1. INTRODUCTION

Storm surge is the abnormal rise in water level caused by wind and pressure forces of a hurricane. Storm surge produces most of the flood damage and drownings associated with tropical storms that make landfall or that closely approach a coastline (Anthes, 1982).

A numerical storm surge model developed by Jelesnianski (1967, 1972), Jelesnianski and Taylor (1973) and Jelesnianski et al. (1984) has been applied to the Long Island Sound, NY region. The model, which calculates sea, lake and overland surges from hurricanes, and has the acronym "SLOSH," is a pairing of a model of a hurricane coupled to a model for storm surge. Crawford (1979) discussed some preliminary results using this model in the southeast Louisiana region.

The purpose of this atlas is to provide maps of SLOSH-modeled heights of storm surge and extent of flood inundation, for various combinations of hurricane strength, forward speed of storm and direction of storm motion. Strength is modeled by use of the central pressure and storm eye size using four of the five categories of storm intensity that Saffir and Simpson have categorized (Simpson and Riehl, 1981). Six storm-track headings were selected as being representative of storm behavior in this region on the basis of observations by forecasters at NOAA's National Hurricane Center.

The maps in this atlas summarize surge calculations made using the SLOSH model, when initialized with observed values (depths of water and heights of terrain and barriers) in the region centered on Long Island Sound, NY.

2. THE GRID FOR THE SLOSH MODEL OF THE LONG ISLAND SOUND AREA

Figure 1 illustrates the area covered by the grid for the Long Island Sound SLOSH model. The area covered by the grid is called a "basin"—the "Long Island Sound Basin." The grid is a telescoping polar coordinate system with 90 arc lengths ($1 \leq I \leq 90$) and 76 radials ($1 \leq J \leq 76$). Unlike a true

polar coordinate grid, which would have radial increment (ΔR) that was invariant with radius, this grid uses a ΔR that increases with increasing distance from the grid's pole. The result is that in each grid of the mesh, the increment of arc length (ΔS) of the side of a grid "square" is approximately equal to the radial increment of the "square," or $\Delta S \approx \Delta R$.

The telescoping grid is a compromise between conflicting needs. What is desired is that a large geographical area, but with small, detailed topography be modeled. In a Cartesian coordinate system, this combination of big area, but spatially-small grid increment, requires that a computational mesh with many grid squares be used. A large mesh requires a computer with a large central processing unit (CPU) as well as more time to perform calculations in the more numerous grid squares. The telescoping grid, by comparison, permits a resolution of these conflicting needs: it has an acceptably small spatial resolution of 1 to 10 mi² per grid square over land, which is the area of greatest interest. Thus, topographic details, such as highway and railroad embankments, and dikes in harbors of cities are included in the model. However, the range increment contained in each grid square becomes progressively larger with increasing distance from the pole. As a result, a large geographic area is included in the model, so that the effects of the model's boundaries on the dynamics of the storm are diminished and the storm's physics are better emulated.

The grid is tangent to the earth at the basin center, Coney Island, New York at 40°36'13"N and 74°03'15"W. There, the grid increment is 0.675 statute mile. The pole (or origin) of the grid is located at 40°43'20"N and 74°20'30"W.

The telescoping grid has some disadvantages. Primarily, these stem from the distortion that occurs when the basin is remapped onto a display that has constant-sized increments in the vertical and horizontal, as happens when the

basin is printed out by a conventional (computer) line printer. This distortion from remapping produces some difficulties in "reading" the results by the uninitiated. For example, neither latitude nor longitude lines remain uncurved and "parallels" become non-parallel. However, the projection is conformal. The projection scheme results in each grid square at $I = 1$, closest to the pole, representing an area of about 0.11 square mile. By contrast, at maximum distance from the pole, at $I = 90$, each grid square contains about 106.1 square miles. Thus, the distortions require that aids be provided to "read" and interpret the results.

3. SLOSH MODEL

A. Hurricane Model and Input

The hurricane model which drives the storm surge model was developed by Jelesnianski and Taylor (1973). It is a trajectory model of a stationary vortex and it balances the forces from pressure gradient, centrifugal, Coriolis and surface frictional effects. Adjustments are made to the computed vector wind to incorporate the hurricane's forward motion. The model's input includes the radius of maximum wind (RMW) and the difference (ΔP) in sea-level pressure between the ambient value and the minimum value in the storm's center. Directly measured wind vectors are not used. The model also requires input of the coordinates of the storm's center. Thus, input data include thirteen sets of latitude, longitude, ΔP and RMW, at six hour increments, beginning 48 hours before storm landfall and ending 24 hours after landfall. These 13 sets are then linearly interpolated into values/positions at hourly (or smaller) time increments. The model then generates the meteorological forces—surface stress and the gradient of atmospheric pressure—that drive the underlying ocean.

B. Storm Surge Model

Storm surge is the response by the ocean to meteorological forces. The model's governing equations are those given by Jelesnianski (1967), except now for the inclusion of the finite amplitude effect. Coefficients for surface drag, eddy viscosity and bottom slip are the same as those used in an earlier model (Jelesnianski, 1972). There is no calibration or tuning to force agreement between observed and computed surges; coefficients are fixed, and do not vary from one geographical region to another.

Special techniques are incorporated to model two-dimensional inland inundation, routing of surges inland when barriers are overtopped, the effect of trees, the movement of the surge up rivers, and flow through channels, cuts and over submerged sills. Besides surge, other processes affect water height (section 4B), but are not incorporated in the model.

Not surprisingly, the accuracy of modeled surge values increases as the accuracy of the input terrain and storm data improves.

4. OUTPUT AND INTERPRETATION OF THE MODEL RESULTS

A. Output from the SLOSH Model

The output for the Long Island Sound "SLOSH" model consists of maps of water heights. At each grid point, the water height is the maximum value that was computed at that point during the 72 (maximum) hours of model time. Thus, the map displays the highest water levels and does not display events at any particular instant in time. The analyzed envelopes of high water show shaded areas that represent dry land which has been inundated and contours of high water relative to mean sea level (MSL). Height of water above terrain was not calculated because terrain height varies within a grid square. For example, the altitude of a grid square may be assigned a value of 6-ft MSL, but this value represents an average of land heights that may include values ranging

from 3 ft to 9 ft MSL. Thus, a surge value of 8 ft in this square, implying 2 ft average depth of water over the grid's terrain, would include some terrain without inundation and other parts with as much as 5 ft of overlying water. Therefore, the depth of surge flooding above terrain at a specific site in the grid square is deduced by subtracting the actual terrain height from the model-generated storm surge height in that square. Also supplied are printout lists of values of surge height, wind speed and wind direction for each of 120 sites. The values are ten-minute averages, every 30 minutes. These are useful for determining the time of onset of gale force winds and surge heights, for evacuation planning.

B. Interpretation of Results

Even if the model is supplied accurate data on storm positions, intensities and sizes, the computed surges may contain errors of +/- 20% of observed water levels. These primarily stem from:

- 1) Maps that are outdated: The maps which supplied heights of terrain and depths of water sometimes did not include changes, often man-made, that had been made to the heights and positions of barriers (e.g., highway and railway embankments) and depths and locations of channels. Inaccuracies of topography or bathymetry will contribute directly to errors in the modeling of all storm surges.
- 2) Anomalous water heights: Sea level can be at an altitude different from "mean sea level," days or even weeks before a storm is actually affecting a basin. The value of the actual, local sea level — the "local datums" for pre-storm anomaly in the Atlantic Ocean — must be supplied to the model, before calculations are initiated.

3) Local processes, such as waves, astronomical tides, rainfall and flooding from overflowing rivers: These processes are usually included in "observations" of storm surge height, but are not surge and are not calculated by the SLOSH model.

Factors such as the foregoing must be considered when comparisons are made between modeled and observed values of storm surge.

5. HURRICANE CLIMATOLOGY

A. Tracks

Between 1886 and 1986, 11 tropical cyclones of hurricane intensity passed within 100 statute miles of Coney Island, New York (Neumann et al., 1985), for an average of one hurricane within the 100-mile circle every 9.2 years.

Figures 2-4 show the tracks of these 11 storms with hurricane force winds. Figure 2 depicts the tracks for northwestbound and northbound storms, Figure 3 shows tracks for storms heading north-northeastward, and Figure 4 displays the tracks of storms heading northeastward.

The tracks represent "best estimates" and are based on a variety of data sources. Historically, storm strength, location and motion were only inferred, from analyses of wind, pressure and cloud observations made at ships and land stations being influenced by the storm. In 1943, aircraft reconnaissance of hurricanes began. Not until 1959 were there land-based weather radars, as now at Atlantic City, New York City and Chatham, Massachusetts which could be used to observe and record structure, development and motion of precipitation fields, and help infer center location and radius of maximum winds. The 1960's saw the advent of photography from weather satellites of tropical storms. Observations by aircraft, radar and satellite have shown

that the tracks of centers of hurricanes contain wobbles, gyrations and cycloidal motions (Lawrence and Mayfield, 1977) and that there often are rapid developments in size and intensity of rain bands, contractions of eyewall diameters and formation of concentric ("double") eyewalls. Every one of these factors indicates asymmetries in the storm's dynamical structure; every one of these dynamical asymmetries affects the storm's surge. But these factors were not documented in the earlier storms and remain beyond the reach of present-day forecasting skill.

The tracks in Figures 2-4 are labeled at 6-hour intervals with month/day/hour (GMT).

B. Intensities

Hurricane intensity is usually defined by measurements at sea level of the maximum sustained wind speed and/or by minimum barometric pressure. Neither of these is easily obtained. Accurate estimates of these parameters at sea level were acquired only when a ship or land station was traversed by the storm's "eye." Minimum central pressure was gotten only when a barometer was in the precise path of the storm's center. Because the area covered by the strongest winds is much larger than that covered by the pressure minimum, strength of many older storms was deduced from measurements of wind speed. However, with the advent of aircraft reconnaissance, measurements made at flight level of meteorological parameters allow the calculation of barometric pressure at sea level. By comparison, winds at sea level are not so readily deduced from flight level data. For all the storm tracks in Figures 2-4, an estimate was made of the maximum wind speed at intervals of 6 hours. For some, only very indirect evidence exists of actual speeds. From the hourly values of the maximum wind speed inside the 100 mile circle, the largest value was selected. This maximum sustained wind speed for the hurricane is listed

in Table 1 under the heading of "wind (in circle)." Storm heading and forward speed at hour of closest point of approach are listed in the last two columns.

The values listed in column 6 sometimes are poor estimates of the maximum wind speed; the following must be considered:

- 1) Actual wind speeds and directions exhibit gustiness.
- 2) The "average wind speed" has been calculated with a variety of time intervals over the years; thus, one can find historical wind records that have used time periods such as 1 hour, or 10 or 5 minutes or 1 minute as the "standard" period of measurement. Given the same record from a recording anemometer, the use of each of these measurement periods would likely yield a different average wind speed, with shorter periods probably giving higher average speeds.
- 3) The platforms for measuring maximum surface wind speed have changed over the years; data from ship and land stations now are supplemented by remotely-sensed data from aircraft, satellites and radar. However, the remote platforms, especially the last two, observe the motions of clouds or precipitation echoes, and these motions are not wind speed, nor are they at sea level.

Because of these limitations in determination of maximum wind speed, the SLOSH model uses storm-center sea-level pressure as a measure of storm intensity in modeling the Long Island Sound basin.

6. MAPS OF MAXIMUM ENVELOPE OF WATER ("MEOW") FROM SLOSH RUNS USING DATA FOR HYPOTHETICAL HURRICANES

A. Hypothetical Storm Tracks and Populations

The skill of the SLOSH model was evaluated by Jarvinen and Lawrence (1985), who compared modeled and observed surges at 523 sites during 10

Table 1. Hurricanes passing within 100 statute mile circle of Coney Island, New York (40.60°N, 74.05°W), during 1886-1986.

Notes:

- (1) Storm number for this list.
- (2) Year, month and date that storm had maximum winds exceeding 74 mph and was closest to Coney Island, New York.
- (3) Storms were not formally named before 1950.
- (4)-(5) Distance (statute miles) and direction (degrees) from Coney Island to storm when it passed abeam.
- (6) Maximum sustained wind speed near storm center while center was within 100 statute miles of Coney Island. This is not necessarily the wind recorded at a given site.
- (7)-(8) Storm heading and forward speed (mph) at hour of closest point of approach.

hurricanes. They found that the mean absolute error in surge height calculated by SLOSH was 1.4 ft. Although the error range was from -7.1 ft to +8.8 ft, the standard deviation was only 2.0 ft and 79% of the errors lay within one standard deviation of the mean error, -0.3 ft. (On the average, modeled values were slightly less than those observed.)

Because of this skill in calculating storm surge, the SLOSH model was used to create maps of surge flooding in the Long Island Sound basin for use in evacuation planning. The model was supplied with data from hypothetical storms and the resulting surge calculations were composited to produce maps of the maximum envelope of water. This section details why these calculations were made and how the compositing was done.

Storm surge height, at any particular location, partly depends on distance between that site and the storm's center. For a single storm, the model would produce a map of surge height for the modeled period of time (usually 72 hours), with values valid for only that particular storm track. If there were two storms, identical in every respect except that one followed a track parallel to, but separated from the other by 50 miles,¹ and if the model was run with first one and then the other storm, and a comparison made of surge values, then very likely there would be geographical sites with surge values from one storm that differed markedly from those modeled for the other storm. When preparing plans for emergency evacuation, this dependency of surge height on storm track can be troublesome. What is needed is surge flooding potential

¹A difference ("error") of 50 miles in storm track is not very large when compared to the vagaries of tracks of real hurricanes. The average error of 12-hour forecast landfall position, for U.S. Atlantic coast tropical cyclones, during 1970-1979, was about 59 statute miles, while for 24-hour forecasts, landfall position error was about 125 statute miles (Neumann and Pelissier, 1981). Thus, if a storm were forecast to make (eye) landfall at Coney Island, New York, in 24 hours, and if, in fact, it made landfall anywhere between Cape May, New Jersey, and Montauk Point, Long Island, the error in forecast landfall position would be no worse than average.

for the entire basin; a map of surge heights that depends only on intensity (using the categories defined by Saffir and Simpson), storm speed and direction. To do this, a procedure was adopted that involved making surge calculations for each of an ensemble of 3 to 14 storms; in an ensemble, all storms had the same intensity, speed and heading. Storm tracks were separated by 15 miles. The maximum surge value that was calculated at each grid square from any storm in the ensemble was extracted and saved. After this procedure was performed for all grid squares, the result was a basin map depicting the "maximum envelope of water," or MEOW, for the specified storm category, direction and speed. For the Long Island Sound basin, the hypothetical storms were specified to move in one of six directions, at one of three constant speeds, as summarized in Table 2. There were 11 tracks for the west-northwestward (WNW) moving storms (Figure 5), 13 tracks for the northwest-bound (NW) storms (Figure 6), 14 tracks for the north-northwest (NNW) storm headings (Figure 7), 11 tracks for the northward (N) moving storms (Figure 8), up to 9 tracks for the north-northeastward (NNE) storm headings (Figure 9), and up to 7 tracks for storms heading northeastward (NE), in Figure 10. In total, 533 hypothetical storm tracks were run, using the SLOSH model, to create the results to be presented below. The selection of directions and speeds was based on advice of hurricane specialists at NOAA's National Hurricane Center.

B. Intensities and Radii of Maximum Winds of Hypothetical Storms

Most hurricanes weaken after making landfall because the central pressure increases (the storm "fills") and the RMW tends to increase. Table 3 summarizes pressure filling and RMW increases with time for the hypothetical storm runs. These rates of change were based partly on the work of Schwerdt et al. (1979). Storms heading northeastward were modeled to not undergo filling or to change RMW.

Table 2. Long Island Sound Basin's hypothetical storms: Directions, speeds, (Saffir/Simpson) intensities, number of tracks and the number of runs.

Direction	Speed (mph)	Intensities	Tracks	Runs
WNW	20	1 through 4	11	44
NW	20	1 through 4	13	52
NNW	20, 40, 60	1 through 4	14	168
N	20, 40, 60	1 through 4	11	132
NNE*	20, 40, 60	1, 2, 3, 4	9, 9, 7, 6	93
NE*	20, 40	1, 2, 3, 4	7, 7, 5, 3	44

*Several NNE and NE moving hurricanes near or over land cannot maintain all intensity levels.

Table 3. Time change of pressure difference and radius of maximum wind for hypothetical hurricanes having headings towards the west-northwest, northwest, north-northwest, north or north-northeast in Long Island Sound Basin.

Values of pressure difference (ΔP , millibars) and radius of maximum wind (RMW, statute miles), beginning at time of landfall (LF) of center of storm and every six hours after LF.

Category	Landfall		LF + 6		LF + 12		LF + 18		LF + 24	
	ΔP	RMW	ΔP	RMW	ΔP	RMW	ΔP	RMW	ΔP	RMW
1	20	30	14	30	10	30	10	35	10	40
2	40	30	31	30	22	30	13	35	10	40
3	60	30	48	30	36	30	24	35	12	40
4	80	30	65	30	50	30	35	35	20	40

C. Initial Water Height

Based on observations from tide gages in the area of this basin, tidal anomalies of about +1 ft MSL before arrival of a hurricane are not uncommon. Thus, all SLOSH runs of hypothetical hurricanes were supplied with initial datums of +1 ft MSL. In an actual hurricane, if tide gage data in this basin indicate that there is no tide anomaly, then subtract 1 ft from the modeled values found in the maps (below).

D. The "MEOW" Figures

There are 52 MEOWS. They use the distorted geography mentioned in Section 2 and are presented in the Appendix. The contours represent the height of water above mean sea level, in 1-ft increments. The shaded areas indicate land areas that were modeled to have been inundated.

The MEOW figures are grouped by direction: west-northwestbound storms are in Figures A1-A4, northwestbound storms' MEOWS are in Figures A5-A8, north-northwestbound in Figures A9-A20, northbound in Figures A21-A32, north-northeastbound storms' MEOWS in Figures A33-A44, and northeast-moving storms' MEOWS are in Figures A45-A52.

July, 1988

Background and Approach: Behavioral Science and Hurricane Evacuation Planning

Evacuation outcomes depend upon many factors, including how the public responds to the event, and in hurricane evacuation planning, one must make assumptions about those factors. If one makes unreasonable assumptions, an actual evacuation is unlikely to proceed as anticipated. The public responses having the greatest impact upon an evacuation are

1. The number of people who evacuate.
2. The number of vehicles used in the evacuation.
3. How promptly evacuees leave.
4. The number of evacuees who leave or attempt to leave the local area and where they go.
5. The number of evacuees who seek refuge in public shelters.

Deriving Correct Assumptions

Regardless of how detailed, formal, or quantitative an evacuation plan appears, it contains assumptions about behaviors such as those discussed above. Even if the assumptions are not deliberately and explicitly addressed, there are implicit or implied values for them. For example, planners who say they make no assumptions at all regarding whether people outside the recommended evacuation zone will evacuate are in fact assuming that none of those people will leave. Any time an evacuation plan is "tested" to ascertain the length of time required to complete an evacuation under the plan, the test includes quantitative assumptions

regarding behavioral factors. The issue is not whether such assumptions should be made, because they must; the issue is what the assumptions should be.

There are at least three basic ways to derive behavioral assumptions:

1. Conduct interviews with people in a large number of locations asking what they did in multiple hurricane threats, documenting patterns of behavior under various conditions (general response model).
2. Conduct interviews asking people what they did in one particular evacuation (single event survey).
3. Conduct interviews asking people what they would do during a hurricane threat (hypothetical survey).

An Integrated Approach

Building a Quantitative General Response Model

A response model can be constructed to indicate quantitative values of specific responses, given a particular set of circumstances which the planner specifies. The extent of shadow evacuation in hurricanes, for example, can be forecast by specifying the severity of the storm, hazardousness of the neighborhood, and actions taken by public officials.

This is the heart of HMG's approach to formulating behavioral assumptions for hurricane evacuation planning. We are fortunate to have amassed actual response data from many hurricane evacuations spanning a wide geographical area and a variety of hurricane threat circumstances over a period of roughly three decades. Figure 1 shows locations where post-hurricane sample surveys have been administered. Multiple markers at a location indicates that more than one survey has been conducted.

FIG. 1

HMG's general response model has been used successfully in evacuation plans along the Gulf and Atlantic coasts. Thus, for each of the behaviors to be anticipated, the model predicts a quantitative value, depending upon specific situations and circumstances specified. The structure of the general response model, including the variables affecting the principal behaviors, appears in Figure 2.

A common concern expressed about the general response model is that it is based upon responses of people in "other places" and that "our people are different." Actually the strength of the general model is that it accounts for differences in responses as they vary because of demographic characteristics of the population, actions by emergency management personnel, physical hazardousness of the study area, and so forth. Evidence of the model's validity lies in its history of accurately explaining and forecasting actual response behavior observed in a variety of places.

Single Event Actual Response Data

It is tempting to overgeneralize from a single evacuation in a particular location. Even the same people will respond differently in different sets of circumstances. Single event data can be very useful if not overused, however. If an evacuation occurs late at night, for example, and the evacuation is urgent, those circumstances tend to lead to fewer people leaving the local area than other circumstances. Thus, if the single event was a late night, urgent evacuation, it should provide an indication of the "worst case" to expect in that location for certain types of behaviors.

Single events also provide opportunities to validate the use of the general response model for forecasting in a specific location. Actual behavior in a single event can be documented and compared to that which would have been predicted

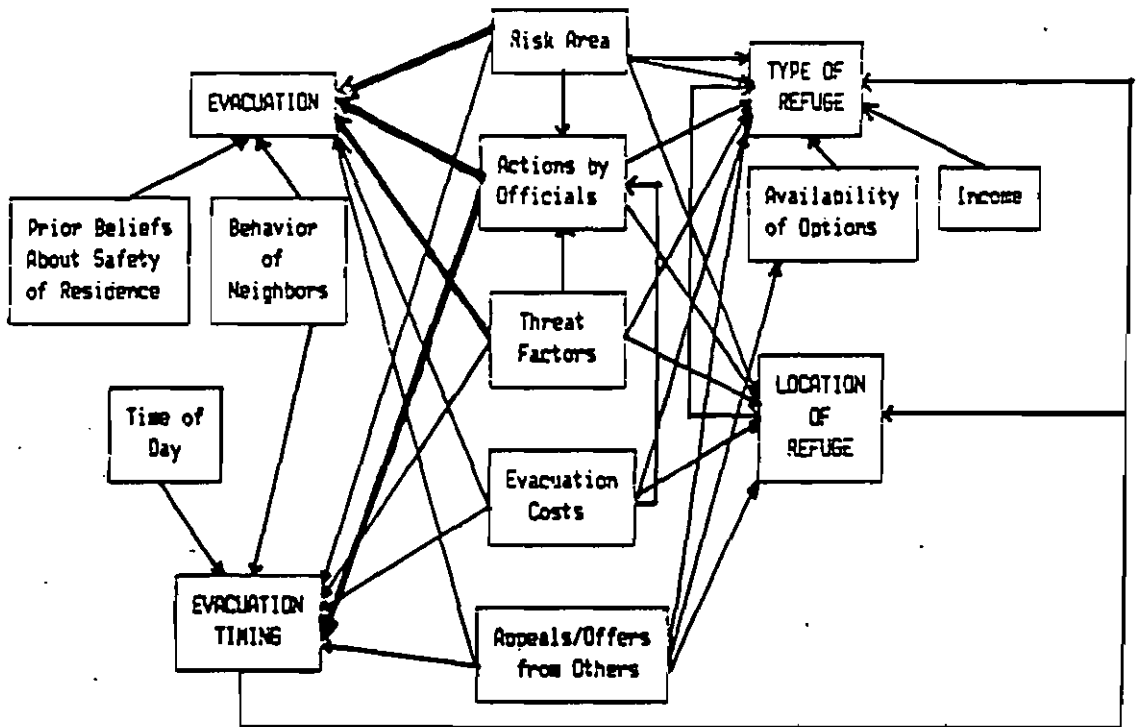

FIG. 2

by the general response model. Its "fit" gives a clue to how much the model would have to be adjusted to work for the specific location and hazard.

