, detection was good throughout the season, and data was collected consistently with very little lost throughout the entire season. Though 24 -hr sonar sampling was not used as a qualitative assessment tool this season, it may be conducted in future seasons as budget and scheduling allows.
The DIDSON sonar contributed significantly to the total passage estimate when deployed on left bank in 2005, and was therefore fully integrated into the sampling schedule for the 2006 season. The proportions of total passage of fish passing in sectors 1 and 2 of the nearshore, the area counted by the DIDSON, in the 2005 season ( $32 \%$ of the Chinook, $21 \%$ of the summer chum and $9.3 \%$ of the fall chum) are very similar to those found in 2006 ( $28 \%$ of Chinook, $27 \%$ of summer chum, and $16 \%$ of fall chum). The DIDSON-generated estimates appear to contribute more significantly to overall passage in the summer season when water levels are higher, and fish are distributed closer to shore. Although the percent passage detected nearshore on left bank with the DIDSON were significant in 2005 and 2006, the change in the left bank profile is a relatively recent event. Given the more linear profiles seen in the past, it is probable the splitbeam system was detecting passage more accurately in earlier years, therefore, estimates for fish passage prior to 2005 have not been adjusted or changed (Appendix G). The DIDSON was also deployed on the right bank in 2005 as an assessment of nearshore detection, and the counts were comparable to those obtained with the split-beam. This was an expected result because the rocky, stable substrate on the right bank has maintained a consistently good profile throughout the project's history.

In 2006 the summer season testfish net schedule was modified in an attempt to improve estimates of Chinook salmon passage (Table 9). In previous years the 5.25 " and 6.5 " mesh nets were fished at both the end of period 1 and the beginning of period 2 . Since these 2 net sizes primarily target chum salmon (which are often an order of magnitude greater in abundance than Chinook), in 2006 we reordered the sequence in which nets were fished. In order to direct some fishing effort away from the more abundant chum salmon and towards the more sparse Chinook, the $7.5^{\prime \prime}$ mesh drifts were duplicated rather than the 5.25 " mesh drifts.
Prior to adjusting the schedule, we examined the effect of reducing effort to fishing each mesh only once per day on the cumulative passage estimates of each species. This entailed simulating
the elimination of both the duplicate $5.25 "$ and $6.5 "$ drifts, either during period 1 or period 2, using data from the years 2003 and 2004. Although point estimates for season totals were little changed, in several cases the confidence intervals increased substantially (as was expected) due to the reduced sample sizes. While this exercise was not designed to directly simulate the schedule change, it did provide some guidance as to the effects of dropping the duplicate drifts. Although all 6 mesh sizes continued to be fished each day, the 5.25 " mesh was fished only once per day while the 6.5 " and 7.5 " mesh were fished during both period 1 and period 2 . The fall schedule remained unchanged.
In previous seasons, conductivity, turbidity, and settleable solids measurements were collected regularly. In the 2006 season, these hydrological measurements were discontinued because of equipment malfunction and reprioritization of data collection goals. Water temperatures were not consistently recorded in 2006, but in future seasons, temperature data loggers may be used as well as water temperatures measured in the fishing zones daily. An in-camp staff gage was used to track daily water changes, and the measurements have tracked well with those recorded at the official USGS water gage at Pilot Station in past years, therefore, overall water level results were reported directly from the USGS. In future seasons, it may be necessary to benchmark the camp water gage and to calibrate it with the USGS gage in case a large portion of data is not available from USGS.

In 2006 all project goals were met, with passage estimates given to fisheries managers daily during the season. Information generated at the Yukon River Sonar project was also disseminated weekly through multi-agency international teleconferences and data-sharing with stakeholders in areas from the lower Yukon River all the way to the spawning grounds in Canada.

## ACKNOWLEDGEMENTS

The authors would like to thank the following organizations for their support: Yukon River Drainage Fisheries Association for providing a technician, Association of Village Council Presidents and Bering Sea Fisherman's Association for jointly providing a technician; Yukon Delta Fisheries Development Association for providing funding for the project's early start-up, and U.S. Fish and Wildlife Service for providing funding for genetic analysis and transport of samples. This project was also supported by U.S./Canada funds administered by the U.S. Fish and Wildlife Service, Agreement \# NA03NMF4380185.

The authors would also like to thank the following people for their hard work during the 2006 season and dedication to the project: crew leader Mike Parker, and technicians Renee Reed, Mathew Joseph, Rex Nick, Naomi Brodersen, Gabriel Heckman, Donald Kelly (AVCP technician), Richard Nick (YRDFA technician), and Carl Pfisterer (Regional Sonar Biologist IV) for his assistance in the field and careful review of this report.

| Season Total | 5,850,452 |  |  | 5,228,544 | 3,177,474 | 3,103,448 | 2,283,770 | 1,408,900 | 1,320,778 | 2,027,761 | 1,768,387 | 2,846,488 | 5,910,900 |

${ }^{\text {a }}$ Estimates for all years were generated with the most current apportionment model and may differ from earlier estimates.
${ }^{\text {b }}$ Estimates include extrapolations for the dates June 10 to June 18 to account for the time before the DIDSON was deployed.
c Record high water levels were experienced at Pilot Station in 2001, and therefore passage estimates are considered conservative.
${ }^{\text {d }}$ The Yukon River sonar project did not operate at full capacity in 1996 and therefore there are no passage estimates.
${ }^{\mathrm{e}}$ Chinook salmon $>655 \mathrm{~mm}$.
f This estimate may not include the entire run.
${ }^{\mathrm{g}}$ Includes sockeye salmon, cisco, whitefish, sheefish, burbot, suckers, Dolly Varden, and northern pike.
