FOR THE BROADCAST ENGINEER

This 8th edition of the *NAB Engineering Handbook* records the march of technology and regulatory changes affecting broadcast engineering since the 7th edition was published in 1985. We hope the 8th edition contributes to every engineer's ability and understanding of these changes.

The broadcasting industry is in the midst of an increasingly challenging economic environment. Under these circumstances the industry critically depends on its engineers to maintain high standards of quality and efficiency in the face of difficult economics and ever-changing technologies. One can only admire the individuals who meet these challenges and, every day, work to keep the broadcasting industry on the air.

Edward O. Fritts
President and Chief Executive Officer
National Association of Broadcasters

March 1992

ACKNOWLEDGEMENTS

The *NAB Engineering Handbook* was produced by NAB Science and Technology in cooperation with NAB Services. We gratefully acknowledge the assistance of those who contributed to the completion of this edition.

We also thank the members of NAB's committees, particularly NAB's Engineering Advisory Committee, along with countless industry experts who reviewed manuscripts and graciously offered their technical guidance and time in the preparation of this book.

FOREWORD

So much has changed since the 7th edition was published in 1985. New technology, revised FCC regulations, better understanding of basic broadcast technologies, are all reflected within this new 8th edition *Handbook*. It was not an easy task preparing this edition! NAB is indebted to all the talented individuals who have worked so hard to bring the 8th edition to your hands. I am proud of the thoroughness and attention to detail that is apparent in any chapter of this book.

The *NAB Engineering Handbook* is a reference book on broadcast engineering skills and practices. Its purpose is to collect, in one place, the information needed by broadcast engineers to operate and maintain state-of-the-art radio and TV stations. There are precious few technical standards and even fewer references to help develop the skills needed by a successful broadcast engineer; so far as we know, the *NAB Engineering Handbook* is the only such reference that comprehensively covers all aspects of radio and television broadcast engineering.

We have chosen not to include materials on HDTV or Digital Audio Broadcasting (DAB). These emerging broadcast technologies have not matured to the point where we can publish an authoritative broadcast engineering guide. We're all still learning about these technologies and how they will affect broadcast operations. NAB offers separate publications that are updated annually on these important new technologies.

NAB Science & Technology welcomes your comments and suggestions for improvement on any aspect of our operations. In particular, suggestions for future editions of the *NAB Engineering Handbook* are especially appreciated.

Michael C. Rau
Senior Vice President, Science & Technology
National Association of Broadcasters

March 1992

TABLE OF CONTENTS

SECTION 1. PROCEDURES AND PRACTICES

1.1	FCC Organization and Administrative Process	1
1.2	FCC Field Operations Bureau	11
1.3	Frequency Coordination	23
1.4	Frequency Allocations for Broadcasting and the Broadcast Auxiliary Services	33
1.5	Environmental Concerns	49
1.6	Consultant Services: When and How to Use Them	59
1.7	Source Guide: Broadcast Standards and Information	63

SECTION 2. ANTENNAS AND TOWERS

2.1	Design, Erection, and Maintenance of Antenna Structures	79
2.2	Lightning Protection for Broadcast Facilities	101
2.3	Transmission Lines	115
2.4	Diplexers, Combiners, and Filters	161
2.5	AM Broadcast Antenna Systems	
	Part I: System Design	187
	Part II: Antenna Coupling and Phasing Systems for AM Broadcasting	215
	Part III: Maintenance	229
2.6	FM Broadcast Antennas	237
2.7	Antennas For Television Broadcasting	273
2.8	Radio Wave Propagation	297
2.9	Human Exposure to RF Radiation	311
2.10	AM Field Strength Measurements and Proof-of-Performance	327
2.11	FM and TV Field Strength Measurements	335

SECTION 3. TRANSMITTERS

3.1	AM Transmitters	353
3.2	AM Stereo Broadcasting	405
3.3	FM Broadcast Transmitters	429
3.4	Subcarrier Transmissions and Stereophonic Broadcasting	475
3.5	TV Transmitters	499
3.6	Multichannel Television Sound	553
3.7	Transmitter Control Systems	569
3.8	Frequency and Aural Modulation Monitoring	609

SECTION 4. PROGRAM TRANSMISSION FACILITIES

4.1	TV Signal Transmission Standards	617

4.2 Microwave Engineering for the Broadcaster 653
4.3 Aural Broadcast Auxiliary Links 671
4.4 Satellite Earth Stations 679
4.5 Fiber Optic Transmission Systems 717
4.6 An Overview of Cable Television 731

SECTION 5. PRODUCTION FACILITIES

5.1 Microphones 749
5.2 The Broadcast Television Camera System 775
5.3 Video Signal Switching, Timing, and Distribution 807
5.4 Magnetic Recording Media 825
5.5 Principles and Current State of the Art
Part I: Analog Magnetic Recording 845
Part II: Digital Audio Technology 863
5.6 Videotape Recording 877
5.7 Videotape Editing 913
5.8 Film for Television 933
5.9 Studio Audio 947
5.10 Transmission Audio Processing 967
5.11 Television Camera Robotics 981
5.12 Planning of Broadcast Facilities 989
5.13 Principles of Acoustics for Broadcast Applications 1013
5.14 Lighting For Television 1033

SECTION 6. REMOTE PROGRAM ORIGINATION

6.1 Radio Electronic News Gathering and Field Production 1051
6.2 TV Field Production: An Overview 1073
6.3 Telephone Network Interfacing 1083
6.4 Telco Audio Program Service 1111

SECTION 7. SPECIAL SYSTEMS

7.1 Broadcast Audio Measurement 1121
7.2 Radio Receivers 1139
7.3 Color Television
Part I: The Basic NTSC System 1149
Part II: Worldwide Color Television Standards 1193
7.4 Color Television Receivers 1209
7.5 Closed Captioning Systems 1237
7.6 Weather Radar 1251
7.7 Distance and Bearing Calculations 1259
7.8 The Emergency Broadcast System 1265
7.9 AC Power Systems 1281
7.10 Low Power TV Transmission Systems 1297

Index 1317
Author Listing 1341

1.1 FCC Organization and Administration Process

Staff
Federal Communications Commission, Washington, District of Columbia

STATUTORY AUTHORITY

Congress, through adoption of the Communications Act of 1934 (the Act), created the Federal Communications Commission (FCC) as an independent regulatory agency. Section 1 of the Act specifies that the FCC was created:

> "For the purpose of regulation of interstate and foreign commerce in communication by wire and radio so as to make available, so far as possible, to all the people of the United States a rapid, efficient, nationwide, and worldwide wire and radio communication service with adequate facilities at reasonable charges, for the purpose of the national defense, for the purpose of promoting safety of life and property through the use of wire and radio communication, and for the purpose of securing a more effective execution of this policy by centralizing authority heretofore granted by law to several agencies and by granting additional authority with respect to interstate and foreign commerce in wire and radio communication. . ."

THE "COMMISSION"

The "Commission" consists of five Commissioners appointed by the President, by and with the advice and consent of the Senate. The President designates one Commissioner as Chairman. The Commissioners make their decisions collectively by formal vote although authority to act on routine matters is normally delegated to the staff.

FCC ORGANIZATION

The staff of the FCC performs day-to-day functions of the agency, including: (1) license and application processing, (2) drafting of rulemaking items, (3) enforcing rules and regulations, and (4) formulating policy. The staff is divided along functional lines into various offices and bureaus. Normally, broadcasters deal with the Mass Media Bureau (MMB) or the Field Operations Bureau (FOB); however, actions by other elements of the agency may directly affect broadcasters. The major organizational units are shown in Fig. 1.

Office of the Managing Director (OMD)

The Managing Director serves as the chief operations and executive official, as supervised and directed by the Chairman. OMD recommends, to the Chairman, program priorities, resources and position allocations, management and administrative policies. OMD operates the agency's personnel office and has responsibility for emergency communications policies.

Office of Public Affairs (OPA)

OPA functions as the FCC's primary point of contact with the public in dissemination of information about the Commission.

Office of Legislative Affairs (OLA)

The Office of Legislative Affairs is the primary point of contact with the Congress in dissemination of information about the Commission. Among its functions, the Office facilitates responses to congressional inquiries, drafts Commission legislative proposals and bill comments, and helps the Commission prepare for congressional hearings.

Office of Plans and Policy (OPP)

This Office makes recommendations to the Commission on development and implementation of communications policies.

Office of General Counsel (OGC)

The General Counsel advises the Commission in all matters of law and litigation, and interprets and implements statutes and treaties.