Single event data was collected in this study documenting how residents responded during hurricane Gloria in 1985. This marks the first time actual response data has been collected systematically in the study area. The Gloria results will be compared to patterns predicted by the general response model to assess the model's applicability to the region. It is tempting to overgeneralize from any single evacuation, and response to future hurricane threats could vary substantially from the Gloria findings.

Hypothetical Responses

Although hypothetical response data can hardly ever be used literally for quantitative forecasts, HMG has collected much data of this nature, and it does have utility in experienced, knowledgeable hands. There are certain consistent biases in hypothetical response data, for example. People are more likely to say they would evacuate in "low risk" situations than they usually do, more likely to say they would leave early than they usually do, and more likely to say they would use public shelters than they usually do. Hypothetical response data can be adjusted to account for those sorts of known biases. Hypothetical data in one location can be compared with that collected elsewhere for an indication of relative variation between the samples. If more people in one location say they would refuse to leave than in another, they probably really are more likely to refuse. At least more effort will be required to have them move. So, although the magnitude of people saying they wouldn't leave might not be quantitatively valid, it at least gives a relative indication. This can be particularly useful when actual response data is also available in the second location.

Many respondents to the Gloria survey did not evacuate in response to the threat. That information is useful in assessing evacuation rates forecast by the general response model, but provides no information concerning other behaviors such as shelter use by those respondents. Therefore residents not evacuating in Gloria were asked hypothetical questions about what they believe they would do in future hurricane threats or what they would have done if they had evacuated in Gloria. The hypothetical responses will be compared to intended response data collected elsewhere and to actual response by other respondents in Gloria.

Vacationers

Unfortunately, the general response model is well developed only for residents. Actual response data is virtually nonexistent concerning how tourists, including RV operators, respond during hurricane threats.

HMG collected hypothetical response data with many vacationers in both North and South Carolina, but that data has most of the same weaknesses as hypothetical response data from residents. In addressing vacationer response we base most of our conclusions upon interviews conducted with tourism officials, hotel/motel managers, and campground operators following hurricane threats elsewhere.

Purpose of This Report

Methodology and results of the post-Gloria survey will be presented in the following sections of this report. Findings for all 19 survey sites will be included, with consistencies and differences noted among sites. The results will be compared to results normally observed in other hurricane prone areas to assess the

applicability of the general response model to the study area. The survey data will be used in supplementary reports for each state to refine the general response model if necessary for use in deriving planning assumptions for each state.

Survey Methodology

Sampling

Corps of Engineers representatives from Norfolk, Baltimore, Philadelphia, New York, and New England districts worked with HMG and state and local emergency management officials to select survey sites and sample sizes in each state from Virginia through Massachusetts. Criteria for selection varied from state to state, but in most instances the locations were important in and of themselves because of evacuation concerns at those sites or because the places were representative of other areas to which generalizations could be extended. The sample sites are displayed in Figure 3.

Virginia Beach, Virginia

Approximately 100 telephone interviews were completed with households having telephone prefixes 420, 427, and 428. Phone numbers were selected from the local telephone directory.

Norfolk, Virginia

Approximately 100 telephone interviews were completed with households having telephone prefixes 480, 489, 583, 587, and 588. Phone numbers were selected from the local telephone directory.

FIG. 3

Newport News, Virginia

Approximately 100 telephone interviews were completed with households having telephone prefixes 245 at addresses south of 39th street and east of Jefferson Avenue. Phone numbers were selected from the local telephone directory.

Virginia Eastern Shore

Approximately 100 telephone interviews were completed with households in a number of Northampton and Accomack County towns suggested by local emergency management officials. Phone numbers were selected from the local telephone directory after cross referencing the addresses with elevation maps of the area. Predominant prefixes were 331, 787, 442, 336, 824, and 891.

Chrisfield, Maryland

Approximately 100 telephone interviews were completed with households having telephone prefix 968 and having a Chrisfield address. Phone numbers were selected from the local telephone directory.

Anne Arundel County, Maryland

Approximately 100 telephone interviews were completed with households having telephone prefixes 741, 798, 867 and having an address in one of several specific towns on or near Chesapeake Bay south of Annapolis (including Deale, Avalon Shores, Rose Haven). Phone numbers were selected from the local telephone directory.

Denton, Maryland

Approximately 100 telephone interviews were completed with households having telephone prefix 479 and having an address in Denton or West Denton. Phone numbers were selected from the local telephone directory.

Ocean City, Maryland

Approximately 100 telephone interviews were completed with households having telephone prefixes 250, 289, 524, 723 and having an address in Ocean City. Phone numbers were selected from the local telephone directory.

Delaware "Beach"

Approximately 100 telephone interviews were completed with households having telephone prefix 539 and having an address in Bethany Beach or South Bethany. Phone numbers were selected from the local telephone directory.

Delaware "Mainland"

Approximately 100 telephone interviews were completed with households having telephone prefix 945, which included Millsboro and nearby towns. Phone numbers were selected from the local telephone directory.

"Southern" New Jersey

Approximately 100 telephone interviews were completed with households in Ocean City having telephone prefixes 390, 391, 398, and 399. Phone numbers were selected from the local telephone directory.

"Northern" New Jersey

Approximately 100 telephone interviews were completed with households in Ocean Grove, Bradley Beach, and Avon having telephone prefixes 774, 775, 776, 918, 922, and 988. Phone numbers were selected from the local telephone directory.

"Rockaway" New York

Approximately 200 telephone interviews were completed with households in the Far Rockaway, Belle Harbor, Edgemere areas of Queens. The area is referred to as Zone 13 in the NYNEX directory and includes several prefixes (318, 327, 337, 471, 474, 634, and 945). Phone numbers were selected from the local telephone directory.

"Suffolk" New York

Approximately 200 telephone interviews were completed with households in Quogue and Westhampton Beach in Suffolk County on Long Island (with prefixes 635 and 288). Phone numbers were selected from the local telephone directory.

"Fairfield" Connecticut

Approximately 100 telephone interviews were completed with households in Fairfield, Bridgeport, Stratford, and Milford. Phone numbers were selected from Hill-Donnelly directories after identifying streets from maps provided by the New England District showing Category 2 surge inundation areas.

"Groton" Connecticut

Approximately 100 telephone interviews were completed with households in Groton, Stonington, and Mystic. Phone numbers were selected from Hill-Donnelly

directories after identifying streets from maps provided by the New England District showing Category 2 surge inundation areas.

Warwick, Rhode Island

Approximately 100 telephone interviews were completed with households in Warwick. Phone numbers were selected from the Polk directory after identifying streets from Flood Insurance maps provided by the New England District.

Newport, Rhode Island

Approximately 100 telephone interviews were completed with households in Newport. Phone numbers were selected from the Cole directory after identifying streets from Flood Insurance maps provided by the New England District.

Wareham, Massachusetts

Approximately 100 telephone interviews were completed with households in Wareham. Phone numbers were selected from the New Bedford and vicinity Cole directory after identifying streets from Flood Insurance maps provided by the New England District.

Sample Size Considerations

There is always some probability of error when generalizing from a sample to the larger population from which it was drawn. If 100 residents of the surge prone area of Warwick, Rhode Island are selected randomly and interviewed, those 100 people are referred to as a sample. All people living within the Warwick surge zone from which the sample was selected constitute the population to which we attempt to generalize from information gained only from the sample.

A sample of 100 provides figures which, 90% of the time, will be within 5 to 8 percentage points of the actual population values. A sample of 200 will be within 3 to 5 percentage points of the true population value 90% of the time. This is true even if the population includes millions of people. For some purposes such small samples are not adequately reliable. In this case, however, the survey data is but one component in a broader, more important methodology and provides sufficient precision for the comparative purposes intended for it. The responses obtained in this survey are compared to response patterns observed under the general response model to assess whether the two are generally consistent. Small differences are not of consequence.

One should be especially cautious when generalizing from subsets of the samples of 100. For example, in many locations only about a third of the respondents evacuated. Therefore, in those sites only about 35 people were asked what sort of shelter they used. Answers based on interviews with 35 people are usually reliable within only 11 percentage points, which is a substantial margin of uncertainty.

One point to keep in mind, therefore, is that sample differences are not necessarily indicative of differences within the population. For example, if 70% of 100 respondents in one site left the local area when evacuating in Gloria, and only 60% of 100 respondents in a second site left the local area, that would probably not be sufficient evidence to conclude that people in the former location were more likely overall to leave the local area than people in the latter location. Figures of 70% and 50%, however, would usually indicate population differences in that example.

At times it is useful to ascertain whether, for example, wealthy evacuees were any less likely to use public shelters than low income evacuees. To answer those sorts of questions reliably, samples must sometimes be fairly large.

Therefore, to analyze those kinds of crosstabulations, the individual site samples will be aggregated in this report. Samples from Virginia through New Jersey are lumped into a single group which will be referred to as the southern sample, and New York through Massachusetts are grouped into a northern sample.

In all the tables presenting survey results, sample sizes are included. The reader is advised to always note the sample size before deciding how much confidence to place in a particular result.

Interview Questions

The questions asked of respondents are included as Appendix I. Questions 8a, 14a, 16a, 17a, and 17b were asked in the northern area only. Question 17 was asked in both areas, but in the northern area the response categories were made more specific.

Sample Characteristics

Age

Four questions were asked which could provide background information useful in explaining variations in response to Gloria and to the hypothetical questions. Figure 4 shows the age distribution of respondents across the 19 sites. From a behavioral perspective the most meaningful age group is probably people over 65. At a few of the sites a third of the sample is over 65. Warwick has the smallest percentage (10%) over 65.

Income

Respondents were asked to indicate which of five categories described their annual family income. Income categories were used to make the information less specific and therefore to increase the willingness to provide the information. Nevertheless roughly 15% of the respondents refused to reveal their income. Moreover, there is no way of knowing whether other respondents were candid and accurate in their responses.

Based upon answers provided, Figure 5 indicates incomes at the 19 sites. Chrisfield, MD and Newport News, VA had the greatest incidence of low income interviewees. More than a third in those locations reported incomes below \$10,000.

Housing

The vast majority of respondents lived in single-family detached housing units (Figure 6). The only two exceptions were Rockaway, NY where 39% said they lived in high-rise apartments and on the Delaware mainland where 55% lived in

Respondents' Reported Age

FIG. 4

Respondents' Reported Annual Family Income

(Excludes approximately 15% refusals.)

FIG. 5

Housing of Respondents

FIG. 6

mobile homes. "Other" refers primarily to duplexes and medium density apartments or condos.

Proximity to Water

The sample sites themselves vary in terms of flooding propensity and proximity to water, but there is also variation within the sites (Fig. 7). At most interview locations between 25% and 50% of the respondents said they lived within a block of a water body (ocean, harbor, bay, sound). As many as 31% (Groton) said they lived adjacent to such a water body. Many of the sites also had a substantial portion of the respondents living more than a mile from any water.

To some extent measurement of this variable is subject to judgment on the part of people answering the question. Most people underestimate distances, for example, so some of the individuals saying they lived more than a block but less than a mile from water might actually live more than a mile from water. Overall, though, it's reasonable to assume that most people in the "more than a mile" category are in fact farther from water than most in the other categories.

Respondents' Reported Proximity to Water

FIG. 7

Evacuation

In only 5 of the 19 survey sites did a majority of respondents evacuate: Delaware beaches, Delaware mainland, Ocean City, MD, Southern New Jersey, and Warwick, RI (Figure 8). Denton, MD had by far the lowest evacuation rate (8% and too small to break down in a number of subsequent figures). These figures alone, however, are not useful in evaluating the applicability of the general response model to the region. For that, response variations in the sample must be analyzed.

Reasons Given for Evacuating

Figure 9 depicts the reasons given for leaving. It should be noted that these answers were in response to an open-ended question in which people simply volunteered reasons. Asking specifically whether each factor played a role in their decision to leave would have almost certainly resulted in more people attributing their decision to these factors.

It should also be noted that this is not the most reliable procedure for ascertaining what actually determined evacuation behavior. Most people are poor at articulating the factors which truly cause their behavior.

Reasons fall into two general types of response: information sources and information itself. Most evacuees in all 19 sites indicated that they left because of information from public officials, the National Weather Service, police, media, or friends and relatives. The proportions vary from place to place, but the media was mentioned more than other sources in most locations.

Evacuation in Gloria

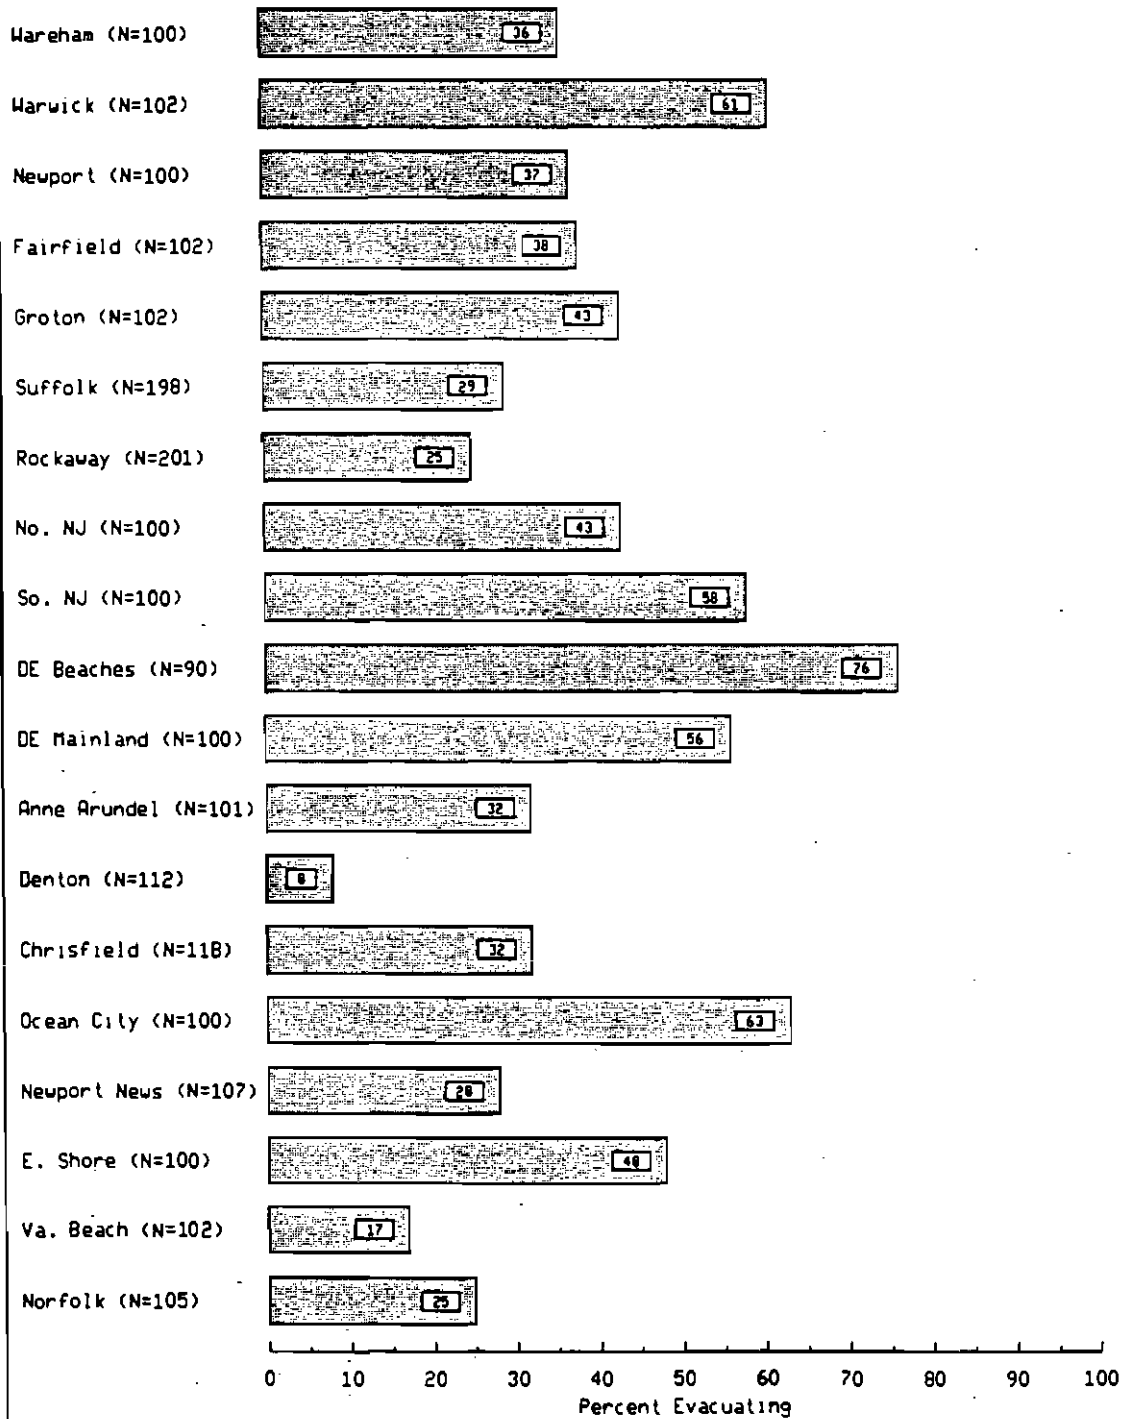

FIG. 8

Reasons Given for Evacuating

(Numbers do not sum to 100%)

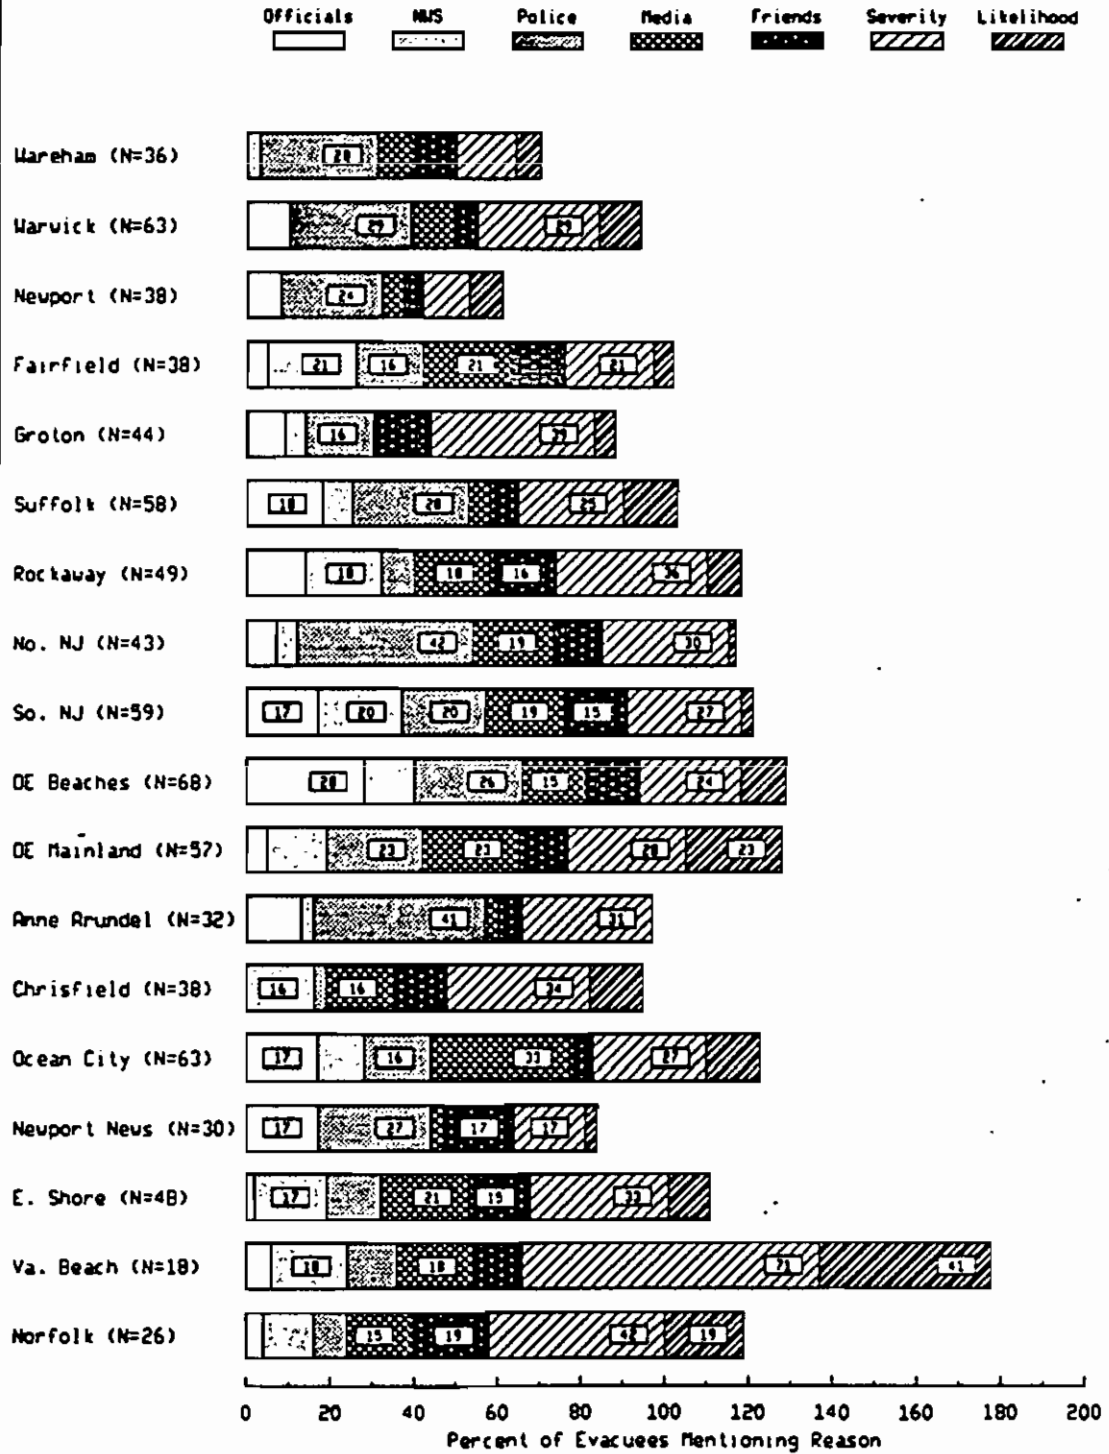

FIG. 9

The two sorts of information mentioned concerned either the severity of hurricane Gloria or the likelihood that the storm would strike the respondent's location. Severity was cited more frequently than likelihood of hitting.

Effect of Evacuation Notices

Figure 10 shows the percentage of interviewees who, when asked explicitly, said they that public officials in their area said they should evacuate. Affirmative responses do not necessarily mean that officials actually said the respondents should leave, but the respondents believed that to have been the case. At 7 sites more than 45% said they heard officials say to leave. The beach area of the Delaware sample was highest at 74%. Denton was by far the lowest at 6%. It is no coincidence that the Delaware beach sample also had the highest evacuation rate and Denton the lowest.

Figure 11 illustrates the point even more clearly. In every survey site, people who said they heard evacuation notices from officials were substantially more likely to evacuate than those who said they didn't hear such notices. Only in Delaware and Ocean City, MD were the differences small, but in those instances a high percentage of both groups left. Overall, as indicated by the two sets of bars at the bottom of the graph, people hearing from officials that they were supposed to evacuate were three times as likely to evacuate as others.

Most people saying they heard an official evacuation notice understood the notice to be a recommendation rather than a mandatory order (Fig. 12). Respondents believing they were being ordered to evacuate were much more likely to leave than those who believed the notice was advisory (Fig. 13). In the northern sample 93% "hearing" an order evacuated, as did 84% in the southern area.

The effect of perceived notices and orders in Gloria was exactly the effect observed elsewhere in other hurricanes. If officials want residents to evacuate, they must tell them. But if they tell them, compliance will be good.

Percent Hearing Officials Say to Evacuate

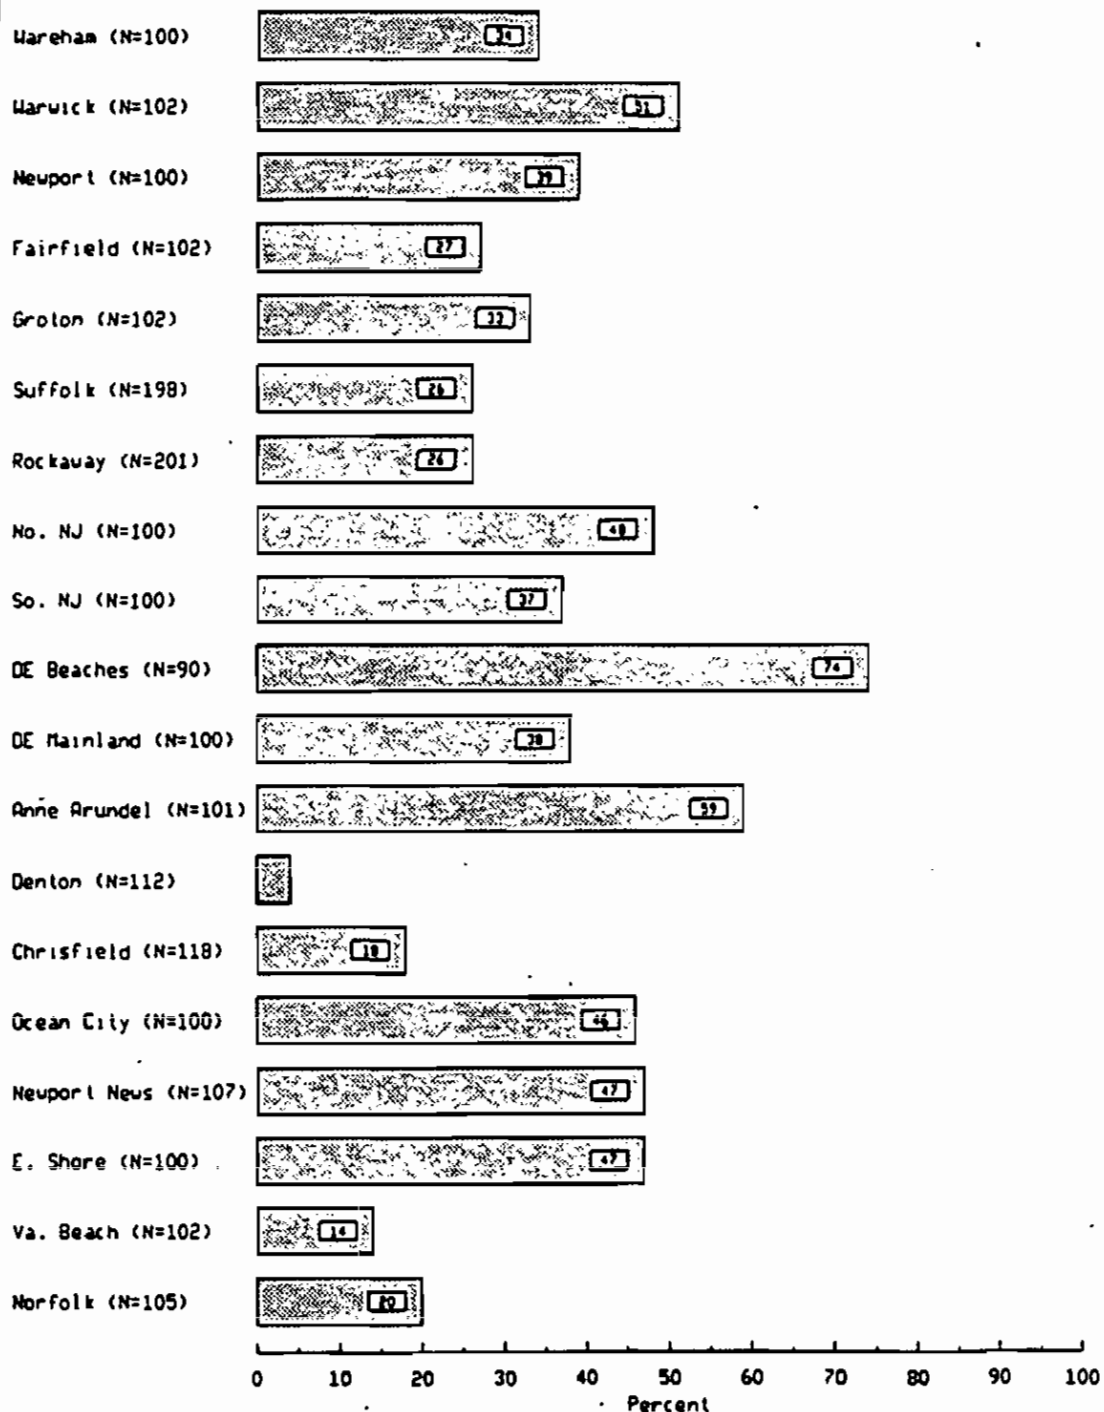

FIG. 10

Evacuation in Gloria Heard Evacuation Notice vs. Didn't Hear

FIG. 11

Percent Hearing Order vs. Recommendation

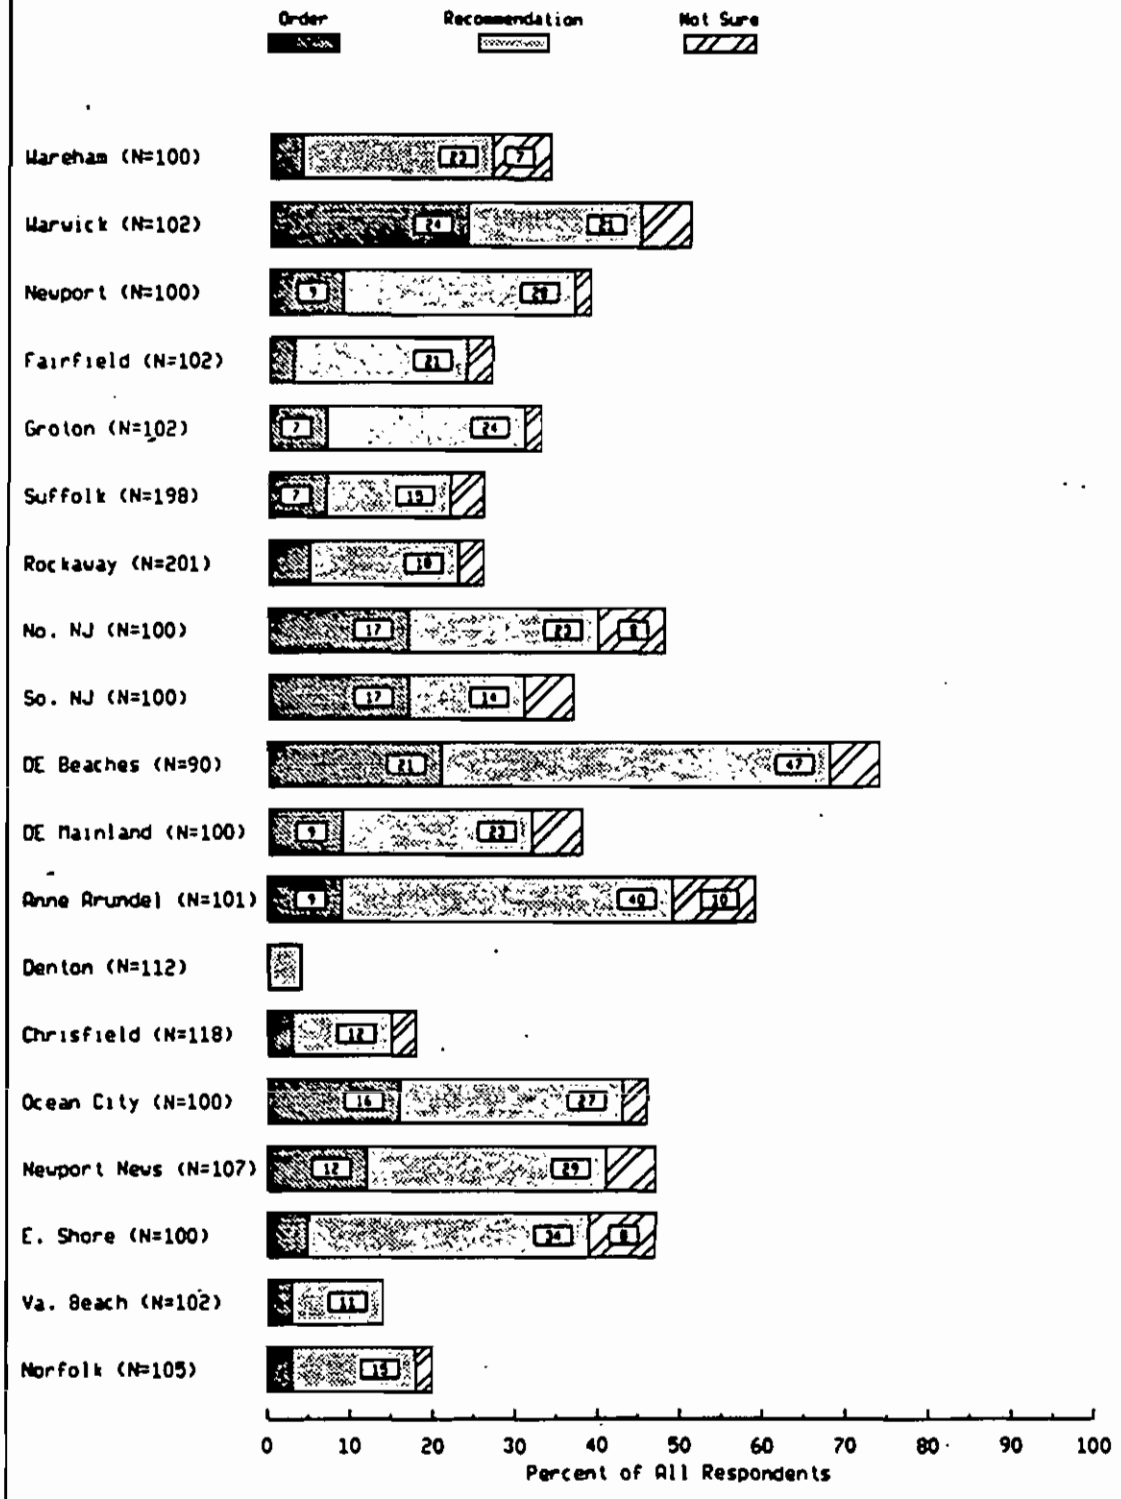

FIG. 12

FIG. 13

It is also important that roughly 25% of the people not hearing official evacuation notices also left. The "shadow" evacuation phenomenon, whereby more people leave than actually need to, is common.

Effect of Perceived Safety

Proximity to water is not a perfect surrogate for hazardousness of a dwelling because elevation might rise quickly only a short distance from the shore or flooding might extend miles inland. In general, though, people who lived closer to the water were more likely to evacuate than other people (Fig. 14). The only confusion in the trend was in the southern sample where people living within a block of water appeared slightly more likely to evacuate than waterfront residents.

This pattern is common in hurricane evacuations and predicted by the general response model. Officials are more likely to tell people in more hazardous locations to evacuate, but residents of those areas are also more aware of the risk they take in staying.

Interviewees in the northern sample were asked whether they felt their house would be safe in a hurricane. A majority in all sites except Warwick felt their home would be safe, but in all locations a substantial minority considered their dwellings unsafe (Fig. 15). People believing their house was unsafe were more than twice as likely to evacuate as others (Fig. 16). The fact that only about half those saying their home would be unsafe evacuated in Gloria attests to the fact that more than belief that one's dwelling is dangerous is necessary to compel people to evacuate. Figure 17 depicts the association between belief one's house is safe (unsafe) and proximity to water.

Evacuation in Gloria by Proximity to Water

FIG. 14

FIG. 15

FIG. 16

Belief House Safe by Proximity to Water

FIG. 17

Reasons Given for Not Evacuating

The most common reason given for not evacuating in Gloria was that respondents felt safe staying where they were -- either they didn't believe the storm was severe enough to threaten their dwelling or the storm wouldn't strike their area (Fig. 18). A variety of other reasons were also volunteered.

Reasons attributing the decision to not evacuate to specific types or sources of information are graphed in Figure 19. As many as 19% (in Denton) said they stayed because officials didn't tell them to leave. Many respondents said they stayed for reasons having nothing to do with safety or information (Fig. 20). In only three survey locations (Rockaway, Denton, and Ocean City, MD) did anyone say they failed to evacuate because they had no transportation. A number in most places, however, said they stayed because they had no place to go.

There are no clear differences in reasons given across the region as a whole to distinguish the area from other locations in other hurricane threats.

Other Predictors and Non-predictors

Housing varied too little to test for response differences in all but two locations. Thirty-nine percent of the Rockaway sample contained high-rise residents, and only 8% of them evacuated, compared to 40% of single-family homes. In the Delaware mainland sample 45% of the dwellings were mobile homes, 75% of which were evacuated, whereas only 35% of other housing was evacuated. The mobile home finding is common, but there has been little comparative evidence elsewhere concerning high-rise dwellings.

Neither income nor age were associated with whether people evacuated. Income is seldom found to predict evacuation in other parts of the nation. Age is usually a factor only in areas where there are a large number of retirees such as south Florida.

Stayers Not Leaving in Gloria Saying They Felt Safe.

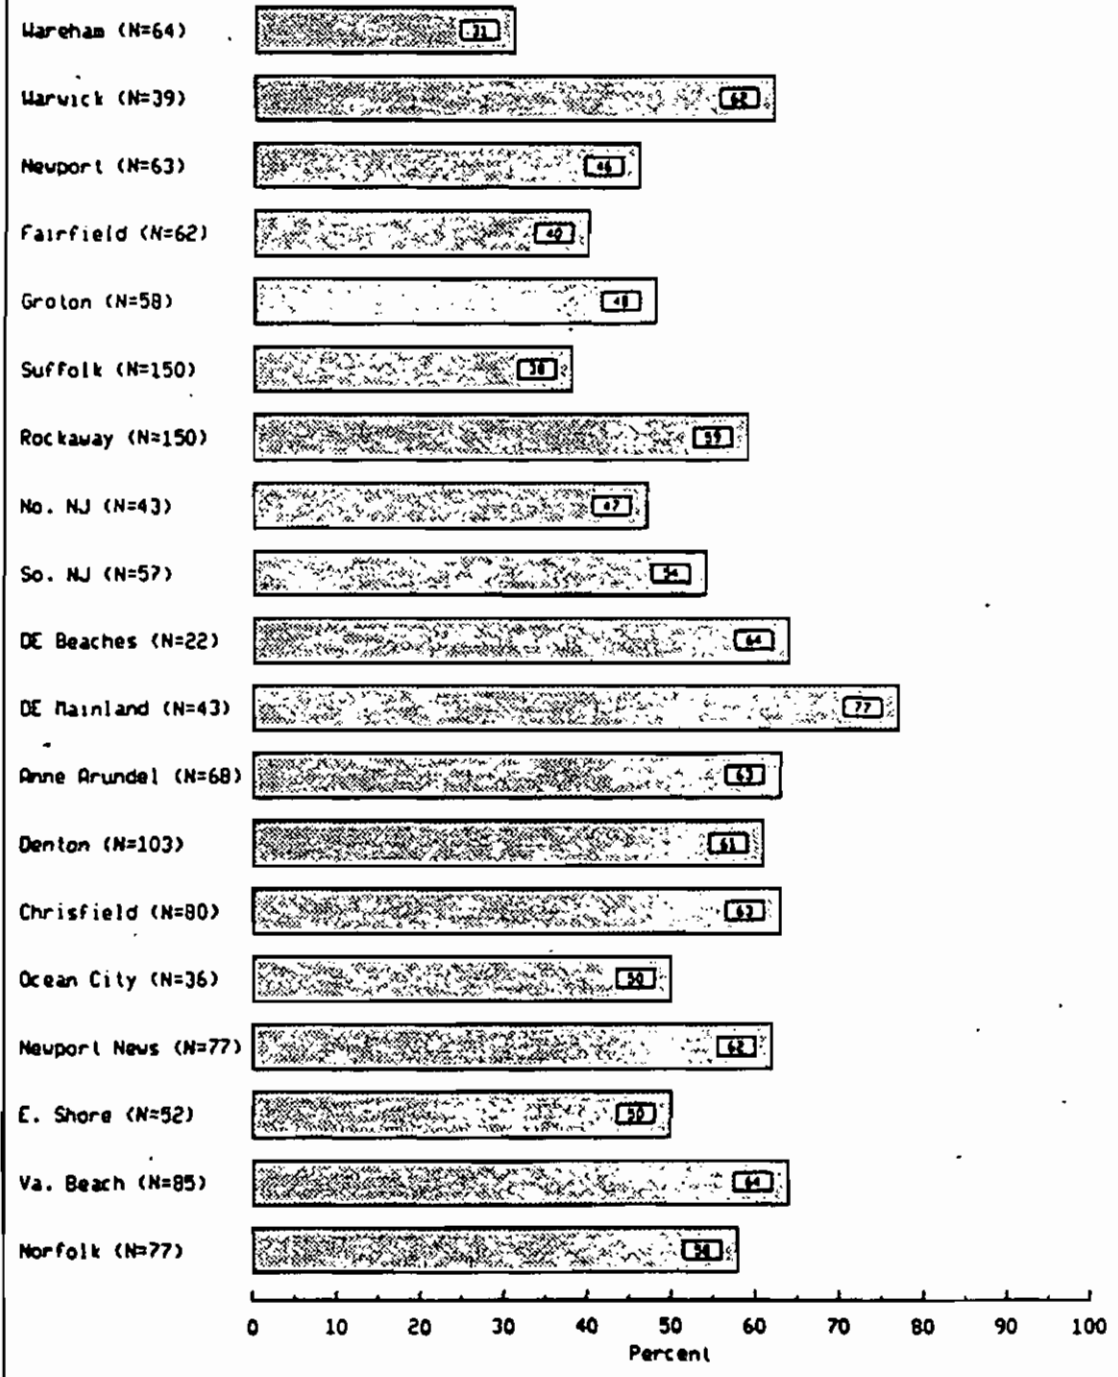

FIG. 18

Stayers Not Leaving in Gloria Saying They Stayed Because of Specific Information

FIG. 19

Stayers Not Leaving in Gloria Saying They Stayed for Reasons Other Than Information

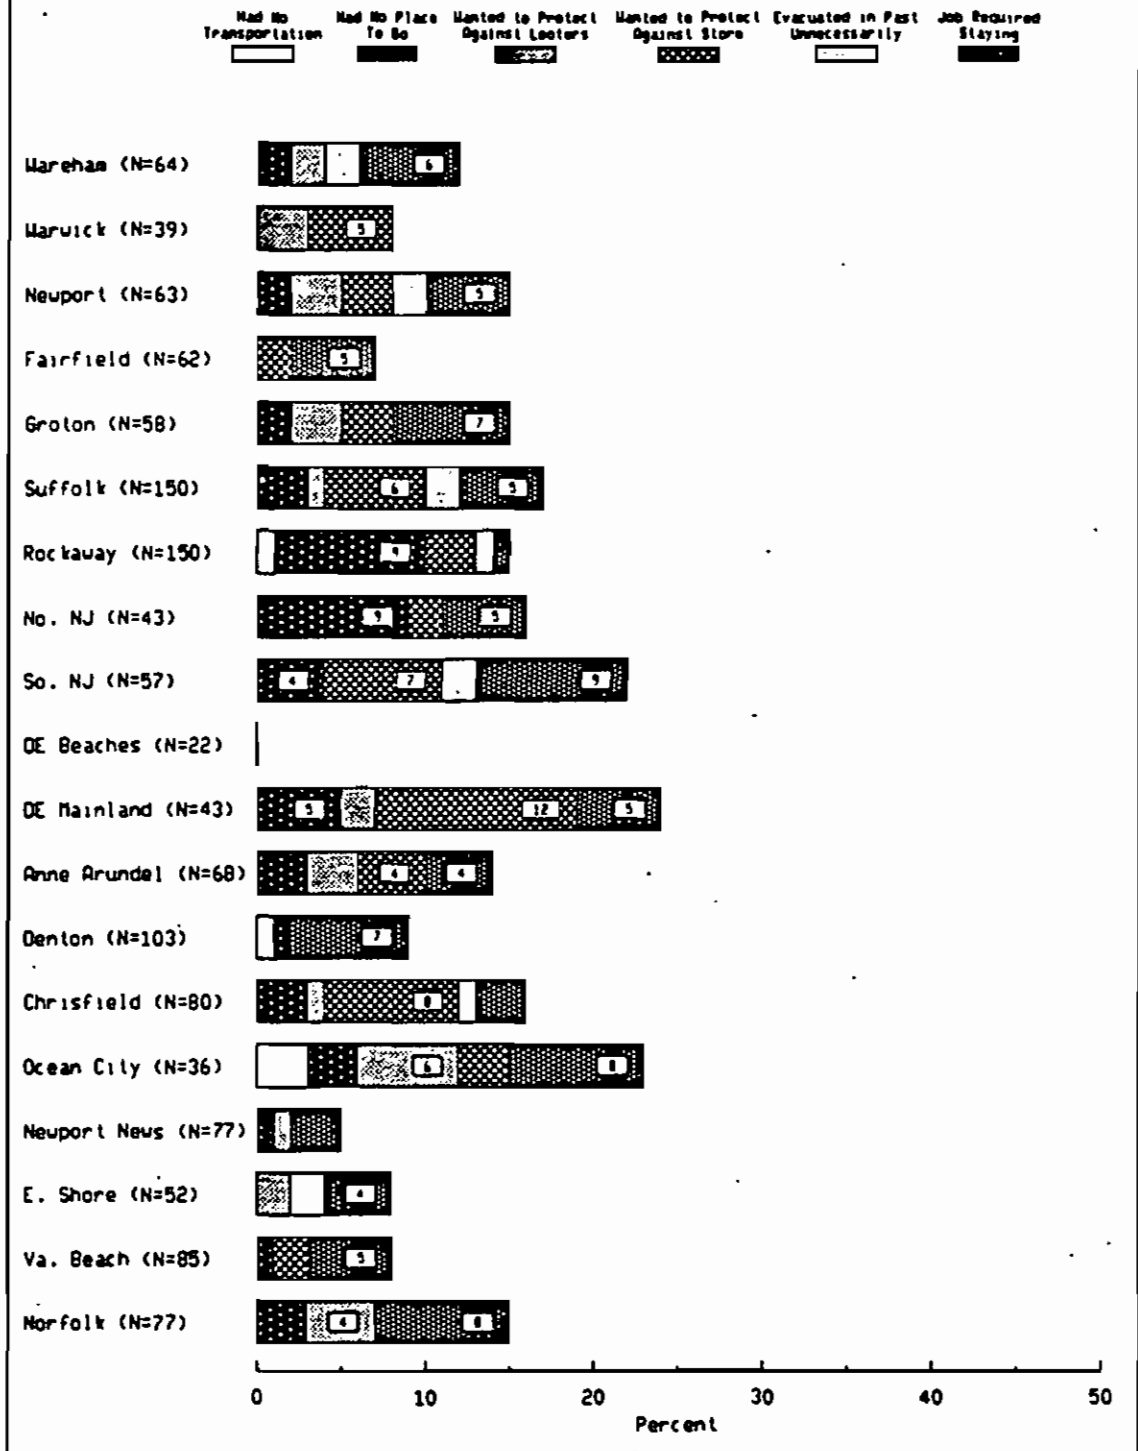

FIG. 20

In the northern area income was not correlated at all with proximity to water, and in the southern area, the association wasn't strong (Figure 21). In neither area was age related to water proximity. Elderly residents were slightly more likely to say their house would be safe in a hurricane than other respondents (Fig. 22).