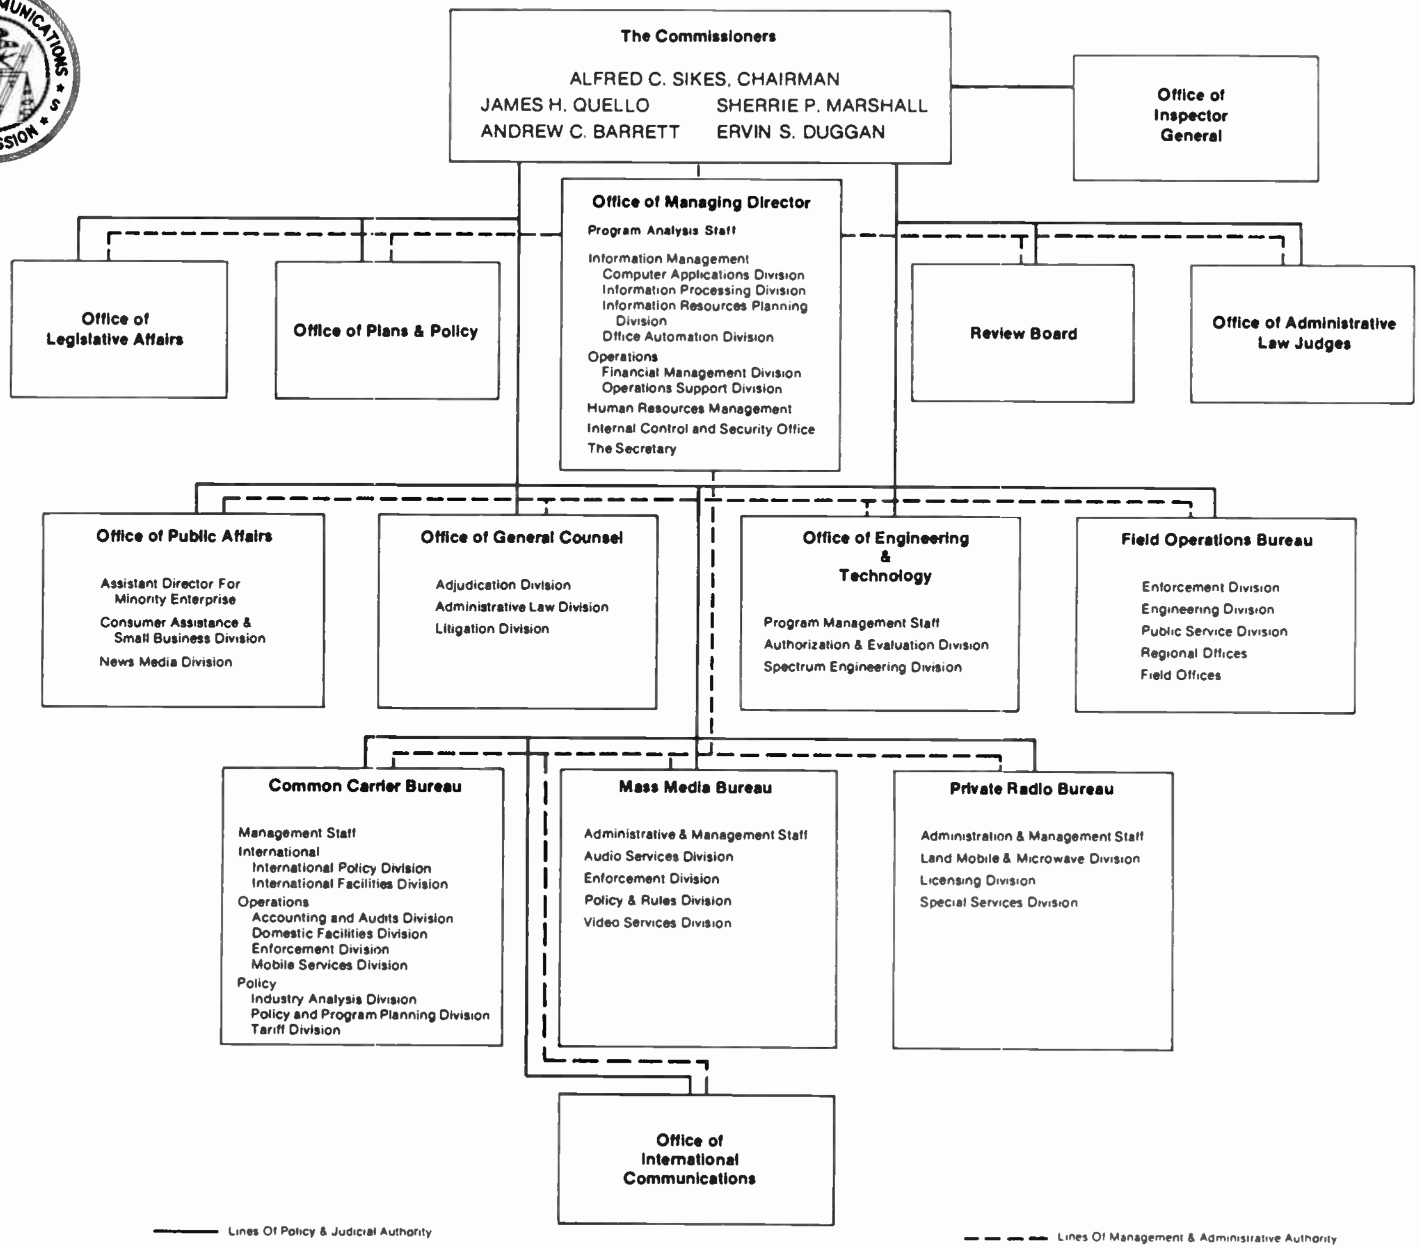

Figure 1. Federal Communications Commission organization chart.

Office of Administrative Law Judges (ALJ)

The Law Judges have responsibility for hearing and conducting all adjudicatory cases designated for any evidentiary adjudicatory hearing other than those to be heard by the Commission en banc.

Office of Science and Technology (OST)

OST conducts scientific and technical studies related to communications and operates the FCC Laboratory in Columbia, Maryland. This Office has primary responsibility for overall spectrum management. The Chief Scientist administers the equipment authorization program (type acceptance, certification, etc.). Additionally, the Office issues authorizations for experimental communications work.

Review Board (RB)

The Review Board (three or more FCC personnel) is set up within the FCC to review decisions of Administrative Law Judges in all adjudicative proceedings, unless the Commission specifies otherwise.

Common Carrier Bureau (CCB)

CCB develops, recommends, and administers policies and programs for the regulation of services, facilities, rates and practices of entities (excluding maritime) which furnish communications services for hire.

Private Radio Bureau (PRB)

PRB develops, recommends, and administers policies and programs for development and regulation of the private radio services, such as those used by persons, businesses, state and local governments, and other organizations licensed to operate their own communications systems for their own use (not for hire).

Field Operations Bureau (FOB)

FOB operates the Commission's field offices, monitoring stations, and mobile monitoring vehicles. It administers the radio operator licensing programs, the field enforcement programs, and the field public service programs. The Bureau has responsibility for the nationwide program of lighting and marking antenna structures.

Mass Media Bureau (MMB)

MMB develops, recommends, and administers policies and programs for development and regulation of the broadcasting and cable television industries. This includes auxiliary services such as translators, low power television, and operational circuits.

MASS MEDIA BUREAU ORGANIZATION

Because the Mass Media Bureau regulates broadcasting and cable television, most broadcast engineers will deal primarily with this Bureau. (Certainly, contact with the Field Operations Bureau can also be expected; see Chapter 1.2: "FCC Field Operations Bureau.") There are four major operational divisions within MMB. Each division has subdivisions, called branches, to handle specific areas of regulation, enforcement, licensing, or policy development, as shown in Fig. 2.

Audio Services Division

Licensing, license modification, and license renewal of AM and FM broadcasting stations fall under the Audio Services Division. The Division also handles the aural auxiliary services, such as Broadcast Remote Pickup, Studio-Transmitter-Links, and FM Translators. Questions concerning pending applications, processing policies, and filing requirements should be directed to the appropriate branch as listed below. Also, requests for waivers of the Rules, requests to operate with parameters at variance (i.e., directional AM antenna out of tolerance), and other requests to operate inconsistently with the station's instrument of authorization (license or construction permit) are handled by this Division. The Audio Services Division branches are:

AM Branch: AM Broadcast radio.

FM Branch: FM Broadcast radio.

Auxiliary Services Branch: Broadcast Remote Pickup, FM Boosters and Translators, and Studio-Transmitter-Links. This division also manages the Mass Media Reference Room.

Video Services Division

Licensing, license modification, and license renewal of television stations are handled by the Video Services Division. In addition to over-the-air television, the Division's responsibilities include Low Power Television (LPTV), Direct Broadcast Satellite (DBS), Cable Television (CATV), Community Antenna Relay Service (CARS), and the Instructional Television Fixed Service (ITFS). Questions concerning pending applications, processing policies, and filing requirements should be addressed to the appropriate branch as listed below. Also, requests for waivers of the Rules or for authority to operate inconsistently with the station's instrument of authorization (license or construction permit) are handled by this Division. The Video Services Division branches are:

Cable Television Branch: CATV and CARS Microwave.

Distribution Service Branch: ITFS and DBS.