FIG. 21

FIG. 22

Evacuation Timing

Evacuation timing is concerned with how many of the eventual evacuees leave at various times after (or before) being told to evacuate or relative to the arrival of a hurricane. Figure 23 shows the date on which Gloria evacuees said they evacuated. Clearly and understandably, people left earlier in the southern area than in the northern. This was undoubtedly a consequence of the fact that the storm threatened southern sites earlier and officials told people earlier to leave.

Evacuees were also asked what time of day they left. Plotting that data yields a cumulative evacuation curve like the ones in Figure 24 for the two Delaware survey locations. In this particular case, such curves could be misleading, however. Respondents are being asked to recall the time of day they did something two years earlier, and recall might not be good enough to place great confidence in such specific information. Even if people could remember accurately, the sample sizes make the exact shape of the plotted curves suspect.

These considerations present no difficulty in deriving planning assumptions for the region, however. Other evidence has already shown that most people didn't evacuate in Gloria without being told to do so by officials. The timing of evacuation notices, therefore, will be the primary determinant of evacuation timing, just as it is in other locations. Just how promptly people will leave after being told can't be generalized from a single evacuation in any case. People will leave as promptly or as leisurely as they believe they must, based upon information available during a particular threat. Planning recommendations, therefore, will contain three different response timing curves, each fitting a set of circumstances which are plausible at each study location.

Date Evacuees Left

FIG. 23

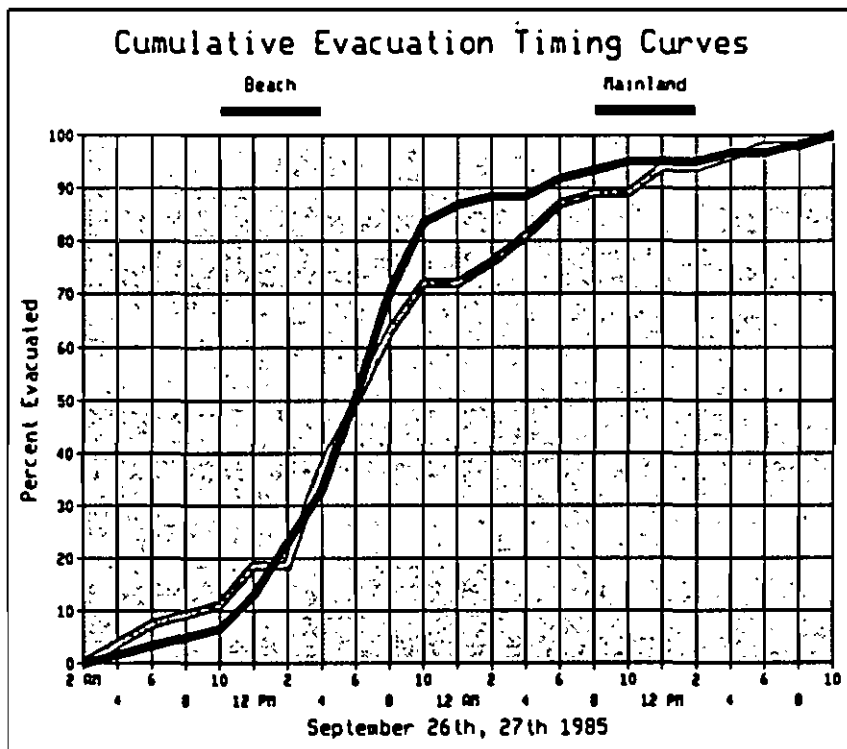

FIG. 24

Types of Refuge Used

Response in Gloria

Figure 25 indicates the types of refuge used by evacuees in Gloria. Bear in mind that in most of the samples fewer than 50 people evacuated, yielding only marginally reliable data on this variable. (A sample of 50 will yield data accurate within 10 percentage points of the population value 90% of the time.)

In all but five survey sites a fourth or fewer of all evacuees went to public shelters, but there was widespread variation from site to site. Anne Arundel and Newport News had the highest shelter use rates, at 49% and 45% respectively, but both also had relatively few total evacuees (33 and 29). Newport, RI had the lowest use of public shelters, but Warwick, Rockaway, southern New Jersey, and Norfolk also had very low shelter use rates. Very few people evacuating out of their own town went to public shelters, but more did so in the southern sample than in the northern (Figure 26).

The "other" category was large in some locations. The most common of these responses was going to a second home the respondent owned, their place of work, or to a church not being operated as a Red Cross shelter.

(Non)Predictors of Shelter Use

Common predictors of public shelter use were not verified in the Gloria data. It is unclear whether the region is different, Gloria was different, or idiosyncrasies of the data set simply make verification impossible.

Refuges Used in Gloria

FIG. 25

FIG. 26

For example, income is normally associated with shelter use: low income evacuees are usually more likely to go to public shelters than more affluent evacuees. There is some evidence to support the notion in the Gloria data. Newport News and Chrisfield, with the highest incidence of low income residents in the samples, had two of the highest rates of public shelter use. Anne Arundel, however, with the highest shelter use rate, also had the lowest percentage of surveyed households reporting incomes below \$10,000/yr.

Because of the small number of evacuees and even smaller number of public shelter users at each interview location it was not possible to test reliably for associations between income and shelter use in each location. When the samples were aggregated into northern and southern areas to increase sample sizes, no relationship was found between income and shelter use. Aggregating samples, however, can sometimes obscure relationships which exist at lower levels, and that could be occurring in this case. For example, actions by local officials can either encourage or discourage shelter use at the local level. As such actions undoubtedly varied from site to site in Gloria, lumping all the sites together would tend to make it more difficult to detect the effect of other factors such as income. There is also the larger question of whether respondents were candid about their actual incomes and whether the refusal of many people to answer that question might have affected these tests.

Another common predictor of shelter use is hazardousness of one's location. Evacuees from dangerous places such as barrier islands are less likely to use public shelters than evacuees from low-risk areas. Again, there is evidence of this at one scale in the Gloria data: Evacuees from the Delaware beach sample were much less likely to use public shelters than Delaware mainland evacuees. Other beach sample areas such as Ocean City, MD, and the New Jersey samples had some of the lowest shelter use rates.

Sample sizes were too small in individual survey sites to test whether people living farther from water bodies were more likely to use public shelters. When the data was aggregated into northern and southern areas, no relationship was found.

Age is not usually associate with shelter use except in retirement areas, and this proved also to be the case in Gloria.

Hypothetical Refuge Use

Respondents who didn't evacuate in Gloria were asked what sort of refuge they would have sought if they had evacuated. As indicated in Figure 27, hypothetical shelter use was much higher than actual use in most locations. An initial interpretation might be to infer that the people who didn't evacuate in Gloria were actually more prone to use public shelters than those who did evacuate. This relationship between hypothetical and actual shelter use is common, however, and the very same individuals who say they would use public shelters are actually about half as likely to as they themselves believe. Figure 28 compares intended and actual shelter use in a number of locations and storms.

In some surveys people who said they would use public shelters were then asked whether they had friends or relatives in safe locations with whom they could stay if necessary. Most answered affirmatively. Those were then asked whether they might not actually stay with those friends and relatives rather than going to a public shelter. Again, most answered affirmatively, indicating the tenuousness and instability of the hypothetical response.

One reason that actual shelter use tends to be lower than hypothetical is that during hurricane threats, people tend to contact one another, with residents in safe locations often inviting and even urging friends and relatives to come to their houses. Thus options become available that might not have been assumed during a

Hypothetical Refuges

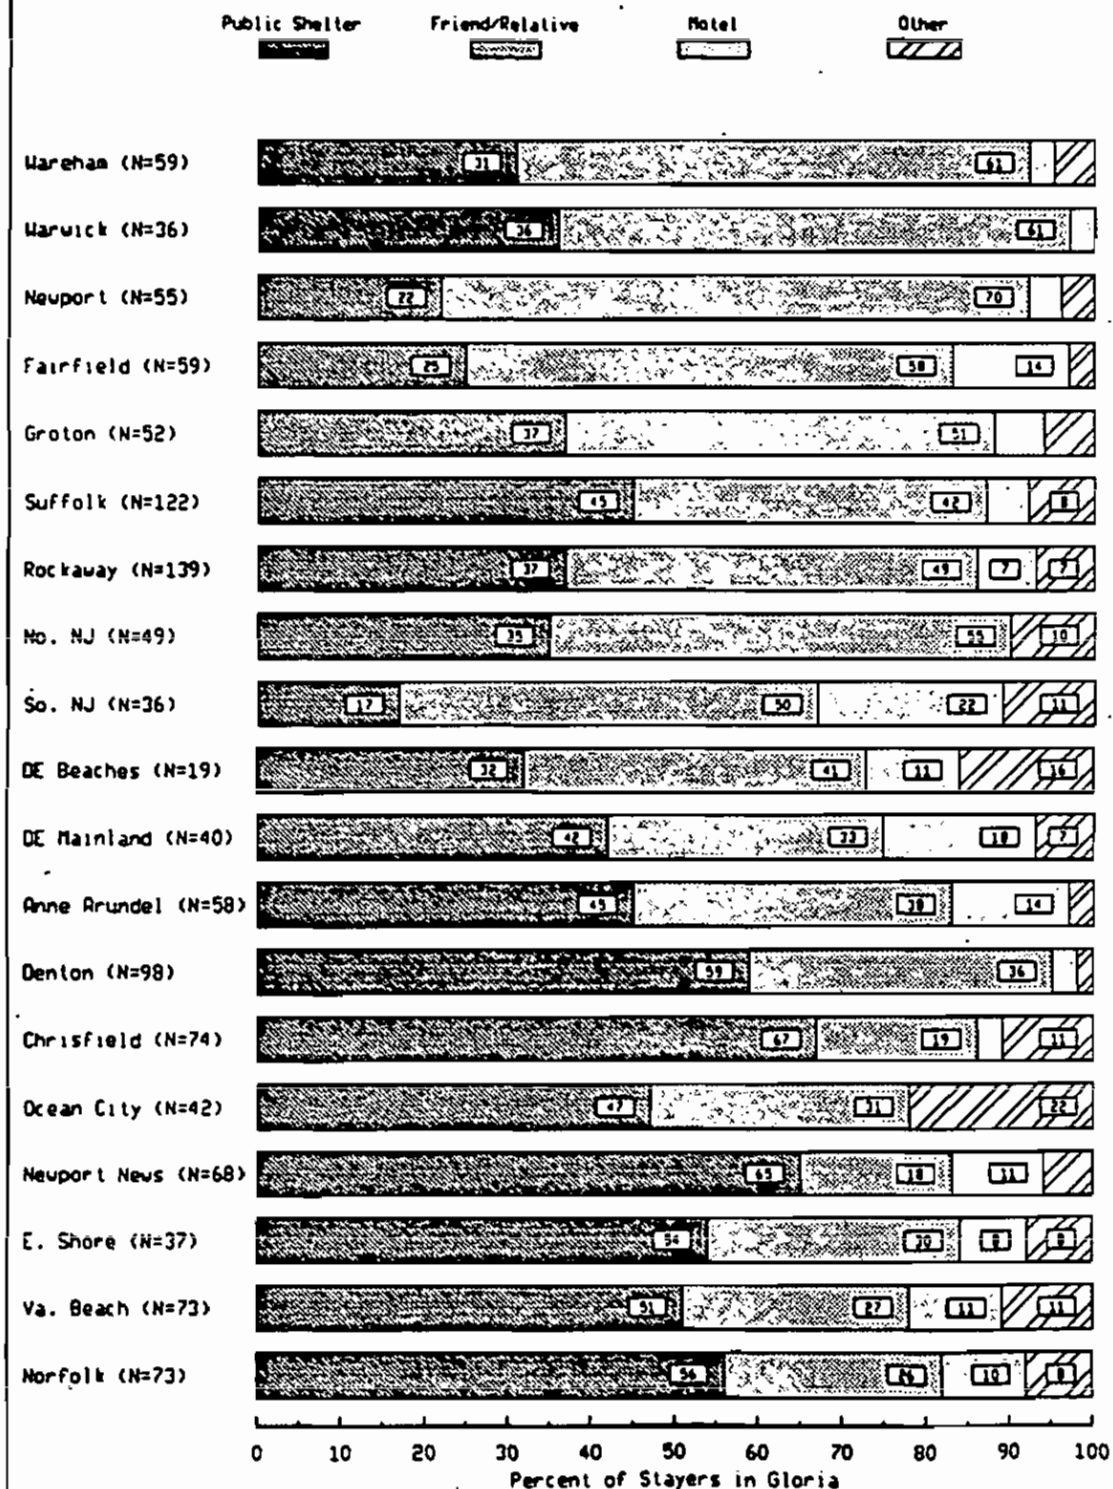

FIG. 27

FIG. 28

hypothetical interview. It is also likely that as evacuation nears, people consider the pro's and con's of public shelters more carefully, with many deciding in retrospect that public shelter conditions are not so attractive after all.

Although hypothetical shelter use figures are not reliable in the absolute sense, they do have some validity in a relative sense. That is, if more people in one location say they would use public shelters than people in a second location, more of them probably will actually use public shelters in an evacuation, although the hypothetical numbers from both groups are inflated. More people in the southern area sample said they would use public shelters than in the northern sample, for example. This also appeared true, but less definitely, in the actual response data.

It's interesting that the income vs. shelter use relationship discussed earlier and not verified in Gloria is clearly present with hypothetical shelter use data (Figure 29). This gives a bit more reason for applying the generalization when deriving planning assumptions for the region.

Hypothetical Shelter Use by Reported Annual Family Income

FIG. 29

Evacuation Destinations

Response in Gloria

There was much variation from site to site with respect to whether evacuees in Gloria left their local areas (usually meaning towns) or sought refuge nearby (Figure 30). Only 7% of the evacuees in Newport News left their local area, compared to 88% in the southern New Jersey area. In half the locations more than 50% of the evacuees went out-of-town.

Figure 31 suggests, though, that most evacuees didn't go very far, even if it was out-of-town. In 13 of 18 sites more than half the evacuees said they reached their destination in 30 minutes or less. In the New England states between 83% and 100% of the evacuees took less than 30 minutes.

It was noted previously that very few of the people going out of their local area went to public shelters, and that is common throughout the Gulf and Atlantic coasts. In most locations people in the highest risk locations (barrier islands primarily) are more likely to go out-of-town than evacuees from lower-risk areas. The proximity-to-water test tends to verify that generalization for Gloria in the southern area but not in the northern area (Fig. 32). Proximity to water, however, is not a good surrogate for hazardousness in all locations or when comparing one site to another. When simply looking at interview sites consisting primarily of beach areas (Delaware beaches, southern New Jersey, Ocean City, MD, etc.), it appears that those locations had substantially more evacuees leaving the local area and taking more than 30 minutes to reach their destinations than did most other sites.

Evacuees Going Out-of-Town

FIG. 30

Evacuees Reaching Destination in 30 Minutes

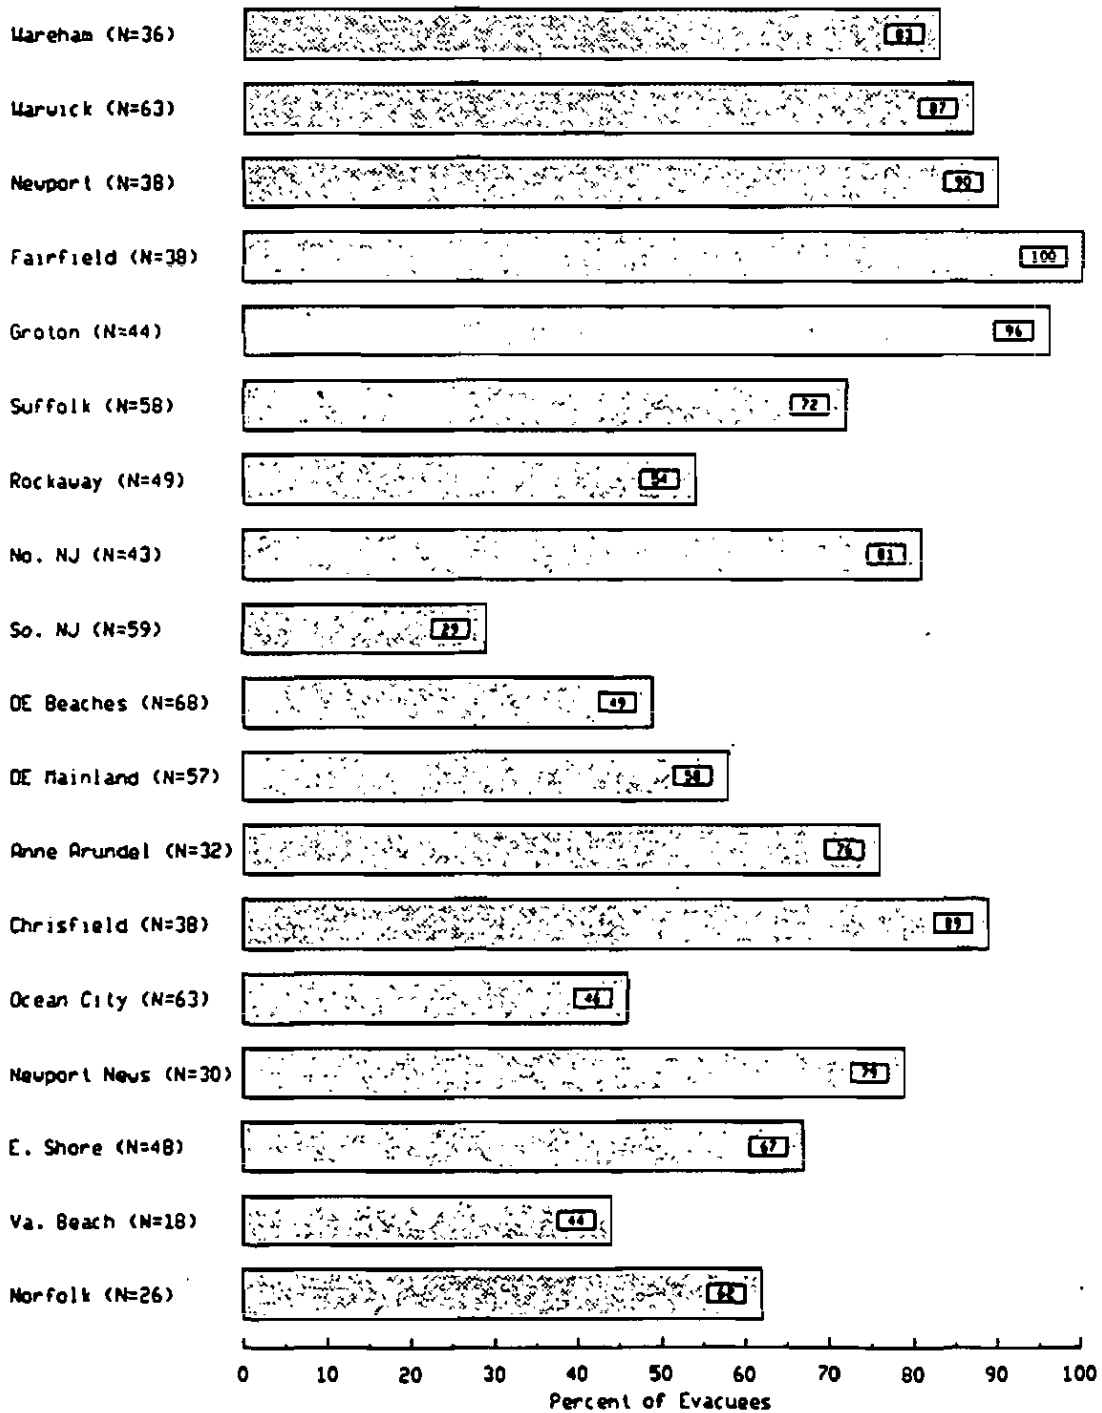

FIG. 31

Evacuation Out-of-Town in Gloria by Proximity to Water

FIG. 32

Income can also be a clue to whether evacuees will leave their local area. This probably results from the fact that people with higher incomes are more likely to live near the beach, they are less likely to use public shelters, and they can more easily afford motels. In the Gloria data there was no income vs. out-of-town evacuation relationship in the southern sample, but there was in the northern area (Fig. 33).

Hypothetical Responses

In the northern area people who didn't evacuate in Gloria were asked where they thought they would have gone if they had evacuated. The results were fairly consistent with actual response data for the sites (Fig. 34). Higher income respondents were somewhat more likely to say they would leave the local area (Fig. 35).

Evacuation Out-of-Town in Gloria by Reported Annual Family Income

FIG. 33

Hypothetical Out-of-Town Evacuation

FIG. 34

FIG. 35

Vehicle Use

Household Transportation

The great majority of evacuees in Gloria used only one vehicle, although some used more (Figure 36). That is almost always the case in hurricane evacuations. Figure 37 shows two additional variables: the percentage of available vehicles actually used by evacuating households and the average number of vehicles used per evacuating household. The average ranged from 1.0 to 1.5. In most cases between 65% and 75% of the vehicles available to households are actually used in evacuating. Fourteen of eighteen Gloria sites were within one percentage point of that range. The Delaware beach sample was abnormally high, and Virginia Beach and Anne Arundel were unusually low. Not all vehicles are used in evacuations because families want to avoid separating any more than necessary.

Public Transportation

In the northern area evacuees were asked what sort of transportation they used (Fig. 38). Almost everyone said they left in their own vehicle. Only in Rockaway did anyone mention using public transportation. Northern area respondents not leaving in Gloria were asked whether they had a car available in which to evacuate if they had chosen to (Fig. 39). Only in Rockaway, and to a much lesser degree Newport, did people say no. Recall also that people in only three sites said they didn't leave because of a lack of transportation (Ocean City,

Number of Cars Used in Gloria

FIG. 36

Percentage and Average Vehicle Use in Gloria

FIG. 37

FIG. 38

Car Available in Households Not Evacuating in Gloria

FIG. 39

MD, Denton, and Rockaway) and in those cases it was 5% or fewer (of the nonevacuees). Rockaway (the question being asked only in the northern area) also had the greatest incidence of people saying they would need to use public transportation if they evacuated (Fig. 40).

Evacuation Assistance

Evacuees in all sites were asked whether they required outside assistance in evacuating in Gloria (Fig. 41). Very few said they did. In most locations no one said they needed help from an agency to evacuate, and of those who did, the figure was 5% or less every place except Chrisfield where it was 11% (+ or - 10% points).

Respondents not evacuating in Gloria were asked whether they would need help if they evacuated (Fig. 42). The question was asked the same way in the northern and southern areas, but responses were coded in more detail in the northern area. Thus, in the southern area there is the "yes, general" category, whereas in the northern area it is broken down into "yes, agency" and "yes, other." Variation in response was substantial from site to site. Where they could be specific, few said they would need agency assistance. In the southern area it's probably reasonable to assume that agency dependence would be comparable to that mentioned in the northern area. Newport News had the highest overall percentage saying help would be needed from someone outside the home.

These figures are not unusual. Most help from outside the household usually comes from friends and relatives. Even when residents believe they would require agency assistance, friends or relatives usually fill the need instead.

Questionnaire Used in Survey

HURRICANE GLORIA/MID-ATLANTIC/NORTHEAST SURVEY
 PHASE II
 NOVEMBER, 1987

1. Did you leave your home to go someplace safer in response to the hurricane threat?

----- 1 Yes (GO TO Q.2)
 5 No (SKIP TO Q.11)
 7 Other (GO TO Q.2, IF APPLICABLE)

- > 2. Did you go to a:

1 Public Shelter
 3 Friend or Relative's Home
 5 Hotel/Motel
 7 Other (_____)

3. Where was that located?

1 Locally (in same town as residence)
 5 Out-of-town (_____)
 (Specify name of town)

4. What convinced you to go someplace safer?
 (CODE UP TO 3 RESPONSES)

22 Advice or order by elected officials
 33 Advice from Weather Service
 44 Advice/order from police or fireman
 55 Advice from media
 66 Advice from friend/relative
 77 Concern about severity of storm
 88 Concern that storm might hit
 91 Heard probability (odds) of hit
 95 Other: (_____)
 (Specify)

5. When did you leave your home to go someplace safer?

TIME: : AM

PM

DATE:

M	T	W	R	F	SA	SU
23	24	25	26	27	28	29

6. How long did it take you to get to where you were going?

__ __ Hrs (to nearest 1/2 hr)

(Never reached original destination=99.9)

7. When did you first return home from the place to which you evacuated?

T	W	R	F	SA	SU	M	T
24	25	26	27	28	29	30	31

8. Did you or anyone in your household require special assistance in evacuating?

- 1 No
- 3 Yes, by agency
- 5 Yes, by friend or relative within household
- 7 Yes, by friend or relative outside household
- 9 Don't Know/Not Sure

8a. Did your household use your own vehicle(s) in evacuating, leave with someone else in theirs, or did you use public transportation?

- 1 Own
- 3 Other's
- 5 Public Transportation
- 7 Other _____

9. How many vehicles did your household take in evacuating?

10. How many vehicles were available to take in evacuating?

_____ (GO TO Q.12)

NON-EVACUEES ONLY

11. What made you decide not to go anyplace else?
(CODE UP TO 3 RESPONSES)

- 05 Storm not severe/house adequate
- 20 Officials said evacuation unnecessary
- 30 Media said evacuation unnecessary
- 35 Friend/relative said evacuation unnecessary
- 45 Probabilities indicated low chance of hit
- 55 Information indicated storm wouldn't hit
- 60 No Officials said to evacuate
- 65 Had no transportation
- 70 Had no place to go
- 75 Wanted to protect against looters
- 80 Wanted to protect against storm
- 85 Left unnecessarily in past
- 90 Job required staying
- 95 Other: _____

FOR EVERYONE:

12. Did you hear from anyone in an official position -- civil defense, the mayor's office, the governor, police -- that you should evacuate to a safer place?

1 Yes
 ----- 5 No (GO TO Q.14)
 ----- 9 Don't Know (GO TO Q.14)

13. Did they say that you should evacuate or that you must evacuate?

1 Should
 5 Must
 9 Don't Know

- >14. How well do you think the warning and evacuation process was handled in the Gloria threat?

11 Good/DK
 22 Traffic a problem
 33 Not enough information
 55 Shouldn't have been told to evacuate
 66 Shelters bad, crowded, etc.
 77 Other: _____

- 14a. Do you think your home would be safe to stay in if a major hurricane were to strike this area directly?

1 No
 3 Yes
 5 Don't Know

15. Would you do anything differently if you were in the same situation again? (CODE UP TO 3 RESPONSES)

11 Would evacuate
 22 Wouldn't evacuate
 33 Would leave earlier
 44 Would wait later to leave
 55 Would go further away
 66 Wouldn't go as far
 77 Would go to public shelter
 88 Wouldn't go to public shelter
 90 No
 95 Other _____

EVACUEES, SKIP TO Q.18

NON-EVACUEES ONLY

16. If you evacuate in a future hurricane, would you go to:

- 1 A Friend/Relative's Home
- 3 A Hotel/Motel
- 5 A Public Shelter
- 7 Other
- 9 Don't Know/Not Sure

16a. Where specifically would you go if you evacuated, someplace local or someplace out-of-town?

- 1 Local (same town/borough as residence)
- 5 Out-of-town (borough) (_____)
- 9 Don't Know

17. Would you or anyone in your household need special assistance from anyone outside the household in evacuating?

- 1 Yes, from government agency
- 3 Yes, from other
- 5 No
- 7 Other _____

17a. Do you have a car or other vehicle to use in evacuating?

- 1 Yes
- 3 No
- 5 Other

17b. If you evacuated, would you need to use public transportation?

- 1 Yes
- 3 No
- 5 Other
- 7 Don't Know

ASK OF ALL RESPONDENTS

The following questions are for statistical purposes only.

18. Which of the following structures do you live in?

- 1 High-rise (6 or more stories) Condo or Apartment
- 3 Detached Single Family Building
- 5 Mobile Home
- 7 Other
- 9 Don't Know/Refused

19. How far is your home from the water?

- 1 Waterfront on beach
- 3 Waterfront on Sound
- 5 Other Waterfront
- 2 Less than 1 block from beach
- 4 Less than 1 block from bay
- 6 Less than 1 block from water
- 7 More than 1 block, less than 1 mile from water
- 8 More than 1 mile from water
- 9 Don't Know/Refused

20. Which of the following ranges describes your household income for a year?

- 1 Less than \$10,000
- 3 \$10,000 to \$24,999
- 5 \$25,000 to \$39,999
- 7 \$40,000 to \$79,999
- 8 over \$80,000
- 9 Don't Know/Refused

21. How old were you on your last birthday?

- 1 Under 25
- 3 25 to 39
- 5 40 to 65
- 7 Over 65
- 9 Refused

Thank you, that completes our survey. Good Bye!

Hurricane Evacuation Behavioral Assumptions for Connecticut

Appendix to
*Hurricane Evacuation Behavior
in the Middle Atlantic and Northeast States*

U.S. ARMY CORPS OF ENGINEERS

October, 1988

Preface

This document is accompanied by a lengthier report titled *Hurricane Evacuation Behavior in the Middle Atlantic and Northeast States*, referred to hereafter as the "Main Report". That volume provides background information relevant to understanding the following discussion. In particular the Main Report describes methodology and data which form the basis for many of the recommendations included in this volume. On occasion this report will make reference to "MR-Fig. x", meaning a particular figure in the Main Report.

Sample survey results for two Connecticut locations are reported in this document, but the reader should be aware that they are included as "tests" of the general response model's applicability to Connecticut rather than to provide actual figures for evacuation planning. Even for the two sites themselves response in future hurricanes could be considerably different than that observed in Gloria.

**Severe Storm

90% 85% 60% 90% 70% 55%

Note:

Figures will be lower if officials are not successful in communicating orders.

Table 1. Evacuation rates to be used for planning in Connecticut.

Storm Severity

The table addresses two storm scenarios. The first is a strong storm, a category 3 or worse. The second storm is weaker. The difference obviously is that more people are at risk in the more severe storm, and evacuation will be greater from moderate-risk and low-risk locations.

Action by Officials

It is assumed that officials will tell people to leave from high-risk and moderate-risk locations and tell all mobile home dwellers in coastal counties to evacuate in the severe storm. In the weaker storm only mobile home residents and people who live in high-risk locations are told to leave.

It is also assumed that officials are successful at communicating the evacuation notices to residents. The Gloria data attests to the greater likelihood of people leaving if they believe officials have told them to. The only way to ensure that everyone will hear the notice is to have it disseminated door-to-door. If that is not possible, vehicles with loudspeakers are the second best method. If officials cannot disseminate the evacuation notices in either of those manners, evacuation rates will be 25% lower in high-risk areas and 50% lower in moderate-risk and low-risk areas.

Risk Area

High-risk areas refer primarily to barrier islands and other land areas exposed to the open ocean where wave battering and scour are major hazards in addition to flooding. Moderate-risk areas are subject to flooding in moderate to strong storms but do not experience significant battering and scour. Low-risk areas are subject only to wind and are adjacent to moderate-risk locations. Most of the

sample households in the two areas are located in high-risk to moderate-risk locations.

Housing

Table 1 distinguishes between mobile homes and other housing. Neither of the survey locations contained a large percentage of mobile homes, but they should be considered separately for planning. Evacuation will be greater from mobile homes than from other housing, all other factors being the same.

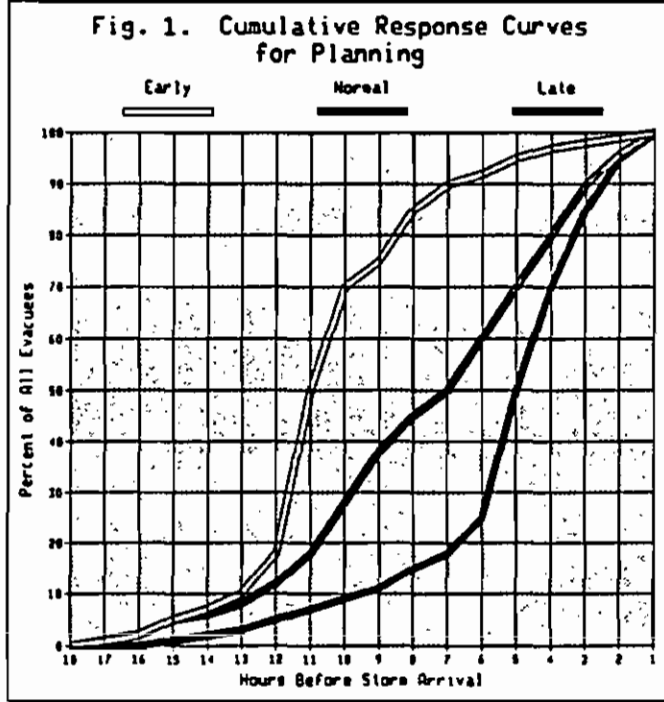

Evacuation Timing By Residents

With so few evacuees in the two samples, it's difficult to make very confident statements about the exact time evacuees left. The matter is further complicated by the fact that interviewees were being asked to recall fairly precise information from something that occurred two years previously. It appears, however, that evacuees began to leave somewhat earlier from the Groton area than from the Fairfield area (MR-Fig. 23). (Figure 23 in the *Main Report* is in error. Fifty-five percent of the Groton evacuees said they left on the 26th, not 21% as reported in the figure.) This probably reflects differences in the timing of actions taken by local officials.

Evacuation timing, however, will vary greatly from storm to storm, and little can be generalized from Gloria. For planning purposes three different sets of assumptions depicted in Figure 1 should be analyzed. The three curves in Figure 1 reflect three different rates at which evacuees leave, reflecting in turn three different levels of urgency.

The left-most curve represents response when forecasts are early and residents are told to evacuate with plenty of warning. That scenario should probably be called optimistic. The middle curve is probably more typical. Warning is not quite so early in relation to landfall. Finally, the right-hand curve will pertain when a storm accelerates, intensifies, or changes course unexpectedly. People will leave very promptly if it is made clear to them that they must. All three curves should be used for planning because all three will occur eventually.

Fig. 1. Cumulative Response Curves for Planning

Fewer than 20% of eventual evacuees will leave before being told to leave. When told, however, people will leave as promptly as they believe they must. Given the luxury of time, most people will not evacuate late at night and will wait until morning if they haven't left by 11 pm or midnight. People will leave in the middle of the night if officials make it clear that circumstances make it imperative that they do so. People from high-risk locations (barrier islands) tend to leave earlier than other evacuees.

Demand for Public Shelters by Residents

Few evacuees in either survey area used public shelters: 23% of the Groton evacuees said they went to public shelters compared to 11% of the Fairfield evacuees (MR-Fig. 25). Due to the sample sizes, however, both figures are subject to enough uncertainty to prevent the conclusion that there were overall differences in shelter use among all evacuees from the two areas. It's likely that overall differences were smaller than those found in the samples. Such figures are normal for high-risk and moderate-risk locations. Residents of beach communities usually have higher incomes and choose not to stay at public shelters and can afford motels if arrangements can't be made with friends and relatives. They also tend to leave earlier and go farther.

Late night evacuation tends to maximize shelter use, primarily because it is occurring with a sense of urgency, leaving no time to make alternative arrangements with friends, relatives, and motels or leaving too little time to travel the distance necessary to go out-of-town, particularly at night.

Hypothetical shelter use among non-evacuees was greater than actual use among evacuees (37% in Groton and 25% in Fairfield) (MR-Fig. 27). These hypothetical responses are typical of the 100% overestimation normally observed when comparing intended to actual shelter use. It does, however, tend to reinforce the notion that dependence upon public shelters will be greater in Groton.

Table 2, showing guidelines for projecting normal shelter demand, reflects these patterns. Late, urgent evacuations, which will roughly double normal shelter demand, are not a function of location. It should also be noted that emergency management officials in some communities encourage shelter use more than others,

and such policies should be taken into account in planning, because officials can take actions which either increase or decrease shelter use. Other factors to note are that retirees living in "retirement areas" are more likely to use public shelters than other groups, some communities have churches and other organizations which reduce "public" shelter use by being more active than normal in providing their own shelters, and some housing developments and mobile home parks provide onsite shelter which will alleviate demand for public shelter.

<u>Income</u>	<u>Risk Area</u>		
	<u>High</u>	<u>Mod</u>	<u>Low</u>
High	5%	10%	10%
Med.	10%	20%	30%
Low	-	40%	40%

Note:

Figures will be higher if officials encourage use of public shelters.

Figures will be lower for developments with on-site shelters (e.g., clubhouses).

Figures will be lower where churches and other organizations shelter members.

**Table 2. Evacuees going to public shelters:
planning assumptions for Connecticut.**

Evacuation Out-of-Town by Residents

Less than half the people evacuating from both survey areas went out-of-town: 45% in Groton and 35% in Fairfield (MR-Fig. 30). Almost everyone in both locations said they required 30 minutes or less to reach their destinations, however, suggesting that evacuees travelled very short distances (MR-Fig. 31).

Differences are accounted for primarily by income (low income residents don't go as far), evacuation timing (late night, urgent evacuees don't go as far), and risk area (evacuees from high-risk beach areas go farther). Table 3 reflects these generalizations. Note too, that emergency management officials can influence this response. In some locations agencies have policies to discourage evacuees from staying in the local area. Communities which aggressively provide and publicize public shelters will have fewer evacuees leaving the local area.

**Very Strong Storm,
Early Evacuation**

**Weak Storm
Typical Timing**

<u>Risk Area</u>			<u>Risk Area</u>		
<i>High</i>	<i>Mod</i>	<i>Low</i>	<i>High</i>	<i>Mod</i>	<i>Low</i>
75%	45%	25%	50%	30%	20%

Note:

- Figures will be lower for low income and elderly retired evacuees.**
- Figures will be lower for last minute evacuations.**
- Figures will be higher if officials encourage evacuees to leave area.**

**Table 3. Percent of evacuees leaving local area:
planning assumptions for Connecticut.**

Vehicle Use by Residents

The average number of vehicles used per evacuating household in Gloria was greater for Fairfield (1.5) than Groton (1.2) (MR-Fig. 37). More people in Fairfield used no vehicles at all, probably walking short distances to friends or to shelters or riding with someone else (MR-Fig. 36).

Normally 65% to 75% of the vehicles available to a household are used in evacuations, and both Connecticut survey locations fell within that range in Gloria (72% and 73%). For planning purposes it would be reasonable to assume that approximately 70% to 75% of available vehicles will be used in most evacuations.

No one in either sample said they required assistance from public agencies in evacuating (MR-Fig. 41), and no one said they used public transportation (MR-Fig. 38). Of those respondents who did *not* evacuate in Gloria, approximately 5% in both areas said they would have needed agency assistance if they had evacuated (MR Fig. 42). Even in communities where agencies prepare lists of people and addresses needing evacuation assistance, it is common to find that those people have already been provided for by friends and relatives when public vehicles arrive to collect them. No one in Groton and 7% of the stayers in Fairfield said they would use public transportation if they evacuated (MR-Fig. 40). Three percent of the stayers in Groton and 8% in Fairfield said they had no cars of their own available (MR-Fig. 39).

Section One INTRODUCTION

1.1 PURPOSE

The purpose of the Transportation Analysis is to estimate roadway clearance times for coastal Connecticut communities under a variety of hurricane evacuation scenarios. Clearance time is defined as the amount of time required for all vehicles to clear the roadways after a regional or state level hurricane evacuation recommendation is disseminated to the public. During an evacuation, a large number of vehicles have to travel on a road system in a relatively short period of time. A virtually infinite number of different vehicle trips are possible, varying by trip origination, time of departure, and trip destination. The number of vehicle trips becomes particularly significant for an area such as Connecticut's coast because its land areas are highly urbanized with many residents living near the immediate shore. The number of evacuating vehicles varies depending upon the intensity of the hurricane, actions taken by local authorities, and certain human behavioral response characteristics of the area's population. Motorists evacuating their homes and intermixing with traffic from people leaving work or traveling for other trip purposes can lead to significant traffic congestion and backups, ultimately delaying the evacuation.

The Transportation Analysis is one element of a much broader study entitled the Connecticut Hurricane Evacuation Study (HES). The Connecticut HES Technical Data Report presents the results of several technical analyses to provide emergency management officials with realistic data quantifying the major factors involved in hurricane evacuation decision-making. The technical data presented in the Study is not intended to replace the detailed operations plans developed by the State and communities. Rather, the data is intended to provide a framework within which each jurisdiction can update and revise hurricane evacuation plans and from which operation procedures and guides can be developed for future hurricane threats. Because the Transportation Analysis builds upon results from other analyses of the Study, in this report, reference is frequently made to information that is presented in detail in the Technical Data Report (TDR).

A transportation modeling methodology and a roadway representation were developed for all counties in the study area to conduct the analysis and estimate clearance times. This analysis establishes the clearance time portions of evacuation times. Clearance time is one component of the total time required for a regional hurricane evacuation to be completed. An additional time component, which considers the amount of time necessary for public officials to notify people to evacuate, must be combined with clearance time to determine the total evacuation time. More information on how decision-makers can use the results of this analysis is discussed in detail in Chapter 8, Decision Analysis, of the TDR.

1.2 STUDY AREA

The study area approximates most of the land areas and highway infrastructure of the four counties of Fairfield, New Haven, Middlesex, and New London, Connecticut. The road system under examination includes all State maintained highways from the New York State line to the Rhode Island State border, 12 to 18 miles inland from the coast. The analysis assumes evacuees originate from the 25 coastal communities and safe destinations include locations within coastal communities as well as locations farther inland, or in adjacent States. The Transportation Analysis was done at a state level, or macro scale, rather than at a community level because the intermixing of traffic from one community to the next was considered perhaps a leading contributor to delays in evacuations.

1.3 METHODOLOGY

The Behavioral Analysis discussed in Chapter Four presents information about which destination types evacuees are most likely to choose during an evacuation in Connecticut. The analysis concludes that people who evacuate surge areas are most likely to seek safe destinations at public shelters, friends'/relatives' homes, or hotels/motels. Although behavioral data provided in Chapter Four can give some guidance in predicting the actual geographic areas people will evacuate to and the evacuation routes people may use to reach their destinations, assumptions of this nature tend to be subjective. This is caused by the vast number of possible destinations and routes available to evacuees in highly populated areas. Clearance time calculations are further complicated by the affects of significant and varying amounts of "background" traffic that will be present on roadways as an evacuation progresses ("background" traffic refers to vehicle trips by people who leave work early and return home, people who travel through the region, and trips made by people preparing for the arrival of hurricane conditions or engaged in normal activities).

The study considered several approaches to estimate clearance times for the Connecticut study area. The first approach considered was the one used by the Corps of Engineers and the FEMA to complete hurricane evacuation studies in the Gulf and southern Atlantic coast states. This approach assigns destinations and evacuation routes for the evacuating population by matching probable evacuee destinations (determined by a behavioral analysis) with the land uses known for the region. A mathematical model of the study area's roadway system is then used to calculate clearance times based on the trip distributions assumed for the evacuation. The time required for all evacuees to reach their predetermined destination is considered the clearance time. As reported in a post-hurricane assessment of Hurricane Hugo in 1989, the transportation analyses conducted for the North Carolina and South Carolina Hurricane Evacuation Studies were found to be very accurate in that the clearance times experienced during evacuations were very near predicted times. These results give evidence that this approach is accurate for study areas with moderate roadway systems and where adequate behavioral data and landuse information is suitable to identify evacuation routes and predict the destinations of

evacuees. The following paragraphs explain some differences in the Connecticut study area in comparison to other areas, and give the reasons why the Corps of Engineers employed an alternative transportation modeling approach for Connecticut.

One concern in using the transportation modeling approach discussed above for Connecticut was the appropriateness of designating evacuee destinations and evacuation routes. Inundation areas in Connecticut are relatively narrow, but densely populated. The complex system of interconnecting freeways, undivided state routes, and numerous local streets offer evacuees, and others on the roadways, many possible travel routes to reach their destinations. The region is generally characterized by diverse land uses in small geographic areas. Hotels and motels are sporadically located in most communities, friends' and relatives' homes could well be distributed over the entire area, and Connecticut communities tend to open public shelters to accommodate their individual demands. The Study concluded that it is not practical to use the behavioral information developed for Connecticut to derive assumptions about evacuee destinations and evacuation routes. The Study did conclude that the behavioral response curves presented in the Behavioral Analysis, and used in other hurricane evacuation studies, are suitable to predict the general response of the people who live in vulnerable areas.

The second concern in using the modeling approach used in other studies was the relationship between the number of people evacuating from vulnerable areas in comparison to the number of background vehicles that would be on the roadways during evacuations. Although surge areas are densely populated, the relatively small land areas that they encompass include only a fraction of the region's total population. When viewing the region's roadways as an entire transportation system, most of the traffic on roadways during initial and mid stages of an evacuation is likely to be from people leaving work early and from vehicles passing through the region. The problem during evacuations is that evacuating vehicles are forced to compete for roadway capacity with a larger amount of background traffic. This can cause increased congestion, potentially delaying the overall evacuation. Because background traffic will travel in both directions on nearly all roadways during evacuations, the Study determined that the transportation methodology for Connecticut should not focus on assigning evacuation routes as typically done in other study areas. Instead, the methodology should focus on analyzing the influence background traffic can have on the overall evacuation.