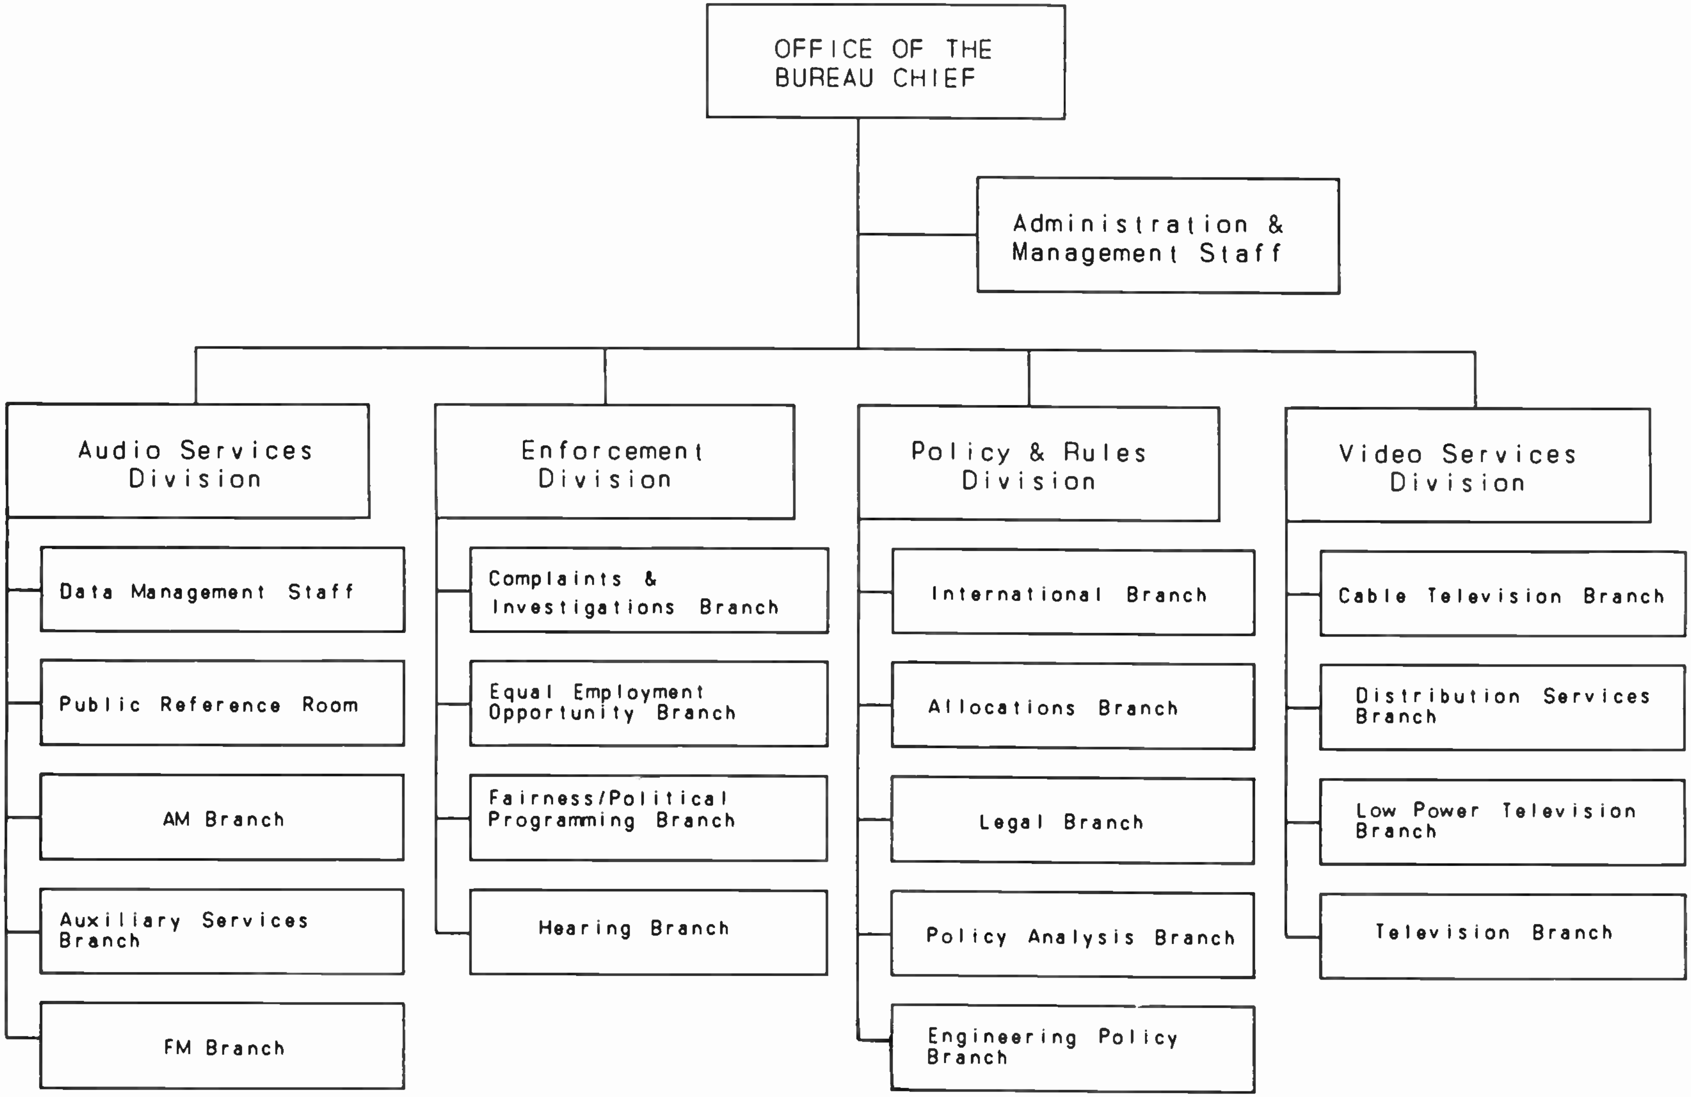
Low Power Television Branch: LPTV and TV Translators.

Television Branch: TV Broadcast.

Enforcement Division

Although the Field Operations Bureau generally conducts station inspections and enforcement monitoring, their work normally concentrates on violations of the technical rules. Enforcement actions in other areas, such as equal employment opportunity or political broadcasting, are handled by the Enforcement Division

MASS MEDIA BUREAU



August 1990

Figure 2. Mass Media Bureau organization chart.

in Washington, DC. This Division also works closely with FOB in enforcement of the technical regulations. Questions regarding enforcement matters should be addressed to the Enforcement Division. The Enforcement Division branches are:

Complaints and Investigations Branch: General.
Equal Employment Opportunity Branch: EEO matters.
Fairness/Political Programming Branch: Fairness Doctrine and Political Broadcasts.
Hearing Branch: Broadcast and CATV hearings.

Policy and Rules Division

New broadcast and CATV rules and regulations generally are written in the Policy and Rules Division. The Division also regularly reviews the rules to eliminate unneeded ones or to modify those that have not kept pace with technology, policies, or legal decision. The Division also interprets broadcasting and CATV rules and regulations. The Division can grant waivers of the Rules to permit experimentation with new technology on broadcast frequencies. The Policy and Rules Division also represents the United States at international forums. Rules and regulations can be classified as: frequency allocations related, legal, policy, or technical. The various branches are:

Allocations Branch: Petitions for Rule Making to amend the FM or TV Table of Allotments.
Legal Branch: Legal rules such as ownership or community ascertainment.
Policy Branch: Rules that are primarily policy decisions such as lottery procedures.
International Branch: International representation, and international coordination of AM and short wave stations.
Engineering Policy Branch: All technical rules.

THE LICENSING PROCESS

Any qualified citizen, firm, or group may apply to the Federal Communications Commission for authority to construct and operate an amplitude modulated (AM), frequency modulated (FM), television (TV), low power television (LPTV) or direct broadcast satellite (DBS) station. The FCC does not license cable television (CATV) systems; however, it does have rules and regulations governing CATV operation and some filings are required. The licensing procedures are outlined in Part 73 of the FCC Rules and Regulations. In general, applicants must satisfy the Commission that they are legally, technically, and financially qualified, and that operation of the proposed station would be in the public interest.

Types of Facilities

Applicants must propose specific station parameters to the Commission. In the case of AM broadcast, applicants generally conduct an interference study to assure that certain field strength contours of the planned station will not overlap existing stations. There are no preplanned AM broadcast assignments to cities or locations. Each application must be uniquely engineered to: (1) serve the community of interest, and (2) prevent interference. Use of a directional antenna will often be required to limit radiation in one or more directions. AM broadcast assignments are made at 10 kilohertz intervals, from 540 kilohertz to 1600 kilohertz, inclusive. Each station has a designation of Class I, II, III, or IV (with additional subdivisions). The classes relate to coverage areas ranging from Class I stations that serve major metropolitan centers and large regions to Class IV stations that serve only one locality. The radiated power of AM broadcast stations varies from 250 watts to 50,000 watts.

Commercial FM and all TV applications differ from AM broadcast in that the Commission has a Table of Allotments in these services. If no allotment exists in the Table, then the applicant must first file a *Petition for Rule Making* to have the proposed city added to the Table. If the proposal meets the Commission's criteria, the proposal will be added to the appropriate Table of Allotments and the applicant can then file for the station. Being successful in amending the Table does not guarantee being granted a station. Once the Table has been amended, other qualified applicants may also file for the station.

Commercial FM stations operate on channels spaced every 200 kilohertz, from 92.1 megahertz to 107.9 megahertz. Stations are classified as A, B1, B, C3, C2, and C, based on location in the country, channel, and power. Class A stations operate between 100 watts and 6,000 watts, while class B stations may operate with up to 50,000 watts and class C stations are permitted 100,000 watts. Television stations have three categories: low VHF, high VHF, and UHF. Channels 2–6 are low VHF and 100,000 watts is the maximum authorized power. High VHF stations operate on channels 7–13 and are permitted 316,000 watts. UHF television stations, which are numbered from 14 to 69, can radiate up to 5 million watts. The coverage areas of all television stations are roughly comparable with the above power levels and with antennas at maximum heights. The power level differences in television compensate for the more difficult propagation conditions at the higher frequencies.

Noncommercial FM (educational) stations have assignments between 88.1 megahertz and 91.9 megahertz. These stations may radiate up to 100,000 watts, but are allocated by actual predictions of service contour overlap rather than by the absolute mileage separations of commercial FM stations. LPTV stations are secondary to full service television stations. LPTV service contours may not overlap full service stations' contours nor cause interference. Successful applicants for direct broadcast satellite transponders receive an exclusive right to use a particular DBS orbital location and channel (or channels) in space. Finally, licensees in the ITFS have exclusive use of a set of frequencies in a given area and may, to a limited extent, merge their facilities with common carrier operations in the Multipoint Distribution Service (MDS).

Applicants may represent themselves before the Commission in licensing matters; however, most applicants employ the services of communications attorneys and consulting engineers. By necessity, to prevent interference and assure license grants to qualified entities, the license process is complex. Professional advice can speed the process and help prevent costly errors.

The First Step to a Broadcasting (AM, FM, or TV) License

After the engineering work has been done to determine that an AM or educational FM station can be designed and built in a community, or that the FM or TV station can be designed and built in a community, or that the FM or TV allotment is now contained in the appropriate Table of Allotments, the next step is to file for a construction permit (CP). Commercial applicants file on FCC Form 301 (Application for Authority to Construct a New Broadcast Station or Make Changes in an Existing Station). Educational station applicants use FCC Form 340 for the same purpose. The application for a CP requests considerable information about the applicant(s) and the proposed facility. Commercial applicants must document the financial ability to operate the station, without revenue, for three months after construction of the station.

If the Commission accepts the application for filing, a *Public Notice* will be released to inform interested parties of the action. After the release of the *Public Notice*, at least 30 days will pass before the Commission again acts on the application. If no objections to the application are received and the Commission otherwise finds the applicants(s) qualified, a construction permit will be issued by the Mass Media Bureau under delegated authority. Again, the Commission issues a *Public Notice* and allows 30 days for interested parties to file for reconsideration of the grant. After grant of the CP, the applicant (now called a "permittee") should file for a call sign. Construction must be completed within 18 months for all classes of station (except TV, which is 24 months) after the grant. Extensions of time may be requested for legitimate reasons.

Contested Applications

Not all applications for construction permits flow smoothly through the FCC. Often other parties will either file applications in competition with the original application or they will contest the application on some grounds. For example, an existing station licensee may disagree with the applicant's basic qualifications or intentions. Any of these protests will undoubtedly delay issuance of the CP, even if the applicant can resolve the conflicts outside the FCC forum. Absent any other method of resolution, the Commission will designate the application for hearing.