To address the unique behavioral and transportation issues of the Connecticut study area, an alternative modeling strategy was used. A mathematical model of the road system was developed and calibrated to simulate the traffic flows of a normal week day. Traffic count data used to calibrate the model were available from the State's Department of Transportation (DOT), which collects information on vehicle movements, volumes, and other traffic data every day. The transportation modeling methodology assumes that the preferences of evacuees to travel on given routes are related to the

traffic patterns of a normal day, except where it is clear that evacuees will travel directly to public shelters. The large portion of vehicles associated with background traffic enables the methodology to neglect assigning specific destinations and evacuation routes to evacuees traveling to hotels/motels and friends'/relatives' homes. This is supported by the fact that Connecticut's large coastal business community and its generally narrow hurricane surge areas will give rise to evacuations involving traffic mostly attributed to people leaving work rather than people evacuating surge areas. Analysis of traffic data collected on the days Hurricanes Gloria and Bob further support this assumption. Accordingly, the modeling strategy used in Connecticut focuses on estimating clearance times which qualitatively measure how competition by evacuating traffic may affect, possibly delay, the movement of all traffic during an evacuation.

1.4 NETVAC2 TRAFFIC SIMULATION SOFTWARE

NETVAC2 evacuation simulation software was used to create a mathematical model representing the study area's road system. NETVAC2 is a special purpose, network evacuation computer model designed by the Massachusetts Institute of Technology in cooperation with HMM Associates, Incorporated. It was specifically designed to represent traffic flows over a transportation system during an emergency evacuation. This particular model was selected from several available models because it can be easily applied to model hurricane evacuations conducted in areas with complex roadway systems such as coastal Connecticut's.

NETVAC2 represents roadways as links and intersections connecting two or more roadways as nodes. Physical characteristics about representative links and nodes, and the logic connecting them are inputs to the model used in computing vehicle capacity constraints and legal turning movements. Traffic flows at nodes are subject to intersection approach capacity constraints, whereas traffic flow assignments on outbound links are subject to the volume capacities of the modeled roads. Capacities are based on the Highway Capacity Manual (Highway Research Board) and Interim Material on Highway Capacity (Transportation Research Board).

A complementary program for use with NETVAC2, entitled POPDIS, converts the population that is assigned to enter onto roadways to an equivalent number of vehicles. The user enters the vehicle occupancy rates and the number of people assigned to enter the network at each node. As many as five different population types can be specified. POPDIS aggregates the population input for each entry node and in turn computes the effective average vehicle loading rate per minute at each node.

As vehicles are modeled to move throughout the road networks, NETVAC2 utilizes dynamic programming theory to update vehicle densities, speeds, flows, queues, spillbacks and other relevant traffic information at a fixed time step prescribed by the user. Traffic assignments from links entering

and emanating nodes are made with each time step. One main feature of the model is that link assignments are made based upon the relative combinations of route preferences input for each node. The model also uses dynamic route selection such that route preferences are modified if significant backups exist at one or more emanating links. Vehicles preferring to travel on links undergoing heavy flows or large queues will be rerouted to another link of second preference. This is an important consideration when simulating hurricane evacuations because evacuees are not likely to wait in traffic for long periods of time if less restrictive, alternate routes are available to them.

Simulations terminate after all vehicles exit the road system. NETVAC2 model results include computer print files of node and link time history flow and queue data, departing vehicle summaries, total simulation time, and total vehicles on the road system at specified report intervals.

Section Two

MODEL DEVELOPMENT

2.1 GENERAL

The following sections discuss the coding assumptions made in applying NETVAC2 for modeling hurricane evacuations in Connecticut. The NETVAC2 User's Manual³ gives specific data format instructions and a complete description of all parameters required by the model.

The Connecticut DOT provided all of the roadway and intersection data for model development. Roadway and intersection data was primarily retrieved from printouts of state routes extracted from the State Highway Master File⁴ and the State Highway Log⁵ maintained by the DOT. The printouts contain detailed information such as the number of travel lanes and auxiliary lanes, lane widths, intersection approach widths, and total length of each road segment. Functional classification of routes and land use information are also listed. As networks were created, field surveys conducted at several locations verified that the modeling strategy and data input in the models were consistent with physical conditions.

2.2 ROAD NETWORKS

NETVAC2 allows networks with up to 500 links and 1000 nodes to be constructed. The vastness of the Connecticut study area necessitated that smaller networks dividing the study area be constructed and analyzed individually. For convenience, the region was divided into three, approximately equal sized areas with boundaries that generally conform to Fairfield, New Haven, and Middlesex/New London county boundaries. Figures 1, 2, and 3 show the link and node configurations that were used to represent the road systems of the three study areas.

For each link, the actual number of lanes, lane widths, total roadway length in feet, roadway type, surrounding land use, and lateral clearances from roadside obstructions were entered into a computer link file. Values for roadway lateral clearances were input such that link capacities were not influenced by roadside obstructions except in cases where a particular link represented a highway bridge with a restrictive road shoulder. The logical turning movements from one link to the next and route preferences controlling traffic flow onto each link were also specified.

Single nodes were used to identify intersections of two or more undivided state roads, or to represent significant changes in roadway characteristics. Traffic flowing through intersections modeled using singled nodes is forced to compete for the right of way with opposing traffic from other approaches. Major interchanges connecting divided and undivided highways, or connecting two undivided highways were modeled with as many as six nodes per interchange. A greater number of

FIGURE 1 - Fairfield Network

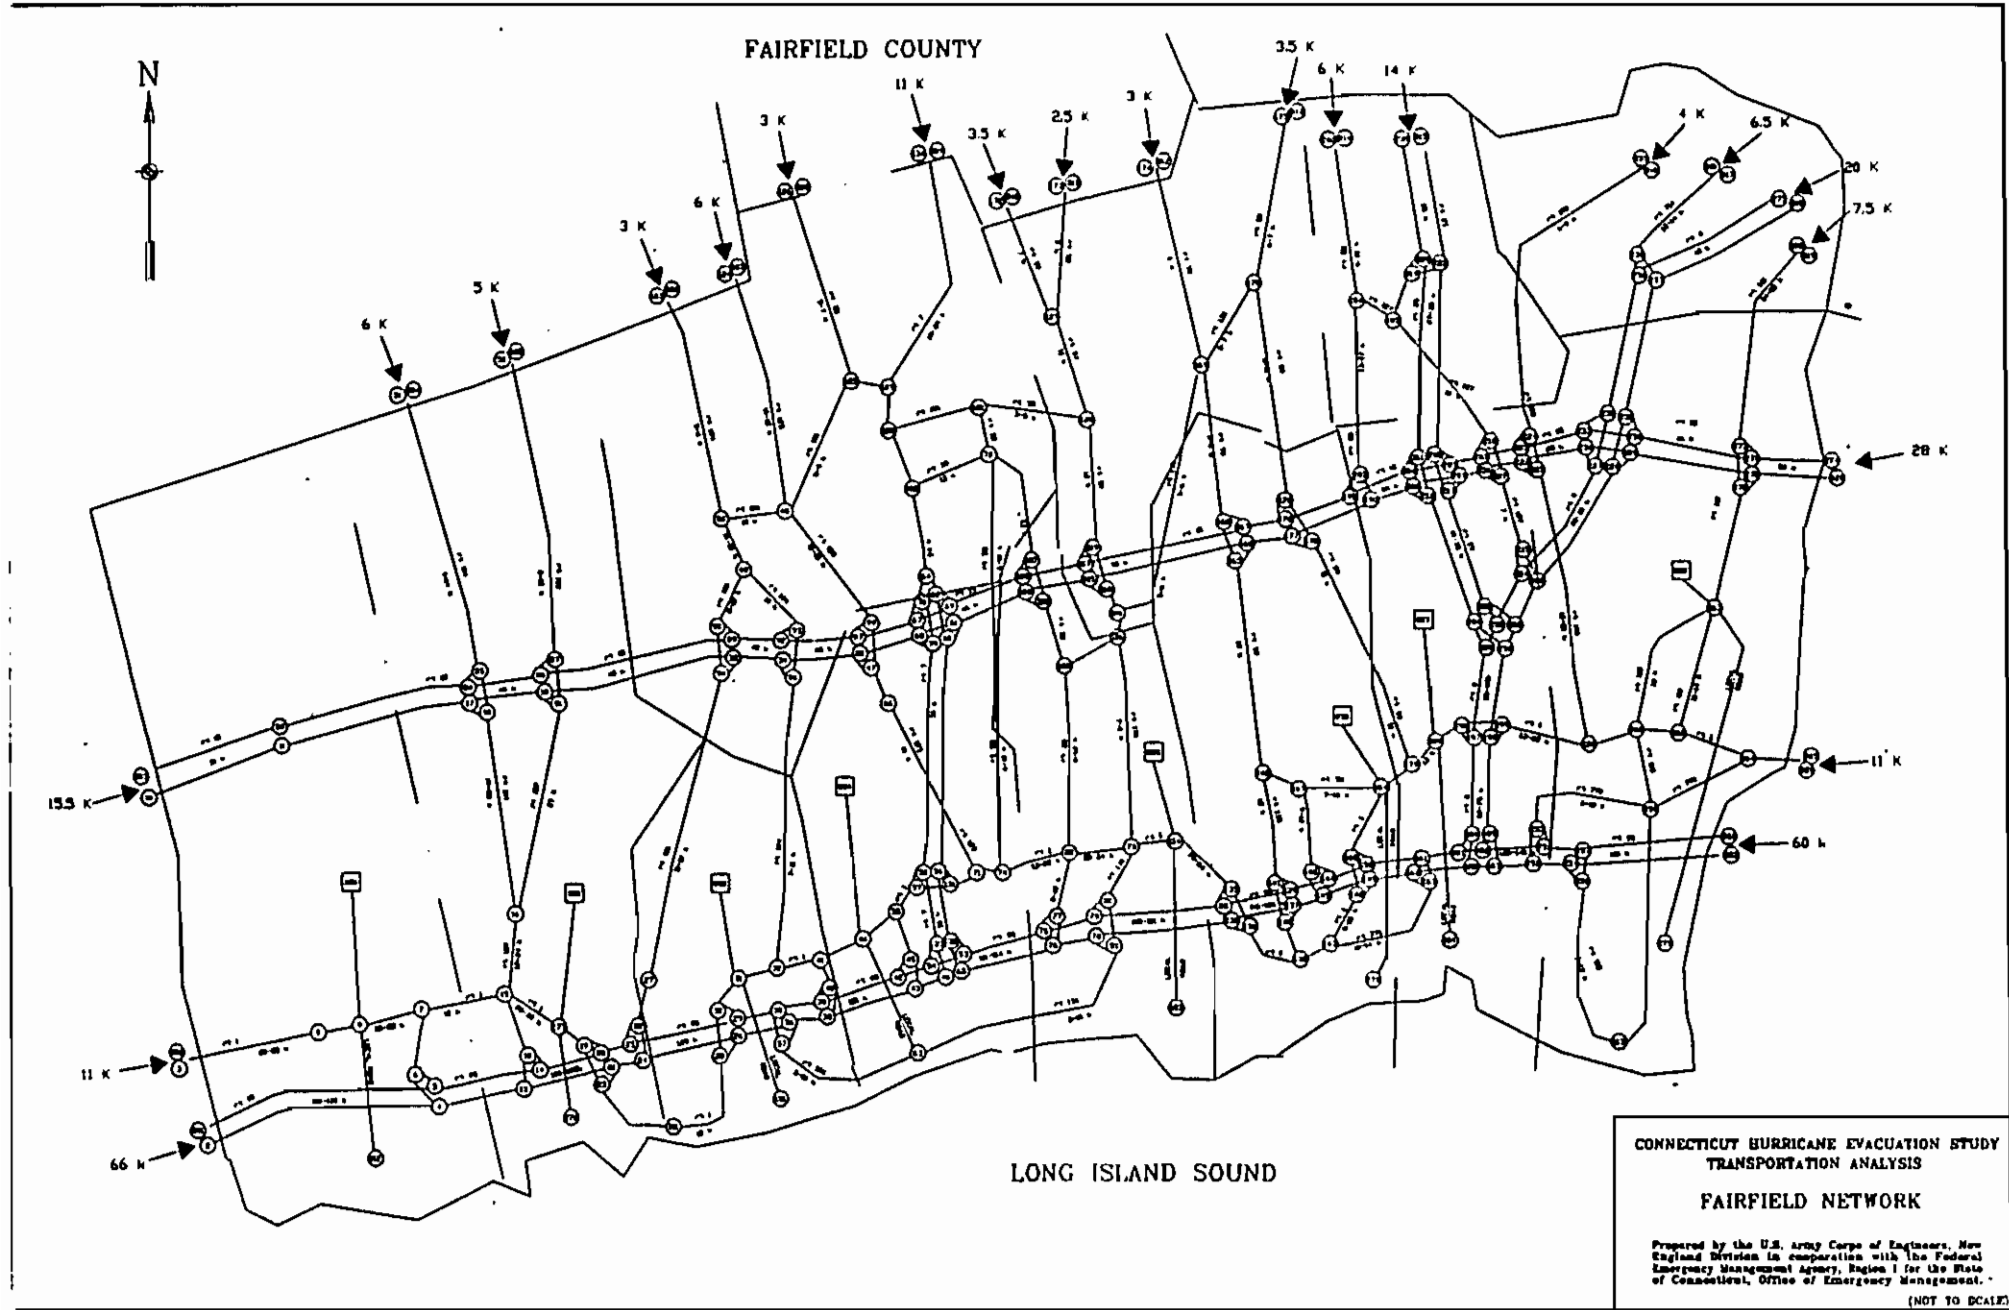

FIGURE 2 - New Haven Network

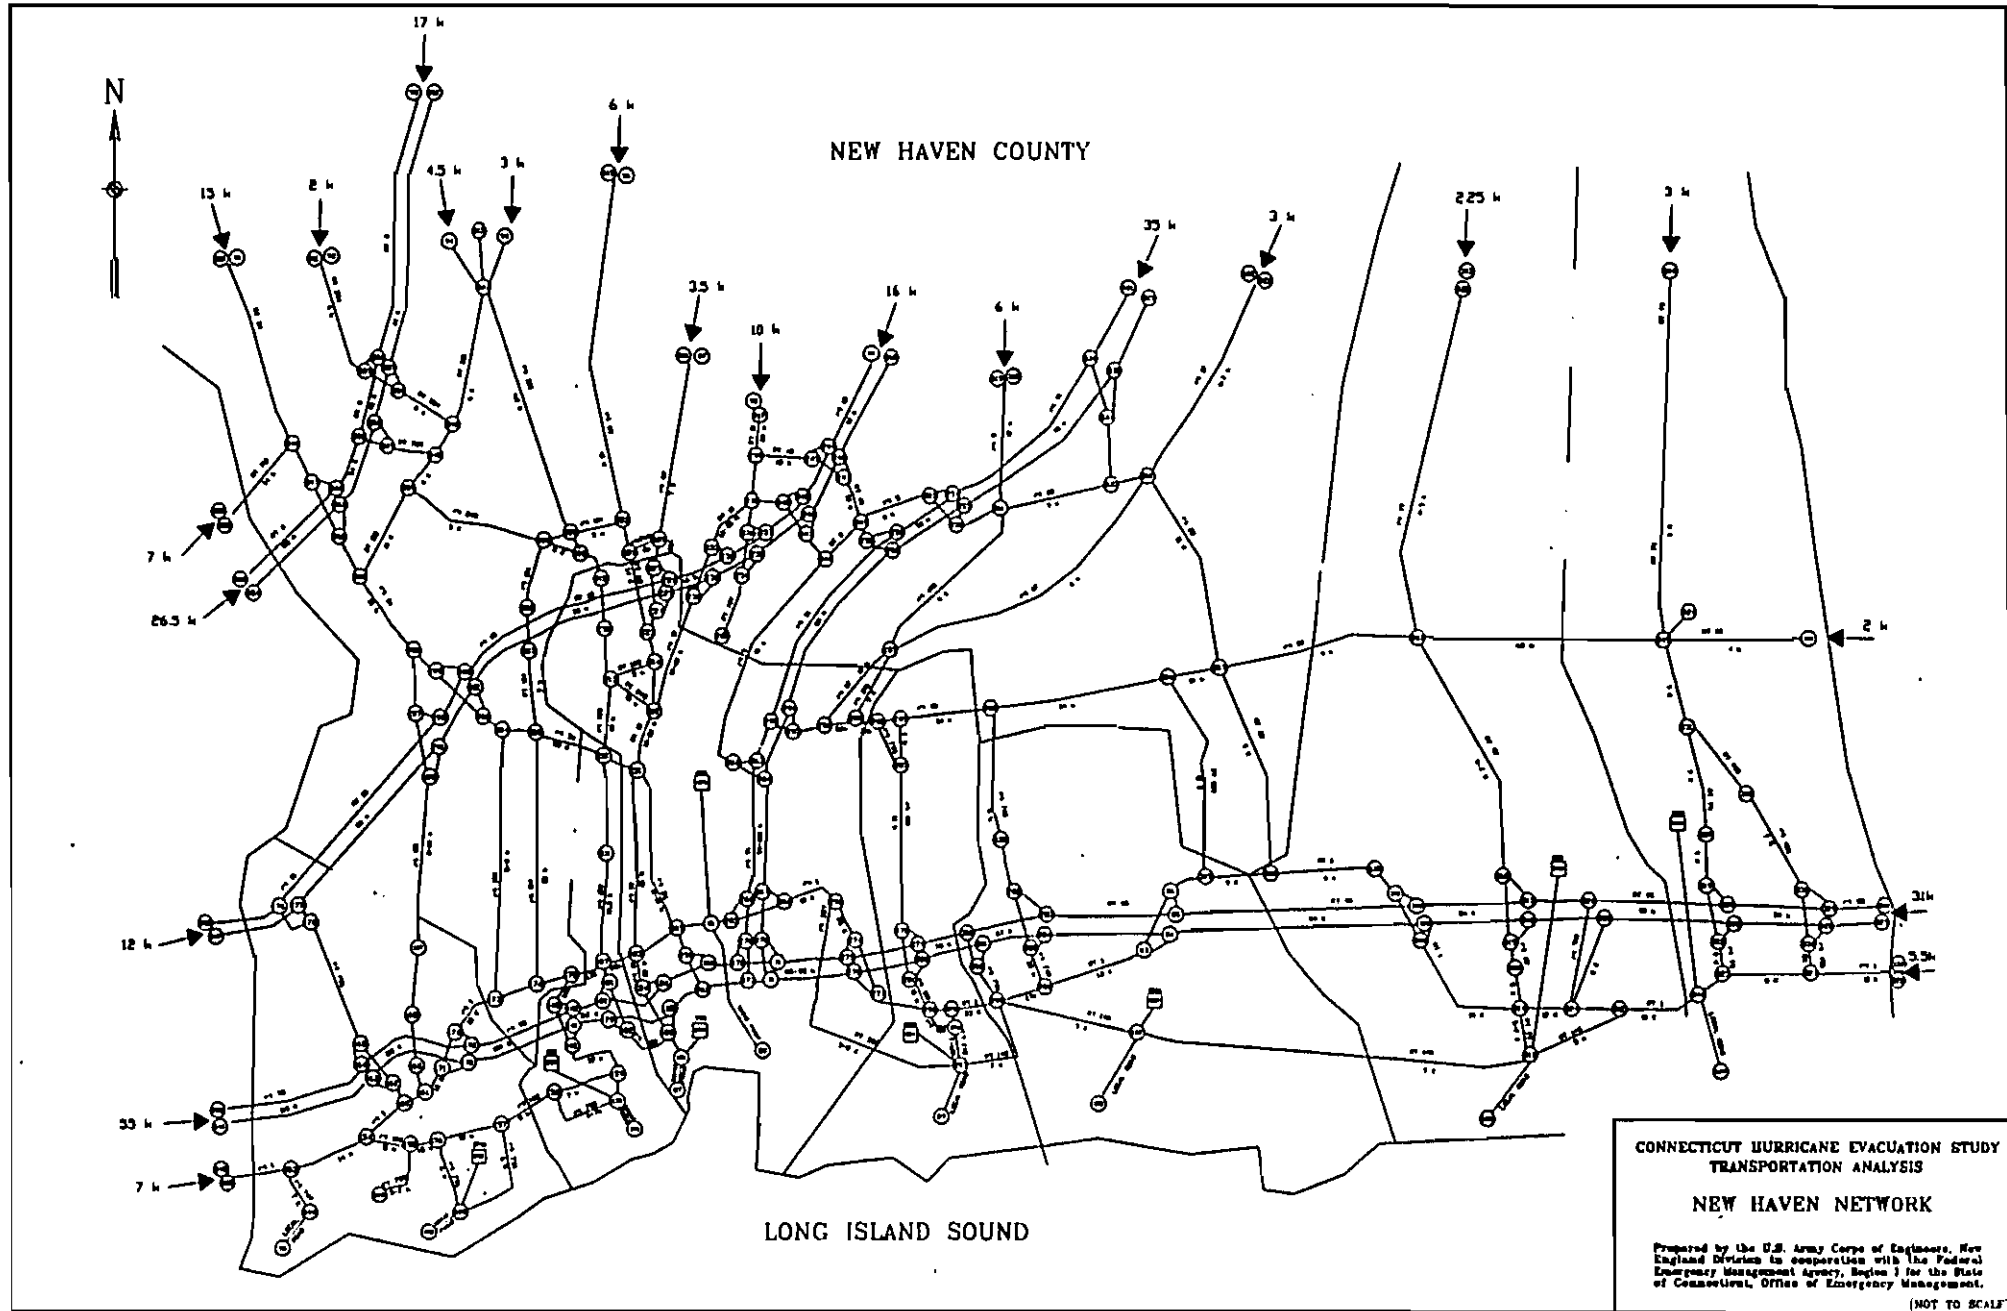

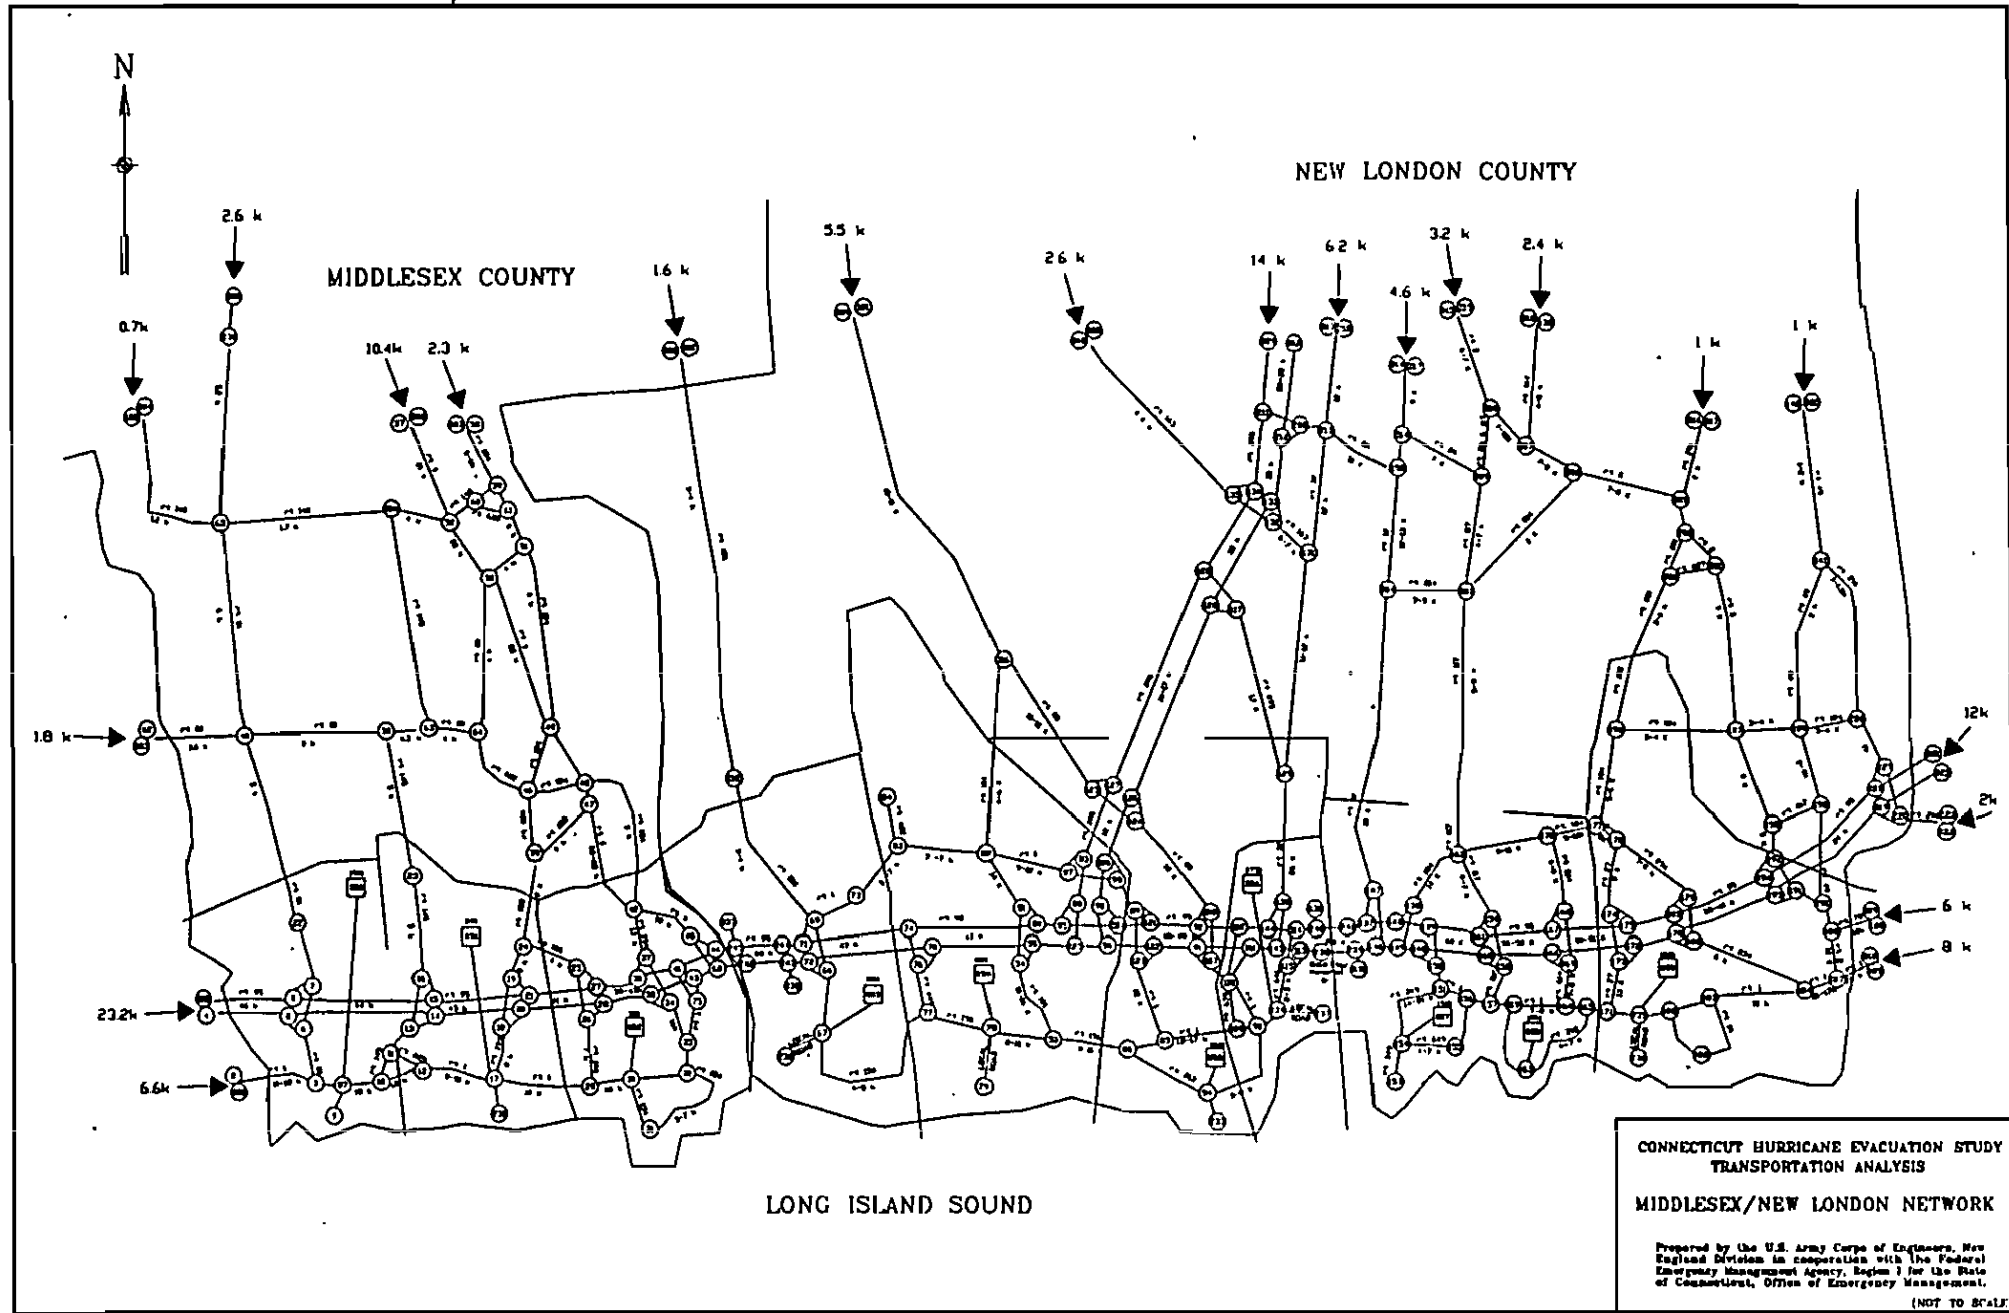

FIGURE 3 - Middlesex/New London Network

nodes at these interchanges were needed to replicate non-opposing continuous traffic flow characteristic of highway on-ramps and off-ramps.

Because areas along the immediate coast lack direct access to state routes, evacuees leaving these areas would first travel on local streets before entering onto state routes. Therefore, areas immediately along the coast, which do not have state routes passing nearby, were provided network access by links representing local streets. The information entered for these links idealized the capacities of several local streets rather than any particular street. The majority of evacuees were programmed to enter networks from local streets extending into coastal areas. However, some evacuees were assigned to enter directly onto the networks at nodes positioned along state routes near the coast.

As a starting point, intersection approaches were all initially coded as equal priority. Coding the model in this manner assumes that at signalized intersections the green time for a particular intersection approach is directly proportional to the relative amount of traffic volume from its approach, to the cumulative volume of traffic from all other approaches. In turn, this forces vehicles to compete for the right of way. However, more green time is allotted to approaches with the highest volumes. As the model was calibrated, the priorities of some intersections were adjusted to better model the actual numbers of vehicles observed to turn onto different roadways.

NETVAC2 only allows vehicles to exit networks at special nodes predesignated as sink nodes. Exits were created within each study area's interior to represent locations of available public shelters (locations are illustrated by the squares in Figures 1 through 3). At a minimum, at least one interior sink node, representing an entire community's shelter capacity, was located in each coastal community. Exterior sink nodes were positioned along the boundaries of study areas to model locations where vehicles move out of the study areas. Transportation modeling assumed only a portion of the evacuating population (defined in the Shelter Analysis in the TDR) would seek destinations at public shelter locations. All other vehicles were assumed to travel on road networks until they eventually arrived at exterior sink nodes.

2.3 MODEL CALIBRATION

Before evacuation simulations were run, each network was first calibrated for its study area. Calibration is performed for two primary reasons. First, it establishes the route preferences that will be used by all vehicles during an evacuation simulation. Route preferences control the numbers of vehicles assigned to travel on each road. Second, calibration determines how many vehicles must be loaded at a given loading rate to achieve traffic patterns typical of a normal day. Before an evacuation takes place, the modeling methodology assumes traffic patterns of a normal day occur. Therefore, NETVAC2 was programmed to simulate normal traffic patterns at the start of all model runs. Only

after a hurricane threat becomes imminent, and people begin responding to warnings, are changes in normal day traffic anticipated. The following paragraphs describe how traffic counts recorded for a normal weekday were used to calibrate each network to its study area.

The Connecticut Department of Transportation Traffic Log⁶ lists the estimated average daily traffic volume (ADT) for segments of highways where significant changes in total traffic volume occur. A sample of ADT volumes along US Route 1 from the New York State line to Westport, Connecticut is shown in Figure 4. ADT volumes listed are the averages of daily traffic volumes recorded over a one year period. These values are the expected numbers of vehicles to travel on segments of US Route 1 on any given day.

The distribution of ADT over a 24-hour period varies with each hour and day of the week. In general, the percentage of ADT is usually many times greater during peak traffic periods compared with times of off-peak traffic. Figure 5 plots averages of the hourly weekday ADT volume recorded at traffic monitoring stations in Branford, East Lyme, Groton, Norwalk, and Wallingford, Connecticut along portions of US Route 1, and Interstate Routes 91 and 95. The distribution of hourly ADT at each location was found to be similar irrespective of monitoring site or direction of travel.

In Figure 5, dashed lines delineate approximate levels of ADT corresponding to off-peak, mid-peak, and peak traffic. For the most part, off-peak traffic refers to light traffic volumes that typically occur late at night or in the early morning. Mid-peak traffic refers to moderate traffic conditions similar to that generally experienced in the late morning or early afternoon on weekdays, or on weekend days. Peak traffic represents the volume of traffic that is typical during rush hour.

Although the distribution of ADT in Figure 5 may not reflect all of the local traffic patterns for each road in the study area, it does however provide a reasonable representation of how most of the vehicle trips along coastal Connecticut are distributed over a normal day. Therefore, Figure 5 was used as a basis by which all the roadways within networks were calibrated.

The actual unidirectional ADT at exterior node locations was entered as vehicles into networks and programmed to flow throughout each system. As simulations progressed, printouts every half hour of simulation time reported the cumulative link departures and link speeds, as well as any spillbacks and queues found at nodes. Calibration was performed using an iterative process of running NETVAC2, comparing the distribution of vehicles on major routes modeled to the distribution in Figure 5, adjusting link preference factors, and rerunning the model. The transportation methodology assumed calibration was complete when the volume of vehicles on each link approximately matched its corresponding ADT volume; and the distribution of traffic shown in Figure 5 was attained for all major routes modeled.

Figure 5 - Average of Hourly ADT Along Major Routes in Connecticut

Section Three
DEVELOPMENT OF TRAFFIC DATA

3.1 CLASSIFICATION OF MOTORISTS

After road networks were developed, the next steps of the analysis were to estimate the total number of vehicles that will load onto roadways, and determine the rates at which vehicles will load onto roadways over the course of an evacuation. To facilitate the development of this information, vehicles were classified as belonging to one of four major categories listed below:

(1) Surge Vulnerable Evacuees: Permanent and seasonal residents living in evacuation zones who evacuate when directed to do so by authorities.

(2) Non-Surge Vulnerable Evacuees: Permanent and seasonal residents, excluding mobile home residents, living outside evacuation zones who choose to evacuate. Most of the evacuees of this category leave their homes because of perceived dangers and not necessarily because of real flooding threats. However, in some cases, officials may deem it necessary to evacuate small groups of people who live in substandard housing units particularly vulnerable to hurricane winds, or those who live in or near areas that may be exposed to freshwater flooding.

(3) Mobile Home Evacuees: All permanent and seasonal mobile home residents of coastal communities. The analysis assumes all mobile home residents will be told to evacuate by local officials due of their high risk to strong winds from storms of even modest intensities.

(4) Background Vehicles: The population associated with all remaining vehicle trip purposes. Examples are: Trips made by people who leave work early and return home, people who travel through the region, and trips made by persons preparing for the arrival of hurricane conditions or engaged in normal activities. This traffic can also include transit vehicles (vans/buses) used to pick up evacuees without personal transportation.

The number of vehicles assumed to participate during an evacuation from each group listed is an important factor in estimating clearance times. Fortunately, human behavioral information developed in Chapter 4, Behavioral Analysis, in the TDR, gives clear estimates of the participation that can be expected from the first three groups. The fourth group, Background Vehicles, is not addressed by the Behavioral Analysis. However, motorists belonging to this group mostly comprise of people making shopping trips or commuting, which is related to the ADT distribution shown in Figure 5. Section 4, Evacuation Scenarios, discusses how Figure 5 was used to develop background traffic distributions used during evacuation simulations.

Tables 1 and 2 list estimates made of the numbers of permanent and seasonal people who were assumed to evacuate their homes by population type for two levels of hurricane threat. Table 1 refers to evacuations for a Category 1 or Category 2 hurricane, and Table 2 gives similar estimates

for a Category 3 or Category 4 hurricane. Estimates were made by applying evacuation participation behavioral assumptions to community population data (see TDR).

3.2 BEHAVIORAL RESPONSE OF MOTORISTS

Perhaps one of the most critical assumptions that must be considered when estimating clearance times is the timing at which evacuees load onto roadways. Behavioral data from research obtained from past hurricane evacuations show that mobilization and actual departures of the evacuating population occur over a period of many hours and sometimes several days⁷. For Connecticut, evacuation simulations were tested for three evacuation rates that are summarized by the response curves in Figure 6. Behavioral response curves describe the percentages of the evacuating population who leave their homes and load onto roadways at hourly intervals relative to when an evacuation recommendation is disseminated to the public.

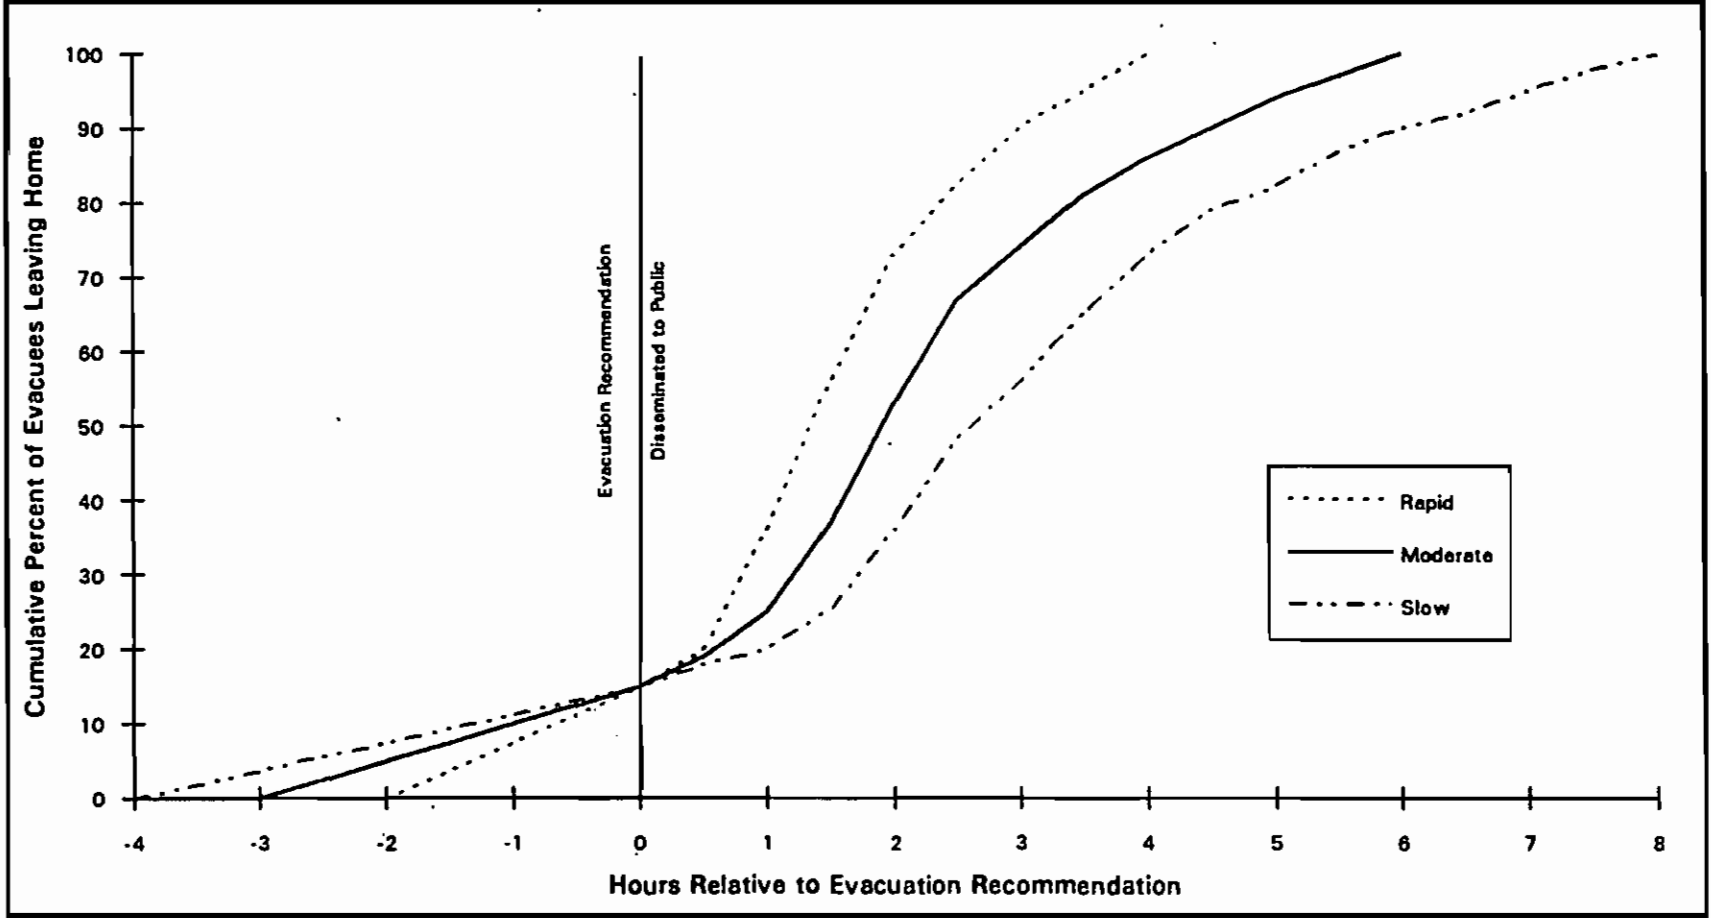

The behavioral response curves are intended to include the most probable range of public responses that will be experienced in a future hurricane evacuation. The rapid response curve depicts the quickest mobilization response by evacuating households. For analysis purposes, the rapid response curve includes two hours of response time occurring before the evacuation recommendation is disseminated to the public and four hours after it is disseminated. For the moderate response curve, three hours of response time is assumed before dissemination of the evacuation recommendation, and six hours after. The slow response curve includes four hours of response time before notification of the evacuation recommendation, and eight hours after. The public's response before evacuation accounts for people who choose to evacuate their homes before being directed to do so by authorities. Regardless of the behavioral response curve used, 85 percent of all people who will eventually leave their homes are assumed to leave after being directed to do so by officials. This is an important point because people's timeliness in responding to a hurricane evacuation is extremely dependent upon the aggressiveness of authorities to encourage them to leave⁸.

3.3 VEHICLE USAGE

The behavioral analysis conducted for Connecticut⁸ estimated that approximately 75 percent of the vehicles available to evacuees will be used during future evacuations. For the most part, families usually evacuate using one vehicle for fear of separation, but some households evacuate using two or more vehicles depending upon how many are available to them. Differences in vehicle ownership may vary with variations in access to public transportation, household income, and other socioeconomic characteristics of the region.

The first and second columns of Table 3 list by community the average numbers of people and cars per occupied housing unit. This information was obtained from socioeconomic data reported in

Figure 6 - Behavioral Response Curves

the 1980 census⁹. The third column of the Table gives the calculated average numbers of people that will travel in each evacuating vehicle, assuming 75 percent of the available vehicles are used. A sample calculation for Greenwich, Connecticut is shown below.

$$\frac{2.63 \text{ people per occupied housing unit}}{1.84 \text{ cars per housing unit} \times 75\%} = 1.91 \text{ people per evacuating car}$$

The transportation methodology used the information in Table 3 to determine the vehicles that would load onto roadways during evacuations. The user enters the vehicle occupancy rates and the number of people assigned to enter the network at each node. NETVAC2's complimentary program, POPDIS, aggregates the population input for each entry node and in turn computes the effective average vehicle loading rates per minute to be input into NETVAC2 at network entry locations.

Section Four

EVACUATION SCENARIOS

Since all hurricanes differ from one another in some respect, it becomes necessary to set forth clear assumptions about storm characteristics and evacuees' expected response before transportation modeling can begin. Not only does a storm vary in its track, intensity and size, but also in the way it is perceived by residents in potentially vulnerable areas. These factors cause a wide variance in the behavior of the vulnerable population. Even the time of day at which a storm makes landfall influences the time parameters of an evacuation response. The transportation analysis computes clearance times based on sets of assumed conditions and behavioral responses. It is likely that an actual storm will differ from a simulated storm for which clearance times are calculated in this report. Therefore, key input parameters were varied to derive a range of evacuation scenarios idealizing many possible situations officials may have to contend with. The three major parameters that were varied with each simulation are described below.

(1) Hurricane Severity: Storms are classified as either Categories 1&2 hurricanes, or Categories 3&4 hurricanes. Evacuating population estimates (see Tables 1 and 2) are significantly greater (approximately double) for an evacuation due to Categories 3&4 hurricanes when compared with that for Categories 1&2 hurricanes. Category 5 hurricanes were not considered because the cooler waters of the Northeast can not sustain hurricanes of this intensity.

(2) Behavioral Response: The time in which evacuees mobilize to leave their homes and enter onto the roadway system is characterized by the behavioral response curves shown in Figure 6. Behavioral response curves are defined for rapid, moderate, and slow responses.

(3) Background Traffic Condition: The traffic condition at the start of an evacuation will depend upon the time of day the evacuation begins as well as other factors that may influence initial traffic conditions. As the NETVAC2 models were run, initial traffic conditions corresponding to off-peak, mid-peak, and peak ADT levels were analyzed. Figures 7a-c plot background vehicle distributions assumed for the three conditions.

- a. Off-peak: The off-peak traffic condition refers to light traffic volumes that typically occur late at night or in the early morning.
- b. Mid-peak: The mid-peak traffic condition refers to moderate traffic conditions similar to that generally experienced in the late morning or early afternoon on weekdays, or on weekend days.
- c. Peak: The peak traffic condition replicates the volume of traffic that is typical of rush hour.

As noted above, background vehicles refer to motorists who travel roadways during an evacuation with trip purposes other than for evacuating their homes. At the start of an evacuation, the number of background vehicles assumed exist on a particular road was taken as the ADT for that road on a

normal day. As an evacuation progressed, the initial ADT assumed was slowly decreased until zero background vehicles were on the roads at the completion of the evacuation.