Once designated for hearing, the applicant and other parties have 60 days to prepare their respective cases. Generally, the hearing will be conducted by an Administrative Law Judge (ALJ). The ALJ has authority to administer oaths, examine witnesses, and rule on the case based on the evidence presented. After the ALJ closes the record, an initial decision will be issued. The applicant, or any other interested party, may then file exceptions to the finding. The Commission or its Review Board may then hear oral arguments and adopt, modify, or reverse the ALJ's initial decision. If the decision was by the Review Board, the matter may be contested and the case taken to the Commission. Court appeals may be filed after the final decision by the Commissioners.

Station Construction and Equipment Testing

Construction should be exactly in accordance with the terms of the construction permit. If deviations must be made, then an amended FCC Form 301 must be filed. If the station cannot be constructed within the required time period, the permittee must file FCC Form 701 (Application for Additional Time to Construct a Radio Station). It is important to remember that filing of the Form 301 or 701 does not guarantee that an extension of the CP will be granted.

Applying for the Station License

After the station is built and the equipment tested, program testing may begin for nondirectional AM and FM stations and TV stations. At this time, the permittee files for the station license on FCC Form 302. AM and FM stations with directional antennas must apply for and secure authority from the FCC before beginning program testing. Stations operate in the program test mode until a license is received. Processing time varies, but the station license should arrive within a few months, assuming the FCC finds no problems with the Form 302. The FCC may suspend the program test authority because of interference or other appropriate reason.

License Renewal

Broadcast licenses have a life of five years for TV stations and seven years for radio stations. Renewal is not automatic. Licensees file for license renewal on FCC Form 303. If the licensee's record is good and if no one contests the renewal, the renewal process remains relatively simple. On the other hand, the renewal may be placed in hearing status for disposition if the licensee's performance during the previous period is in question, if someone contests the renewal, or if another party files an application which is mutually exclusive with the renewal.

Sales and Transfer

If the holder of a construction permit or license desires to assign it to someone else, application is made on FCC Form 314 (Application for Consent of Assignment of Radio Broadcast Station Construction Permit or License). Should the permittee or licensee wish to transfer corporate control, FCC Form 315 (Application for Consent to Transfer Control of Corporation Holding Broadcast Station Construction Permit or License) is used. FCC Form 316 (Application for Assignment or Transfer—Short Form) may be used when the transfer or assignment involves no substantial change in interest.

Auxiliary and Translator Services

Broadcast station permit and license holders can apply for several types of auxiliary radio stations. For example, Aural Studio-Transmitter-Links are available. Also, Broadcast Remote Pickup (two-way) stations can be used for program production communications or remote broadcasts.

FM licensees and other interested parties may operate FM translators and boosters to fill in areas of the coverage pattern. Likewise, TV licensees and other interested parties may operate TV translators and boosters. Each application varies slightly. Details of these services are contained in Part 74 of the FCC Rules and Regulations.

DBS and LPTV

The application process for these services differs considerably from the usual process for broadcast stations. Unless an application for an LPTV station is not contested (which is very rare), the applicant is selected by weighted lottery. Each applicant receives a weighting in the lottery based on factors such as minority ownership. DBS applicants apply to the Commission for a slot in space in the geostationary orbit. The construction permit can be retained only if a showing of due diligence has been shown in the construction of the facility. Final licensing comes after the station has been placed in operation.

THE FCC RULES AND REGULATIONS

Broadcasters should be familiar with the FCC Rules and Regulations. Every station should have at least one copy of the Rules. The Government Printing Office, not the FCC, sells the Rules through their stores or by mail. New editions are printed yearly. The GPO provides no updates throughout the year when Rules are changed. The following FCC Rule Parts pertain to broadcasting and CATV:

Part 0: Commission Organization.
Part 1: Practice and Procedures.
Part 2: Frequency Allocations and Radio Treaty Matters; General Rules and Regulations.
Part 17: Construction, Marking, and Lighting of Antenna Structures.
Part 73: Radio Broadcast Stations.
Part 74: Experimental, Auxiliary, and Special Broadcast and Other Program Distribution Services.
Part 76: Cable Television Service.
Part 78: Cable Television Relay Service.

All of these Rule Parts can be obtained by purchasing two rule books. The FCC Rules are contained in the Code of Federal Regulations (CFR), Title 47. Parts 0–19 are contained in one book and Parts 70–79 are contained in another. Write the Government Printing Office, Washington, DC, 20402, or telephone (202) 783-3238. Or your local GPO sales office can be contacted directly to order the books.

One or more private publishers offer subscription services to the FCC Rules. Generally, these services are more costly, but regular updates of the Rules are provided to subscribers. Subscriptions can also be obtained to receive copies of daily releases from the FCC.

THE RULE MAKING PROCESS

The FCC, like all other federal government agencies, enacts new rules and regulations through the terms of the Administrative Procedures Act (APA). The APA specifies how rules may be proposed, adopted, and appealed. The APA assures that the public has input into the rule making process. Fig. 3 is a flow chart of the process and may be helpful in understanding the steps. Part 1 of the FCC Rules and Regulations provides detailed information on the FCC's general rules of practice and procedure.

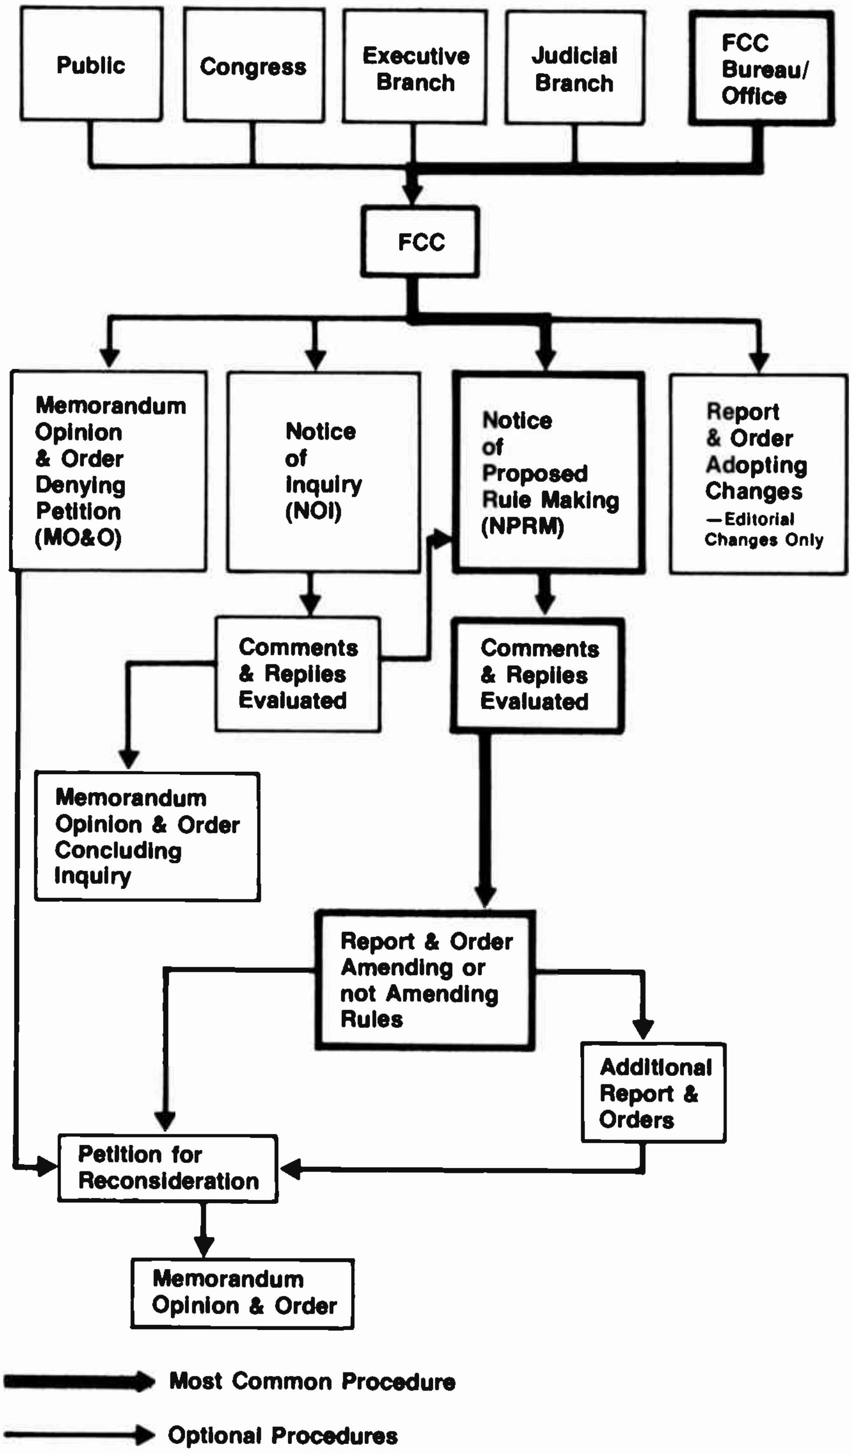
Initiation of Actions

Rule making actions can be proposed by anyone through a *Petition for Rule Making*. Such petitions bring the desires of individuals or groups to the attention of the Commission. The FCC will evaluate the petitions and either dismiss them for one of the reasons in Section 1.401 of the Rules or accept them for action. If accepted, a *Public Notice* will be released giving a brief description of the details of the petition. Others may then submit comments in support of or against the petition.

Other rule makings may begin by direction of Congress, the President, or the courts. The FCC may also initiate rule makings on its own motion.

Early Options

Initiation actions are handled in one of four ways. A petition can be dismissed directly through a *Memorandum Opinion and Order* (MO&O). Minor rule changes of an administrative nature can be made effective directly through a *Report and Order* (R&O). Generally, however, either a *Notice of Inquiry* (NOI) or *Notice of Proposed Rule Making* (NPRM) will be drafted by the staff. If enough information is at hand to draft the proposed rule changes, an NPRM will be issued without first gathering background material in an NOI. After adoption of an NPRM by vote of the Commissioners, the *ex parte* rules become effective (see section below). Because this inhibits direct contact between FCC staff and concerned parties, the NOI may be considered an essential first step in many matters. *Ex parte* does not apply at the NOI stage.



This brief account of how Rules are made at the FCC merely highlights the major components of the process. For details, contact the Dockets Branch.

This article was prepared with the assistance of staff members from several Bureaus and Offices, particularly Sharon Briley, Cable Television Bureau.

Steps:

1. Initiation of Action. Suggestions for changes to the FCC Rules and Regulations can come from sources outside of the Commission either by formal petition, legislation, court decision, or informal suggestion. In addition, a Bureau/Office within the FCC can initiate a Rule Making proceeding on its own.

2. Bureau/Office Evaluation. When a petition for Rule Making is received, it is sent to the appropriate Bureau(s)/Office(s) for evaluation. If a Bureau/Office decides a particular petition is meritorious, it can request that Dockets assign a Rule Making (RM) number to the petition. A similar request is made when a Bureau/Office decides to initiate a Rule Making procedure on its own. A weekly notice is issued listing all accepted petitions for Rule Making; the public has 30 days to submit comments. The Bureau/Office then has the option of generating an agenda item requesting one of four actions by the Commission. If an NOI or NPRM is issued, a Docket is instituted, and a Docket number is assigned.

3. Possible Commission Actions. Major changes to the Rules are presented to the public as either an NOI or NPRM. The Commission will issue an NOI when it is simply asking for information on a broad subject or trying to generate ideas on a given topic; an NPRM is issued when there is a specific change to the Rules being proposed. If an NOI is issued, it must be followed by either an NPRM or an MO&O concluding the inquiry.

4. Comments & Replies Evaluated. When an NOI or NPRM has been issued, the public is given the opportunity to comment initially, and then respond to the comments that are made. When the Commission does not receive sufficient comments to make a decision, a further NOI or NPRM may be issued, again calling for comments & replies. It may be determined that an oral argument before the Commission is needed to provide an opportunity for the public to testify before the Commission, as well as for the Bureau(s)/Office(s) to present diverse opinions concerning the proposed Rule change.

5. Report & Order Issued. A Report & Order is issued by the Commission stating the new or amended Rule, or stating that the Rules will not be changed. The proceeding may be terminated in whole or in part.

6. Additional Reports & Orders Issued. The Commission may issue additional Reports & Orders in the docket.

7. Reconsideration Given. Petitions for reconsideration may be filed by the public within 30 days; they are reviewed by the appropriate Bureau(s)/Office(s) and/or by the Commission.

8. Modifications Possible. As a result of its review of a petition for reconsideration, the Commission may issue a MO&O modifying its initial decision or denying the petition for reconsideration.

Figure 3. How FCC Rules are made.

Comment periods are provided to allow interested parties to express their views. If, based on a review of the comments received, the Commission finds that an NOI should be terminated without further action, it will issue an MO&O stating the reasons for the termination. Otherwise, the matter will be considered for specific rule making in an NPRM. The MO&O is subject to a 30 day period in which parties may file petitions for reconsideration if they have good reason to believe the Commission acted incorrectly.

Notice of Proposed Rule Making

Most rule making items begin as a *Notice of Proposed Rule Making*. The staff prepares the NPRM for consideration by the five Commissioners. An NPRM normally presents the issues and alternatives, may ask specific questions to help finalize the matter, and sets forth proposed rules or rule amendments. An NPRM may address one or multiple topics.

Comments must be filed by the close of the comment period, usually 30 days. Reply comments may then be filed in response to comments, usually for a 15 day period. These two comment periods provide the Commission with a "written debate" of the issues.

The comments and reply comments received are reviewed and enter heavily into the Commission's final actions. However, a comment does not represent a vote for the proposed rules. The Commission must decide on each issue based on the public's interest, convenience, and necessity. Even if the majority of the comments oppose an item, the FCC can nevertheless adopt the proposal. The FCC can also schedule items for oral argument among the interested parties.

Filings should be clear, concise, and address the issues in the NPRM. Emotional responses or uninformed responses are of little value. Copies of the actual texts of the NPRM need to be studied before making comments. All NPRMs are published in the Federal Register and will be available at most larger libraries or law libraries.

The comments are reviewed by Commission staff at the Branch or Division levels. Recommendations are then passed to the Bureau level and ultimately to the Commissioners. The Commissioners will then approve, disapprove, or direct the staff to modify the recommendations.

The staff or the Commissioners may also decide that the record still does not support a decision, and a *Further Notice of Proposed Rule Making* (FNPRM) will be released. Like an NPRM, the comment periods apply. Once the record supports a final decision, the FCC will act by the adoption of a *Report and Order*.

Report and Order

A *Report and Order* may be used to dismiss the proposals in the NPRM, adopt some of the proposals (possibly modified based on the comments), or adopt the rules as proposed. Rules will normally not become effective until 30 days after publication of the R&O in the Federal Register. The R&O constitutes the Commission's final action unless a petition for reconsideration is filed.

Petition for Reconsideration

Any interested person may petition for reconsideration of a final action. The petitions for reconsideration must be filed within 30 days of the date the R&O was published in the Federal Register. The Commission will act on a petition for reconsideration by *Memorandum Opinion and Order*. The initial decision may be modified or the petition may be denied in the MO&O.

Ex Parte Considerations

Most rule making proceedings become *ex parte* upon adoption of an NPRM and remain *ex parte* until 30 days after the Commission's final action (R&O or MO&O for reconsiderations). An *ex parte* contact is any written presentation made to FCC decision making personnel by another person, which is not served on all parties to the proceeding. It is also any oral presentation made to the FCC decision makers, without advance notice to the parties to the proceeding and without opportunity for them to be present. Certain proceedings are "restricted" and no *ex parte* contacts can be made. These would be, for example, contested applications for licenses. Most rule makings are "non-restricted" and do not involve competing claims to a valuable privilege.

Appeal to the Courts

Once the Commission has considered and reconsidered a matter, interested parties may appeal the decision to the federal courts. Ultimately, the Supreme Court could hear the case. Under current law, however, the Federal Communications Commission need not wait for the court decision before enacting the new rules and regulations. As long as the matter has been given full consideration under the Administrative Procedures Act, the FCC may place the new rule in effect until a court rules to the contrary or orders a "stay." The courts typically defer to the expertise of the Commission in technical matters and will often look more to assure that the APA was followed than to try to second-guess the Commission's decision.

1.2 Field Operations Bureau

Staff
Federal Communications Commission, Washington, District of Columbia

THE FIELD OPERATIONS BUREAU

The FCC's Field Operations Bureau (FOB) operates 35 offices throughout the United States, including Alaska, Hawaii, and Puerto Rico. These offices perform liaison between the public and licensees, and carry out enforcement and public service activities.

FOB Headquarters (Washington, DC)

The headquarters of FOB is divided into three Divisions:

1) Engineering Division
2) Enforcement Division
3) Public Service Division

These Divisions formulate policies that guide field work. Responsibilities and functions of the Divisions are:

Engineering Division

The Engineering Division provides engineering expertise for FOB. The Engineering Division develops measurement procedures, designs and builds specialized monitoring vehicles, and develops new tools such as direction-finders. Questions concerning any of these areas may be directed to the Chief, Engineering Division.

Enforcement Division

The Enforcement Division directs all field inspections, investigations, and monitoring (signal analysis) operations. This Division sets priorities for enforcement actions and administers the *Notice of Apparent Liability* (NAL) program. Inquiries concerning enforcement actions may be addressed to the Chief, Enforcement Division. Inquiries may also be made to the Engineer-in-Charge (EIC) of the local field office.

Public Service Division

The Public Service Division administers the Bureau's public service program. This Division assists the public, licensees, and other government agencies with telecommunication-related matters. It also analyzes trends and problems disclosed through public contact. The Division resolves interference problems, supervises the development of publications, and administers the commercial radio operator licensing program.

A subdivision, the Antenna Survey Branch, prescribes painting and lighting requirements for communications towers. Questions in these areas may be addressed to the Chief, Public Service Division.

FOB Facilities

Field offices are grouped into six regions. These offices perform the public service and enforcement functions.

Regional Directors

Each region has a Regional Director whose function is to supervise and administer the operations of the local FOB offices under their jurisdiction. Regional Directors set regional priorities and provide a mid-level supervisory function. They are located in Atlanta, Boston, Chicago, Kansas City, San Francisco, and Seattle.

Local FOB Offices

Most direct contact between broadcasters and the FCC occurs at the local level. Each FOB office is headed by an Engineer-in-Charge, with technical and clerical support staff. These are multi-purpose offices. They provide information, educational activities, radio operator examination and licensing, and conduct enforcement efforts. Off-air and on-site monitoring capabilities are also functions of most FOB offices.

Broadcasters are urged to make contact with their local FOB office and become acquainted with the staff. They can be of invaluable assistance in helping broadcasters understand rules or policies and in resolving interference problems.

Offices are located in: Allegan, MI; Anchorage, AK; Atlanta, GA; Baltimore, MD; Belfast, ME; Boston, MA; Buffalo, NY; Chicago, IL; Dallas, TX; Denver, CO; Detroit, MI; Douglas, AZ; Ferndale, WA; Grand Island, NE; Honolulu, HI; Houston, TX; Kansas City, MO; Kingsville, TX; Laurel, MD; Livermore, CA; Los Angeles, CA; Miami, FL; New Orleans, LA; New York, NY; Norfolk, VA; Philadelphia, PA; Portland, OR; Powder Springs, GA; St. Paul, MN; San Diego, CA; San Francisco, CA; San Juan, PR; Seattle, WA; Tampa, FL; and Vero Beach, FL.

FOB Inspections

Checklists have been prepared by FOB's Public Service Division to assist broadcasters in preparing for an official FCC inspection. It is suggested that the checklists be used on a regular basis to help prevent serious problems from occurring. One checklist covers AM/FM/TV stations, while a second checklist pertains to cable television systems. Copies are available from local FOB offices or from FOB headquarters in Washington, DC.

Elements of an Inspection

Most inspections follow a similar pattern. The inspector will be primarily interested in the technical operation of the station. Although some attention may be paid to required nontechnical records, such as the Public Inspection File, the majority of the time will be devoted to a review of technical parameters. In the case of AM directional stations, the inspection will include visits to the monitoring points.

The following areas are included in inspections, although a particular inspection need not cover all areas, and may be extended to additional areas if needed.

1. Station documents and records, including the Public Inspection File, the tower light inspection log, and other logs as may be required.
2. Transmitter operation.
3. Studio and control point operation.
4. Tower and antenna including painting and lighting.
5. Emergency Broadcast System.
6. Remote control operation.
7. Extension metering.
8. Automatic transmission system.
9. Radio operator licenses.
10. Directional AM antenna parameters.
11. Auxiliary broadcast stations.
12. Signal analysis (frequency, modulation, occupied bandwidth, etc.).