Referring to the ADT distribution shown in Figure 5, the Transportation Analysis simulated evacuations occurring coincident with rush hour by programming evacuees to load onto roadways that were initially set at peak ADT volumes. Conversely, an evacuation occurring at times of light traffic, such as late at night or in the early morning, was modeled by running the model with background vehicles initially set at off-peak ADT volumes. Simulations run with background traffic at mid-peak ADT volumes represented moderate traffic volumes typical of midmorning and mid-afternoon on weekdays or weekends.

The Transportation Analysis assumed the background distributions shown in Figures 7a-c to apply to evacuations assuming a moderate behavioral response by evacuees. Background traffic distributions used for evacuations assuming a rapid or a slow behavioral response (not shown) follow the same curves shown in Figures 7a-c. The only exception is that evacuees are programmed to load onto roadways slightly before or after background traffic starts its decline. The number of background vehicles on any roadway during a model run will vary depending upon each road's particular ADT and the hourly percentage of ADT assumed for the traffic condition modeled. A key point in using Figure 5 to derive background traffic conditions is that all traffic conditions are from actual traffic patterns observed for Connecticut rather than assumed hypothetical conditions.

Combinations of these key input parameters were used in developing 18 possible scenarios. For each of the three networks, simulations were run for evacuations assuming Categories 1&2 hurricanes and Categories 3&4 hurricanes. Initial traffic conditions imparted on the road network followed the distributions shown in Figure 7a-c for off-peak, mid-peak, and peak traffic. Evacuees entered road networks at prescribed time intervals defined by the rapid, moderate, and slow behavioral responses.

Factors such as seasonal population variations or impacts from tourism were not considered because of the negligible increases these population types have on coastal Connecticut's total population. The evacuating population used during simulations included seasonal residents as estimated from the 1990 census¹⁰ from seasonal housing unit information. Coastal Connecticut's seasonal population was found to be less than 5 percent of its permanent population.

Section Five ANALYSIS

5.1 GENERAL

Clearance time and dissemination time are two major considerations in deciding when an evacuation recommendation should be issued. The combination of these times defines a region's total evacuation time. Clearance time begins when the public is first made aware of an evacuation and ends when the last evacuee clears the road system. This time includes the time required by evacuees to secure their homes and prepare to leave (mobilization time), the time spent by evacuees traveling along the road network (travel time), and the time lost due to traffic congestion (queuing delay time). Clearance time does not relate solely to the time any one vehicle spends traveling on the road system.

Dissemination time is the amount of time required by officials to notify the public to evacuate after the decision has been made. These values are subjective times that may differ by region depending on the communication and warning procedures utilized by State and local officials in their areas. The times calculated by the Transportation Analysis include only the clearance time component of evacuation time, and officials using this information must determine the dissemination time appropriate for their areas. Failure to add this component will underestimate evacuation times, which could result in motorists being left stranded on highways during the climax of a storm.

Evacuations must be completed before the arrival of gale force hurricane winds (34 knot/39 mph) and/or storm surge. Vehicle accidents and reduced travel speeds from inclement weather can impede traffic flows, and potentially disrupt the evacuation. Therefore, the transportation modeling assumes that evacuations will occur well enough before a hurricane to preclude possible delays caused by significant weather. Moreover, the analysis assumes that provisions would be made for removal of vehicles in distress during the evacuation. The Decision Arc Method outlined in Chapter 8, Behavioral Analysis in the TDR, explains how the clearance times, in conjunction with the dissemination times specified by officials, can be used in hurricane evacuation decision-making. The time at which gale force winds arrive has been incorporated into the decision-making process of the Decision Arc Method and therefore does not need to be factored into the calculation of clearance time.

5.2 RESULTS

NETVAC2 lists node arrivals, departures, total discharge, link speeds, and total number of vehicles on the network for each report interval specified by the user. The total number of vehicles on a network is plotted versus time to display graphically how quickly vehicles leave roadways. Figures 8a-b, 9a-b, and 10a-b are graphs plotted from analysis results for the Fairfield, New Haven, and Middlesex/New London networks under Categories 1&2 and Categories 3&4 hurricane evacuation

scenarios, respectively. A moderate behavioral response curve was assumed for all scenarios presented in the Figures. In each graph, the curves depict the numbers of vehicles remaining on a network, for each hour of simulation time, for evacuations starting with off-peak, mid-peak, and peak background traffic conditions.

Evacuations were considered complete when 98 percent of all vehicles reached safe destinations. One limitation when calibrating networks to traffic patterns of a normal day is that near the completion of simulations, when most of the vehicles on the network are from evacuees rather than background traffic, vehicles adhere to turning movements of a normal day instead of seeking the most logical exit nodes. The remaining 2 percent on the network accounts for this difference. It is expected that evacuees leaving homes immediately before storm arrival will seek safe destinations of the shortest travel time. Free flow conditions are verified up to one hour before model termination to ensure the last evacuees experience light traffic free from queuing.

Tables 4 and 5 present the clearance times estimated for Fairfield, New Haven, and Middlesex/New London Counties for Categories 1&2 and 3&4 hurricanes, respectively. Times are organized by intensity of hurricane, by the rate of response of the evacuating population, and by the level of background traffic at the start of evacuations.

The clearance times were calculated assuming that each community is capable of sheltering their individual demands and no shelter capacity deficiencies exist. The Transportation Analysis tested how inadequate shelter capacity might influence clearance times using a range of different assumed shelter usage rates. Results showed that deficiencies in shelter capacity have a minimal affect on clearance time. This point is explained by the fact that the numbers of vehicles determined to travel to public shelters is very small in comparison to all vehicles on roadways. Consequently, the clearance times provided in Tables 4 and 5 are considered valid for the existing condition of deficient community shelter capacities and in the future if community sheltering capabilities improve.

The highest clearance time calculated by the Transportation Analysis was ten hours for the New Haven network, assuming a slow behavioral response by evacuees, hurricane Categories 3&4 scenario, and an evacuation occurring during rush hour (peak traffic conditions). Referring to the slow behavioral response curve in Figure 6, the last evacuees do not leave their homes until eight hours after being directed to do so. The late response by these people combined with the effects of heavy traffic from a peak traffic condition creates a substantial amount of congestion along Interstate Route 95 northbound at the junction of Interstate Route 91. Simulation results showed that traffic queuing on Interstate 95 northbound (near the interchanges with US Route 1 and Route 162) can impede people leaving Milford and West Haven exiting US Route 1 and Route 162 onto Interstate 95. Even more queuing was observed in this area when the moderate and rapid behavioral response curves were used.

Figure 8a - Fairfield Network Plotted Results for Moderate Behavioral Response (Categories 1&2 Hurricanes)

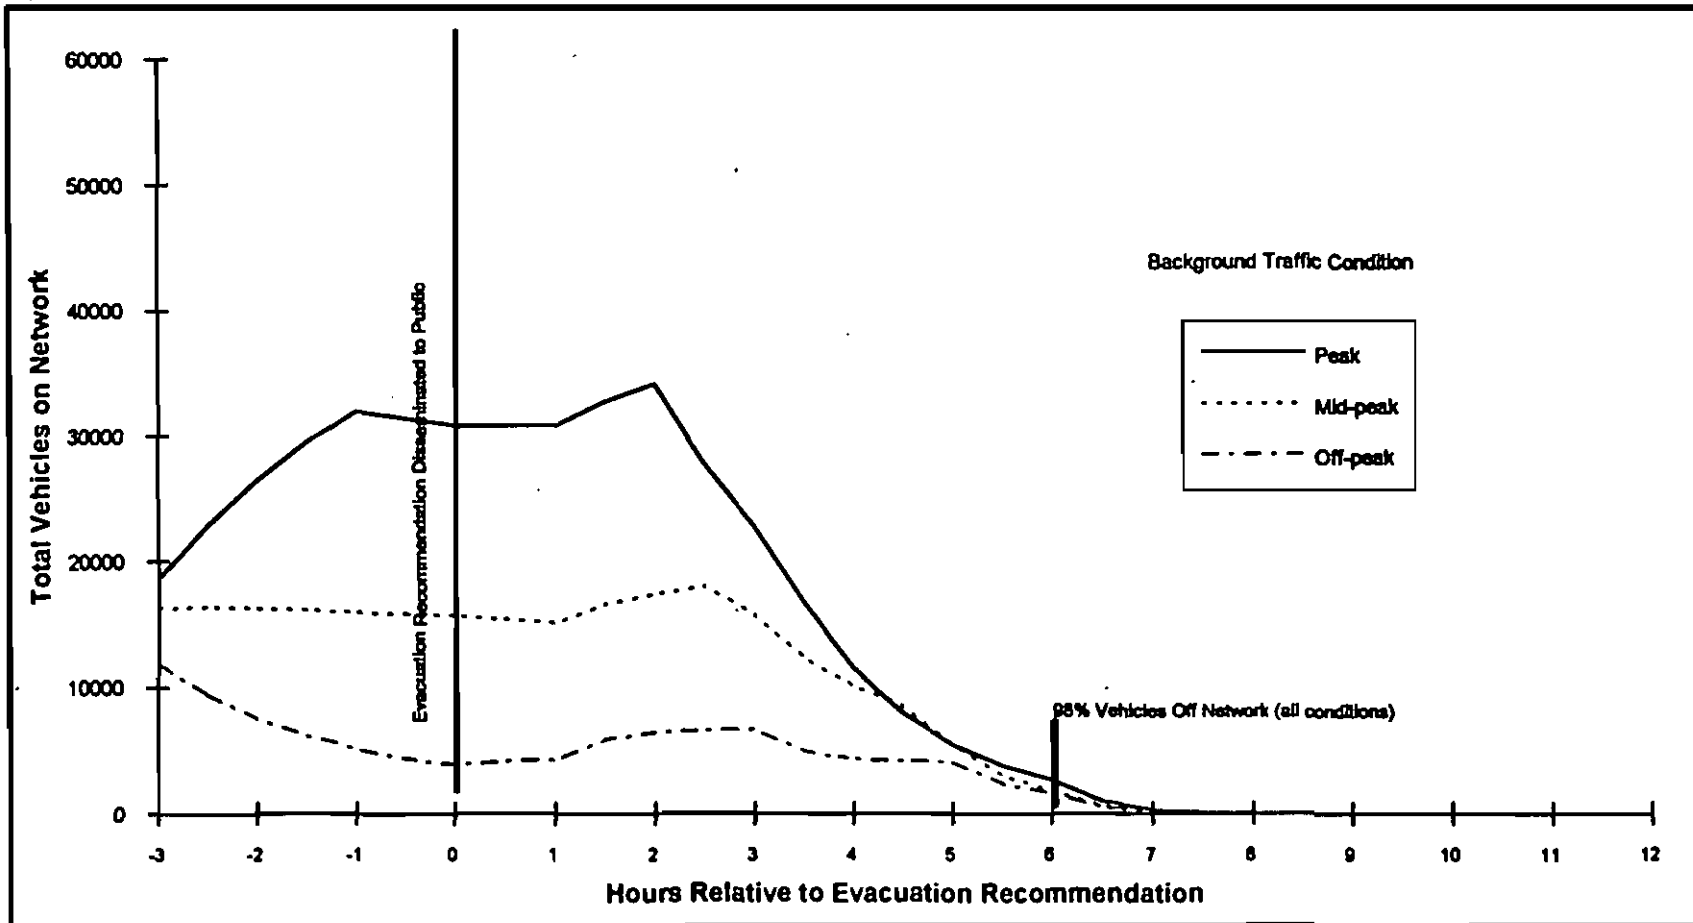

Figure 8b - Fairfield Network Plotted Results for Moderate Behavioral Response (Categories 3&4 Hurricanes)

Figure 9a - New Haven Network Plotted Results for Moderate Behavioral Response (Categories 1&2 Hurricanes)

Figure 9b - New Haven Network Plotted Results for Moderate Behavioral Response (Categories 3&4 Hurricanes)

Figure 10a - Middlesex/New London Plotted Results for Moderate Behavioral Response (Categories 1&2 Hurricanes)

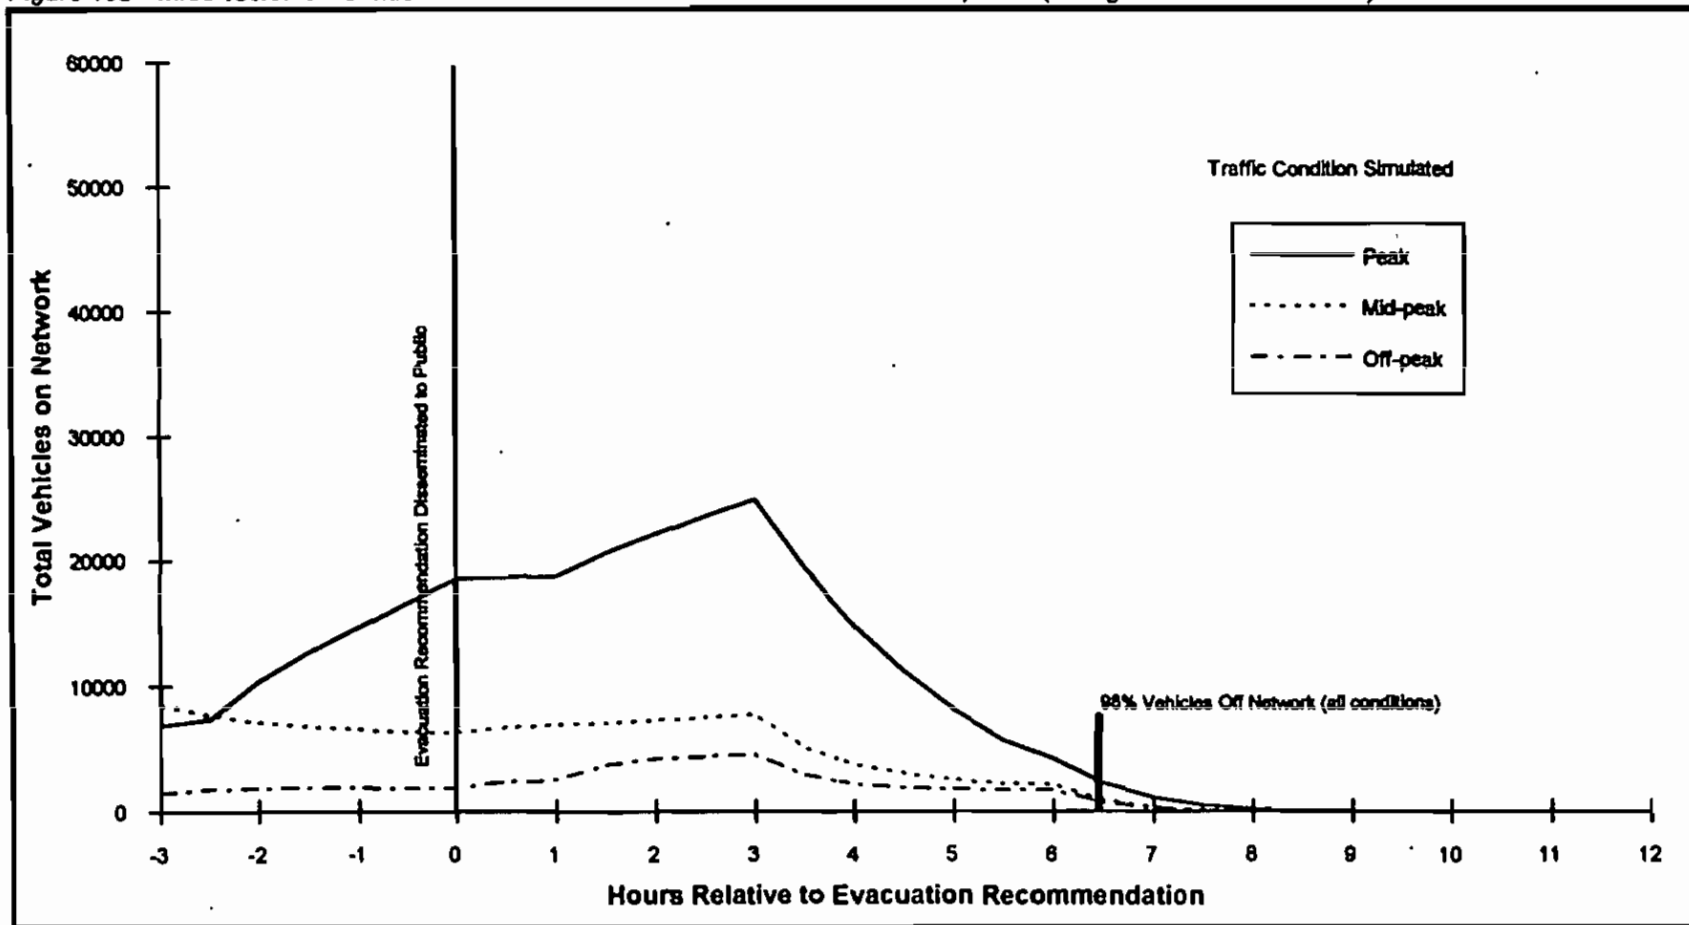

Figure 10b - Middlesex/New London Plotted Results for Moderate Behavioral Response (Categories 3&4 Hurricanes)

In these simulations, the same numbers of evacuees were loaded onto roadways over shorter periods of time thereby reducing the capacities of intersections and roadways still further.

Clearance times for the New Haven network were appreciably reduced with changes in the assumed behavioral response and background traffic condition modeled. Clearance time was estimated to be 8 hours for Categories 3&4 evacuation scenarios occurring at peak background traffic assuming a moderate behavioral response. The same scenario modeled using a mid-peak background traffic condition estimated clearance time to be 7 hours. The reduction in background vehicles under a mid-peak traffic condition resulted in a decrease in clearance time by one hour. The off-peak traffic condition further reduced clearance time by 1/2 hour for a total of 6 1/2 hours time.

For the Middlesex/New London and Fairfield networks, clearance times estimated for the moderate and slow behavioral responses are nearly independent of the background traffic condition and severity of the hurricane. Instead, clearance times are directly correlated to behavioral response. For both networks, clearance times for Categories 1&2 and 3&4 hurricanes were estimated to be 6 1/2 hours assuming a moderate behavioral response and 8 1/2 hours assuming a slow behavioral response. Referring to the behavioral response curves in Figure 6, under a moderate behavioral response, the last evacuees leave their homes 6 hours after being advised to do so. Similarly, under a slow behavioral response, the last evacuees leave 8 hours after being advised to do so. Referring to Figure 6, clearance times of 6 1/2 and 8 1/2 hours suggest that an additional 1/2 hour is required by the last evacuees leaving their homes to travel to safe destinations.

As people respond more quickly to evacuation orders, more vehicles enter onto roadways in a shorter period of time. In effect, roadway capacities are reduced, resulting in slower travel speeds, and more vehicles competing for the rights of way at intersections. The outcome of this can be seen by reviewing the clearance times estimated using the rapid behavioral response. As shown in Figure 6, a rapid behavioral response implies that the last evacuees leave their homes 4 hours after being directed to do so. Clearance times were estimated to be 4 1/2 to 5 hours for the Middlesex/New London and Fairfield networks, and range from 4 1/2 to 6 1/2 hours for the New Haven network. For the New Haven network these results suggest that the last people to evacuate will experience travel times of 1/2 to 2 1/2 hours depending upon the severity of the hurricane and the background traffic condition assumed. In the Middlesex/New London and Fairfield networks, the capacities of the roadway systems are such that in these counties the last people to evacuate will have travel times of one hour or less.

TABLE 4
SUMMARY OF CLEARANCE TIMES (Categories 1&2 Hurricanes)

	BACKGROUND TRAFFIC CONDITION		
	Off-peak	Mid-peak	Peak

Section Six SUMMARY

The Connecticut Transportation Analysis is one element of a more comprehensive study entitled the Connecticut Hurricane Evacuation Study. Two major considerations in hurricane evacuation planning are: 1) how much time will it take to notify people that they must leave their homes after authorities have determined an evacuation is necessary (dissemination time), and 2) how much time will it take for people who evacuate their homes to travel roadways and reach safe destinations (clearance time). Evacuation time is defined as the combination of these two times. The overall objective of the Transportation Analysis is to develop estimates of clearance times under a variety of hurricane evacuation scenarios for coastal Connecticut. Clearance times and the results from other technical analyses are compiled in the Technical Data Report of the Connecticut Hurricane Evacuation Study offering State and local officials state-of-the-art information for which hurricane preparedness plans can be updated.

An evacuation simulation computer model entitled NETVAC2 was used to create a mathematical representation of the road system along coastal Connecticut. The model was calibrated to the traffic patterns of a normal day in Connecticut (a day for which no hurricanes are forecasted) using traffic and roadway data obtained from the State's Department of Transportation. Estimates of the numbers of seasonal and permanent residents that would evacuate prior to future hurricanes were made using estimates of the total vulnerable population and application of human behavioral characteristics known for the State. During evacuation simulations, evacuating vehicles were programmed to enter roadways at prescribed loading rates and compete for roadway and intersection capacities with other vehicles of different trip purposes.

Evacuation scenarios, idealizing some of the possible situations officials may be faced with while contending with the decision to issue an evacuation, were outlined. Key parameters of evacuation scenarios include the intensity or severity of the hurricane, the behavioral response of evacuees to mobilize and leave their homes, and the time of day an evacuation takes place. Because coastal Connecticut supports a large industrial base employing many people for several miles, evacuations are complicated by the presence of commuter traffic which varies at different times of the day. A total of 18 different scenarios formulated from combinations of key parameters were analyzed using NETVAC2.

For areas in Fairfield, Middlesex, and New London Counties, results showed that in situations where people left their homes over a moderate to long period of time (a period of 6 to 8 hours after being told to do so by authorities), the density and capacity of the roadway system are such that evacuating traffic is generally unrestricted. In areas in New Haven County, however, a substantial

amount of congestion was realized along portions of Interstate Route 95 northbound at the junction of Interstate Route 91. Results showed that backups and slow-moving traffic on Interstate 95 northbound can impede vehicles evacuating from Milford and West Haven Connecticut exiting off of US Route 1 and Route 162 onto Interstate 95. As a result, clearance times calculated for areas in New Haven County were longer than those for other areas.

Simulations were also run assuming evacuees mobilized quickly and left their homes over a shorter period of time (a period of 4 hours after being told to do so by authorities). Under these circumstances, depending upon the initial traffic conditions at the start of an evacuation, all areas experienced varying degrees of congestion imposed by limitations of roadways to accommodate all motorists over a shorter time duration.

The lowest clearance times were calculated to be approximately 4 1/2 to 5 hours depending upon initial traffic conditions, a rapid public response, for evacuation in Fairfield, Middlesex, and New London Counties. However, in New Haven county, clearance times were as high as 6 1/2 hours assuming a rapid public response.

The highest clearance time, ten hours, was calculated for New Haven County assuming an evacuation starting concurrently with heavy rush hour traffic, a slow public response, and a severe storm evacuation scenario. Traffic conditions assumed for mid-day evacuations combined with moderate behavioral responses by the public resulted in clearance times ranging from 6 1/2 to 7 hours time in all counties independent of the severity of the hurricane considered.

As stated before, the clearance times calculated in the analysis comprise only a portion of total evacuation times. An additional time component is required for officials to effectively disseminate evacuation recommendations to the public. Dissemination time is a subjective amount of time that will differ by region depending on communication and warning procedures utilized by State and local officials in a particular area. Failure to add this component will underestimate evacuation times which could result in motorists being left stranded on highways in the climax of an actual event. Evacuation times can be determined by adding an appropriate amount of time for dissemination to the clearance times estimated for Connecticut in this analysis. This topic is discussed more fully in Chapter 8, Decision Analysis, of the Technical Data Report.