OFF-THE-AIR MONITORING

Technical parameters of station operation may be monitored off-the-air by FCC Field Offices or by FCC enforcement vehicles. Examples of the forms used by the FOB when checking technical parameters are shown in Figs. 1 and 2 at the end of this chapter. Licensees do not usually know about the Commission's monitoring until after the fact. Violations will be brought to a licensee's attention through an *Advisory Notice*, a tier-two *Advisory Notice*, or a tier-one *Violation Notice*, and may also trigger a station inspection.

After the inspection, the inspector will hold a review session with the chief operator and station licensee or general manager. All areas that need improvement will be discussed. Depending on the severity of a particular violation, FCC actions could range from simply a warning to a *Notice of Apparent Liability*, which could ultimately result in a monetary forfeiture.

NOTIFICATION OF VIOLATIONS

If violations were noted during the inspection, the inspector will return to the FCC office and mail an official notice of the violations to the station. One or more of the following kinds of notices may be issued:

Advisory Notice (FCC Form 790)

Near violations will be brought to the attention of licensees using FCC Form 790. Form 790 indicates that an observed condition in some area of the station operation has a high probability of becoming a violation if the problem is not corrected. No reply to an *Advisory Notice* is required. (See Fig. 3 at the end of this chapter.)

Tier-Two Violation (FCC Form 790)

Violations that have little probability of causing interference with other stations will be notified by the tier-two *Advisory Notice*. Again, FCC Form 790 is used. Although no reply is required, licensees should immediately correct the deficiencies. Left unchecked, these violations could lead to more stringent enforcement actions. (See Fig. 3.)

Tier-One Violation (FCC Form 793)

Violations that involve safety of life or property, have a high potential to cause interference, or are of a serious nature for other reasons, will be documented on FCC Form 793. This is an *Official Notice of Violation*. Licensees must reply to such notices within 10 days of receipt. Failure to reply could result in a monetary forfeiture or ultimately in license revocation. Even if the response cannot be fully completed within the 10 days, an initial response should be submitted and an extension of time must be requested. Violations in this category are serious and require immediate attention. Depending on the nature of the violation, whether it is repeated or willful, and the licensee's response, additional sanctions could be imposed. (See Fig. 4.)

MONETARY FORFEITURES

Serious violations can result in a monetary forfeiture. In most cases, the local field office will issue the monetary forfeiture. However, in extreme cases, some forfeitures will be issued by the FCC in Washington, DC. The field-issued forfeitures may be for items related to safety, interference, tower lighting, or important administrative matters (such as not having a licensed operator on duty). More serious violations may have significantly higher monetary forfeitures imposed by the Commission. Failure to pay a forfeiture will result in court proceedings to collect the monetary sanction.

CRIMINAL PENALTIES

Broadcasters normally will not be involved in violations serious enough to be handled as criminal violations. Criminal acts may be committed by persons operating unlicensed stations or marketing illegal radio equipment. The penalties may include fines and/or prison.

APPEALS

As with any governmental enforcement action, licensees have the opportunity throughout the sanction process to appeal the action. If the broadcaster feels that the sanction is inappropriate or that the amount of a monetary forfeiture should be reduced, the office issuing the sanction should be contacted first. Appeals may be pursued through the FCC Regional Director, through the Chief, Enforcement Division, and at higher levels if warranted. It may be useful to obtain professional counsel.

TO THE LICENSEE:

The facts set forth herein indicate that you have violated the requirements of law or treaty. This Notice is issued in accordance with Section 1.89 of the Commission's Rules.

1. Within 10 days from receipt of this Notice, a written reply shall be addressed to "Federal Communications Commission" and SENT TO THE ADDRESS SHOWN ON THE FACE HEREOF AT THE TOP OF THE PAGE. DO NOT address your reply to an individual.

2. **MAKE CERTAIN THAT YOUR ANSWER:**
   a. Fully explains each violation.
   b. Specifically describes the action taken to correct and to prevent continuation or recurrence of each violation.
   c. Is identified as a reply to this Notice. Include the *call sign* of your station so that your answer may be properly associated with the station file.
   d. Does not refer to a reply to another notice, but is complete in itself.
   e. Is dated and is signed by the licensee or, if appropriate, an officer of the licensee.
   f. Includes all the information requested above in addition to any other information requested in Items 3 and 4, below.

3. **CHANGE OF ADDRESS:**
   If the address appearing in Block 1 on the face of this Notice is not your correct address for receipt of mail, include the correct address in your letter of reply to this Notice.

4. If an "X" appears in the box preceding any of the following instructions, comply with the instruction(s) so indicated and submit the information together with the above described letter.

☐ a. State the name of the person who operated the transmitter at the time of the violation. Does this person hold an operator license or permit issued by the Federal Communications Commission?

☐ b. A second copy of this notice is enclosed for the operator to answer the following questions thereon. That copy must be submitted with the letter of reply described in Item 2 above from the person addressed on the face of this notice. RETAIN THE ORIGINAL OF THIS NOTICE.

I, the undersigned, was the operator on duty at the time of the violation noted hereon, and hereby acknowledge this NOTICE. I hold FCC-issued Radio Operator (Not Station) License or Permit as follows (if none, so state): ____________
Number (If unnumbered, so state): ____________
Issuance date: ________ Birth date: ________
Name (print): ____________
Address: ____________
Signature: ____________

FO Bulletin No. 18
November 1987

I. INTERFERENCE

RULE REFERENCE	SUGGESTED PROCEDURE
[ ] Operation Within Limits Rules: 73.44, 73.62, 73.317, 73.687 73.1545, 73.1560, 73.1570	Develop consistent measurement intervals to maintain operation within authorized limits of your license for: -- operating power -- carrier frequency tolerance -- modulation levels -- spurious or harmonic emission -- directional antenna parameters
[ ] Remote Control, Automatic Transmission System (ATS) Equipment, Extension Metering Rules: 73.57, 73.1410, 73.1500, 73.1550	Provide contingency plan for continuity of operation by direct control if remote or ATS equipment fails. Calibrate indicators and alarms as required to guarantee proper operation and maintenance of technical parameters. Fail-safe capability to turn off the transmitter is essential.
[ ] Directional Antennas - Maintenance Rules: 73.61, 73.62, 73.1745	Perform proper and timely measurements at monitoring point locations specified in license. Change mode of operation as required and review records to verify proper station operation and power levels in appropriate time periods. Keep AM directional antenna parameters within tolerance.

RULE REFERENCE	SUGGESTED PROCEDURE
[ ] Antenna Structures and Lighting Rule: 73.1213	*Develop a verification process for the status of the antenna structure which includes: -- daily observation of lights in accordance with station authorization -- direct an immediate notification to FAA of outage or loss of top beacon -- immediate repair of any defective operation/equipment -- periodic review of condition and color of tower paint.
[ ] Fencing Requirements Rule: 73.49	Prevent access of unauthorized personnel by providing fence and lock for system's antenna area. Check periodically that neither has been tampered with or damaged.
[ ] Emergency Broadcast System Requirements Rules: 73.932, 73.961, 73.1820	Conduct a random test of the EBS system once a week. More often, verify that the EBS monitor receiver and tone generator are operating and set at proper frequencies. Check EBS test entry logs frequently to determine that test has been conducted and received. Familiarize all station personnel with EBS procedures, location of EBS Checklist and Authenticator Word List. Arrange easy accessibility/availability of documents. Ensure that station name is on FCC's mailing list for semi-annual revision of both lists. Be familiar with your State plan.

*Bulletin FO-13, Radio Tower Painting and Lighting, contains additional information. Contact the FCC office nearest you.

III. SERVICE QUALITY

RULE REFERENCE	SUGGESTED PROCEDURE
[ ] Technical Parameters Rules: 73.319, 73.322, 73.682	Monitor equipment as often as necessary to keep parameters within limits. Inspect, adjust or repair equipment frequently to alleviate parameters drifting out of tolerance.
[ ] Modulation Rule: 73.1570	Check equipment frequently to ensure that modulation limits, including stereo and subsidiary subcarrier levels, are maintained. Adjust or repair equipment as required.

IV. ADMINISTRATIVE AND NON-TECHNICAL

[ ] Licensed Operator on Duty Rule: 73.1860	Verify that adequately trained and licensed operating personnel are on duty during all periods of operation.
[ ] Designation of Chief Operator Rule: 73.1870	Ensure that: position of chief operator is a clear-cut designation; documentation is easily accessible; chief operator is well informed on all aspects of technical operation and condition of transmitting system; and that the chief operator keeps management up-to-date with problems detected, status of repairs, adjustments, as well as any unusual operating procedures to be followed.
[ ] Posting of Station and Operator Licenses Rule: 73.1230	Post all required licenses in an easily accessible, highly visible location, visible from the principal control point of transmitter. This helps everyone to be familiar with with the terms of licensing.

IV. ADMINISTRATIVE AND NON-TECHNICAL - CONCLUDED

RULE REFERENCE	SUGGESTED PROCEDURE
[ ] Public Inspection File Rules: 73.3526, 73.3527	Maintain a public inspection file that is complete, current, easily accessible and readily available for inspection by the public, at a permissible location.
[ ] Station Logs Rules: 73.1800, 73.1820	Maintain an accurate, complete and current station log, and ensure that the log is signed.
[ ] Special Technical Logs Rule: 73.1835	Maintain an accurate, complete and current record of any interference situation, malfunction of equipment or significant system adjustments, and operating paramaters as may be directed by the FCC.
[ ] Measurement Records Rule: 73.1225	Update and make available antenna resistance or common point impedance measurements and any required equipment performance measurements.
[ ] Station Identification Rule: 73.1201	Identify station in manner prescribed by rules and as stated in license.
[ ] Specifications for Indicator Instruments Rule: 73.1215	Verify accuracy of instruments and repair, adjust and replace equipment as necessary.

1.3 Frequency Coordination

Robert Van Buhler
KNIX-FM/KCWN-AM, Real Country Network, Tempe, Arizona

Richard Rudman
Radio Station KFWB, Los Angeles, California

WHAT IS FREQUENCY COORDINATION?

The push to leave the studio to originate programs has been a part of broadcasting from the beginning. Now, with over 10,000 radio and 1,400 TV stations on the air, the demand for reliable ways to get news, sports, public affairs, and entertainment programming from the field back to the studio has naturally increased. Part 74 of the FCC's Rules deals with segments of the spectrum that have been assigned to the Broadcast Auxiliary Service to accommodate this demand. Part 74 also covers other services outside the scope of this discussion, such as FM and TV translators, Low Power TV, ITFS, and experimental broadcast stations.

While the number of stations requiring support spectrum has grown tremendously since 1970, the amount of spectrum allocated for this support has stayed relatively constant. Broadcasters using Part 74 spectrum began to experience competition for the limited number of channels allocated not only among broadcasters, but also among the other users who share some of the Part 74 spectrum, such as cable operators. Interference from other broadcasters has gradually become a critical problem in many markets and there are no provisions for exclusive licensing in Part 74. Consequently, frequency coordination is necessary to facilitate the allocation of limited spectrum for a growing number of uses among a growing number of users.

SOME HISTORY OF BROADCAST COORDINATION

Formal coordination has existed for some time for major events such as Olympics, political conventions, and space launches. In the case of the political conventions, the major national television networks have rotated the chairmanship of an "ad hoc" group, known as the National Political Conventions Frequency Coordinating Committee. Washington, D.C. has had unique coordination problems along with a history of cooperative effort for pool feeds to cover events of national interest. Such committee activity has traditionally arisen out of a need, mutually felt by broadcast engineers, to discuss concerns before they become problems. Among the oldest groups formed to deal with mutual operational problems, including coordination, were the Washington Executive Broadcast Engineers (WEBE) and the TV Broadcasters All-Industry Committee in the New York metropolitan area.

The first major region to form a committee to deal exclusively with Part 74 coordination was Southern California. In 1976, the FCC revised Part 74, Subpart D, of its Rules, which deals with the Remote Pickup Service used by radio and television stations for dispatch, on-air remote pickup, cues and orders, communications, and transmitter telemetry. Recognizing the use of narrowband FM technology, the Commission reallocated the UHF (450 and 455 MHz) frequencies from wideband 100 kHz channels to smaller bandwidth 50 kHz, 25 kHz, and 10 kHz channels. Under the FCC's 1976 changes, R and S channels were intended for program material, and cues and orders necessary to implement that programming. N1 and N2 channels were to be used for broadcast program material, cues and orders necessary to that material, and operational communications. Microwave path setup and dispatch functions fall under this last category. P channels may be used only for Operational Communications and telemetry. In 1980 the FCC granted the Southern California Frequency Coordinating Committee (SCFCC) a waiver which further split the S and N1 channel as shown in Table 1.

Note that since the SCFCC plan allows for center channel use of the "split" N1 50 kHz channels, the maximum number of 25 kHz channels can jump from

TABLE 1
1976 FCC 450 Channel Plan Showing SCFCC Waiver Changes

CHANNEL WAIVER DESIGNATION	CHANNEL BAND-WIDTH	PEAK FM DEVIATION	TOTAL # OF CHS.	TOTAL # of SCFCC CHANNELS
N1	50 kHz	10 KhZ	12	0
N2	25	5	24	60
R	50	10	10	14
S	100	35	2	0
P	10	1.5	8	8

24 to 60 since the center channel can be used when geographic separation and or terrain shielding permit.

The FCC will now accept license applications based on channel segments of 5 kHz. These 5 kHz segments can be "stacked" for the Part 74 VHF high band and for the UHF band to form channels of the required bandwidth for a given use. Users should consult either their local coordination group or the FCC's Auxiliary Branch in Washington about a local band plan if questions arise. Regions considering formation of a coordination group can study existing band plans based on segmented channels before implementing new plans. No examples of band plans are given. Plans must be custom tailored for each region.

Coordination activity spans many aspects of broadcasting. Some regions have not experienced congestion and interference with their own licensees, but have organized committees to deal with problems associated with broadcasters who enter their regions for temporary operation. After conducting a survey at the chapter level on how this problem is viewed locally, the Society of Broadcast Engineers (SBE) has identified frequency coordination as a chapter project. The SBE National Frequency Coordinating Committee (NFCC) was formed to assist any chapters interested in this project. In addition, the SBE NFCC publishes a list of volunteer coordinators who are responsible for over 90 regions in 50 states, plus Puerto Rico.

If there is one adjective that can be used to describe the nature of effective frequency broadcast coordination, that word is local. Electronic Newsgathering (ENG) for both radio and television introduces many unknowns. Mobile paths cannot be predicted from day to day, or even hour to hour. Large scale news, public affairs, or sporting events may mean interference for everyone involved unless technical personnel familiar with a number of factors are consulted. Since many of these factors are dependent on local propagation anomalies, terrain considerations, and user patterns, experience has proven that engineers who work with these factors at the local level on a day-to-day basis are the best people to consult with and to ask for advice for successful operations.

PROPAGATION CHARACTERISTICS

A number of factors can modify the expected line-of-sight characteristics of VHF and UHF aural and visual transmission. Many of these can be understood best if the radio waves so affected are compared to light waves. Radio waves sometimes bend around corners in a manner than can be compared to light travelling through the reflective surfaces of a periscope so the viewer can see around corners.

The three most common propagation anomalies are (1) ducting effects, (2) reflection due to thermal inversion layers, and (3) obstacle gain (sometimes referred to as knife edge refraction).

These anomalies can occur for seconds at a time, or may exist in a predictable manner for much longer periods. For instance, obstacle gain can be used in some cases to provide permanent and quite dependable links. In the Part 74 environment, these anomalies have to be recognized and taken into account to assure cochannel and adjacent channel users of adequate protection for both fixed and mobile links. Known anomalies in a region must be factored into any coordinated environment. As in the case of terrain, licensees should seek out engineers who have long-time experience in the region to be coordinated so anomalies that have been identified, and the paths they affect, can be taken into consideration.

THE BROADCAST COORDINATION PROCESS

Successful coordination efforts are all founded on licensee-to-licensee contact. The coordination effort, however it is structured, acts to facilitate this contact. As of this writing, Part 74 of the FCC's Rules places the burden of preventing interference squarely on the licensee. Since broadcasting is highly competitive, no local committee should place itself in a position where it "assigns" spectrum. Eligible radio, TV, cable, and other selected entities have an equal right to use shared frequencies specified under Part 74 or Part 78 of FCC Rules and Regulations, subject only to the service and classifications contained therein. No action taken by a coordination committee should restrain these privileges in any way.

Unless otherwise determined by future FCC actions, committees are voluntary facilitators of the coordination process. The committee has no authority to force adoption of its recommendations. Successful committees never act as policemen. This role is left for the FCC if all other means of settling disputes fails. However, committees can and do use neutral mediators to try to solve the inevitable problems and disputes that arise in a competitive world. The committee exists to facilitate coordination, not to enforce it.

A chaotic situation would already exist in most markets if the engineering community had not developed fundamental coordination techniques and practices. Many cable and network entities, production users, and others who now have access to spectrum originally intended to serve only the needs of local broadcasters would not be able to operate reliably otherwise.

The broadcast or cable engineer does not operate in a purely technical environment with frequency coordination. It is an art and technical discipline that extends beyond the engineering department. There are other key players whose cooperation and participation is essential to efficient frequency coordination.

A news director can create a climate of efficient spectrum management in a radio or TV operation by stressing the importance of adhering to good operating practice and home channel plans.

Both news and engineering managers must realize that frequency (or channel) information must be shared by users for coordination to succeed. The ultimate goal is interference-free operation for all users. This goal must be kept in mind whenever Broadcast Auxiliary Spectrum/Cable TV Relay Service (BAS/CARS) frequencies are employed. Cooperation from all parties, and an active and supportive leadership example from engineering and news managers in charge, is essential. Radio/TV station and cable general managers can make frequency coordination possible by allowing their chief engineers the time and sometimes the financial support needed to get the job done. Many progressive local broadcast associations have seen value in underwriting the costs of frequency coordination by providing computer equipment, postage, stationery, duplication expenses and other support to make frequency coordination a success.

General managers are vital to the process in another way. In many stations, engineering is provided by a contractor whose services are limited to maintenance and repair. By nature of their contract, these providers have very little input on the design of mobile systems or fixed links. In such cases, it is important that the manager insist that his BAS/CARS equipment applications and operation be handled harmoniously with the needs of the local coordinating committee and the broadcast and cable community it serves.

Station or system managers should know if their engineers are involved in frequency coordination. The best approach is to meet with the engineer and discuss the importance of coordination to the well-being of the broadcast and cable community.

Simply requiring chief engineers to attend regular coordination meetings is helpful to the coordination process. By attending the meetings, the engineer is familiarized with the process and becomes acquainted with license changes and coordination problems occurring in the market.

In addition to the reasons mentioned that might lead broadcasters to start coordination activity, one more must be added. Many broadcasters now travel outside their markets to cover news, sports, or public affairs events. In 1983 the FCC revised Section 74.24 of the Rules to make it easier for broadcasters to cover such events. A footnote to this Rules change asked that regional coordinators make themselves known to the Commission. The SBE NFCC was first formed to compile a list of coordinators to go beyond the Commission's request. The SBE NFCC updates this listing several times a year.

COORDINATOR CONSIDERATIONS FOR VARIOUS BROADCAST USES OF PART 74 SPECTRUM

Dispatch and Aural Remote Pickup

Channels for this purpose are currently available in a range from 26 MHz to and including 455 MHz.

In major markets experiencing congestion, and in other markets where older equipment is still in service, 26 MHz operation for dispatch and even some types of remote pickup are still being done. Lower power cuing systems for TV field operations sometimes appear in this band. Since it is near to present Citizen's Band channels, it is subject to interference from this service. Propagation conditions at 26 MHz include "skip," so it is common to experience interference in this band from hundreds, or thousands, of miles away at certain times of the year.

VHF dispatch and aural remote pickup are more common throughout the country. With the advent of excellent commercial narrowband FM mobile tranceivers and remotely operated base stations on hills and mountains, many radio and TV stations have used Part 74 VHF channels reliably for years.

Committees will be confronted with a number of seemingly conflicting uses and users as they sort through the years of accumulated problems in VHF and UHF bands. One guiding principle that has helped many committees is the order of priorities outlined by the FCC in Section 74.403(b). The transmission of remote pickup program material for broadcast, either live or delayed, takes precedence over other permissible uses.

VHF and UHF remote pickup with usable audio frequency response to 15 kHz is available with a variety of equipment. In many regions, interference from adjacent channels licensed to other services makes such operation difficult. A strong adjacent channel signal can "capture" an FM receiver, pulling the discriminator away from the desired signal. As channel use builds in a region, broadband white noise rises, making life difficult for wideband receivers.

Some equipment marketed for broadcast use was not designed for today's levels of channel congestion and sometimes makes the problem appear worse than it really is.

Transmitters should always be connected to antennas through ferrite isolation devices and harmonic filters to minimize generation of mixing products in solid state finals. This applies to repeaters, base stations, and mobile transmitters. This was not as important in the days of tube finals, but is critical in today's non-linear solid state world. Ferrite isolators are used for simplex transmitters. Ferrite circulators are used for repeaters.

Receivers can use combinations of attenuators, helical tuned circuits and cavity filters to protect against first stage overload from out of channel emissions. This is especially important since the 450 MHz Part 74 allocations are within one MHz of Land Mobile dispatch and paging bands. Paging transmitters operating at 250 watts commonly employ two-way sites also used by broadcasters and can greatly overload an unprotected receiver.

Broadband white noise at common sites is now being viewed as much of a culprit to degraded receiver performance as spurious emissions. As the number of transmitters at a site increases, the noise level at the site increases. This noise desensitizes all receivers at the site. If a user is operating a receiver at a common site used for high power paging transmitters that are on the air most of the time, the receiver may be trying to listen in a channel less than 1 MHz away from a 250 watt transmitter with a high gain antenna. The resultant 1000 watts (ERP) can cause problems for even the best equipment. Committees can educate members on this subject as well.

At "quiet" sites, receivers with GAsFET preamplifiers working with preselector/filter network receivers have been used successfully to increase receiver sensitivity or regain insertion losses from various filter elements. Careful design can prevent overloading the receiver with the add-on preamplifier.

Remotely located (satellite) receivers will give users better coverage and better immunity to various types of interference. It is desirable to locate satellite receivers at receive-only locations. Such locations can be selected after spectrum analysis shows that adjacent channel and out-of-band emissions are well within the receiver's ability to function at an optimal performance level. Receive-only locations are also good places to utilize high gain GAsFET preamplifiers. Local coordination groups may be of service in locating such sites, and maintaining their RF integrity. Getting the receiver closer to the transmitter is always preferable to increasing transmitter power as a technique to improve reliability. Leased program circuits can deliver audio back to the studio.

Committees can educate members on the pitfalls of common sites, and work with site managers to let them know of licensee concerns. There is a trend in many markets toward re-engineering common sites using transmitter and receiver combiners, and physical separation of transmit and receive antennas. These changes can improve the transmit and receive performance at most sites. Changes like this are expensive. A committee can educate users on the benefits of such projects, and help generate support to make them happen.

Committees can also make members aware of non-Part 74 licensing options for broadcasters who require two-way communications which are not related to Part 74 priorities such as the business band spectrum or cellular telephones. Cellular telephones have been used by many stations for some years now for coverage of news and even program length material. The FCC makes no distinction between cellular and wired telephones for the purpose of broadcast transmissions as of this writing. Stations should check, however, to see how and if broadcast use of cellular phones conforms with state telephone tariffs. Also, it could be interpreted that extended cellular transmissions from any site that can "lock up" a number of cells may be an abuse of the cellular system.

FCC and Federal Aviation Administration rules prohibit use of cellular phones on airborne aircraft. The FAA is developing rules to govern use of cellular phones while the aircraft is at the departure gate and/or experiencing an extended wait on the ground. Also, many airlines currently have their own rules restricting cellular use on aircraft—airborne or not.

The two blocks of UHF channels available to broadcast licensees are separated by 5 MHz. This is adequate for repeater operations, and many licensees in markets with hilly or mountainous terrain have employed this type of system to allow field units to communicate with the base no matter where they are. The convention of repeater pair frequencies is that the 455 group be used for repeater input and the 450 group should be used for the repeater output. Many markets have taken great pains to correct "reversed" situations for mutual benefit. Simplex channels have to be treated on a case-by-case basis. Repeater operation has the benefit of being truly wireless, since remote base systems usually depend on telephone company local channels for control and audio. Unfortunately, repeater operation requires two channels.

Spectrum efficiency in the UHF bands by splitting channels is an accepted mode of operation in some markets. Since it is possible to derive audio response beyond 5 kHz from a 25 kHz narrowband FM channel, many radio stations which want better audio quality for news reports can get it without using a 50 kHz R channel, provided the receiver used is well into full quieting. Committees can work with their members to make sure everyone is using the least amount of bandwidth consistent with needs.

Similarly, a station engaged in voice dispatch does not need a 50 kHz N1 channel. A 25 kHz N2 channel is more than adequate for this use. Responsible committees can help assure that use is matched to bandwidth.

Narrow band radio systems that exhibit better than 5 kHz audio response with 5 kHz FM deviation made possible use of "splinter" or offset channels where distance separations and relative transmitter power levels would permit. High performance receiver IF filters have been in use for this purpose since the early '80s, usually as a part of audio processing modifications to FCC type accepted transmitters that required an FCC modified type acceptance. Built on a firm base of existing rugged mobile equipment, such systems proved that further channel splitting was practical. Receivers designed to take advantage of the spectrum efficiencies of low FM modulation indexes are now coming to market. These receivers promise even greater quality improvements along with greater spectrum efficiency.

High Band VHF and UHF Coordination

Committees can sometimes arrange sharing of channels between users. This can even involve several licensees operating a community repeater system. This choice not only helps enhance spectrum efficiency, but may mean small stations can become part of a larger system they could not otherwise afford. The following are guidelines for new users of Part 74 communications:

1. The potential user should understand that he must be a Part 73 licensee, or a network (as defined in Part 74) to qualify for Part 74 channels.
2. Know that the committee really exists to help accommodate new users in bands already crowded—not to keep new users out.
3. The potential user should explain his needs during an open committee meeting, and publish what is said in the newsletter so everyone concerned can be aware of what is going on. It may be that someone at the meeting might make a suggestion to the potential user that could improve his system, or even accommodate his needs by some other means. For instance, cellular mobile telephones might be all someone needs to do ENG microwave setup if there are no dispatch channels left in the market.
4. The committee may "recommend" certain frequencies. At this point, it is up to the potential licensee to contact each co-channel and adjacent channel occupant and complete the transaction. It is NOT the responsibility of the committee to do this.
5. In the event the parties reach an impasse regarding an issue, the committee can and should act as a mediating force. Usually a compromise can be arranged.

In a congested RF environment, there is always the possibility of adjacent channel interference. Mobiles operating in the field can find themselves next to other mobiles transmitting on an adjacent channel. If this channel happens to be on the repeater output of the first station, the person in the mobile cannot communicate with its base while the other mobile has its transmitter on. If this is a chronic problem, one station may find it desirable to change frequencies. No amount of coordination will ever solve all of these problems.

There is at least one operating practice a committee can promote that will help: make it a standard in the market for each licensee to use the appropriate station identification and unit designator call sign. Not only is this in compliance with FCC Rules, but call signs make it easier to track down interference problems that will inevitably arise.

THE AURAL STUDIO-TO-TRANSMITTER LINK (STL) BAND

Licensees Operating in the 942–944 Band Segment

Licensees holding authorizations for this band segment dated prior to November 21, 1984, may continue to operate on a co-equal primary basis to other authorized stations and services. Stations in Puerto Rico may continue to be authorized on a primary basis.

950 Band Channel Stacking

A number of coordination groups have suggested standards and band plans. Channel stacking is authorized for this band. The FCC has published a list of authorized center frequencies for channel stacks in Section 74.502(b).

950 Band Recent Developments

In January 1990, the SBE filed a rulemaking petition with the FCC proposing to extend minimum antenna standards and minimum path length requirements to stations in the 950 Aural STL/ICR band. The same category A and B antenna requirements now in place for Private Operational Fixed Microwave Service (POFS) stations in the 952–960 MHz band were proposed by the SBE.

Category A half power beamwidth – ±7°
Category B half power beamwidth – ±10°

Note: Limits apply to parallel polarized antenna performance. No limits apply to cross polarized antenna performance.

A minimum non effective isotropic radiated power (EIRP) restricted path length of 22 kilometers (13.7 miles) has been proposed by the SBE, along with a maximum transmitter output of 10 watts. A 0 dB desired-to-undesired ratio to first adjacent channel stations and a 50 dB ratio to existing co-channel stations was proposed to define a technical standard for 950 aural STL/ICRs. Readers are advised to refer to the latest edition of Part 74 Subpart E, for the most recent regulations.

Wireless Microphones

Wireless microphones are becoming more common and should not be overlooked in the coordination process. Coordinators are often asked to act as a clearinghouse for major events where a large number of such mikes are in use. Wireless microphone operation is a permitted use in the band specified in Part 74.802.

Non-RF Alternatives

There are non-RF alternatives available for STL systems. Laser links are feasible for very short distances where there is little likelihood of any interruption of the line-of-sight path.

Many stations still rely on program channels leased from their local telephone company. For short distances that do not involve very many telephone exchanges, this may still represent the best solution for some stations. This may be true especially in markets that have reached STL saturation.

TV MICROWAVE CONSIDERATIONS

Television has come to rely on either their own or common carrier microwave links to interconnect their studios with their transmitters and to facilitate live remote broadcasts. Rules governing links operated by broadcasters are found in Part 74 of the FCC Regulations and cover frequencies from 2, 2.5, 6.4, 7, 13, 18, 21, 23, and 40 GHz bands.

Microwave transmissions can accommodate one or more subcarriers imbedded in the video signal to carry mono or stereo television sound, aural service for a co-owned AM or FM station, program cuing, telemetry, or a combination of these elements. In congested markets one should use the lowest possible subcarrier frequency combinations to keep occupied bandwidth as low as possible.

In major markets the number of stations engaged in field operations exceeds the number of available channels. While spectrum is available in the 2, 2.5, 6.4, 7, 13, 18, 23, and 40 GHz bands at this time, many stations and coordinating committees in these major markets have opted to make 2 GHz the primary band for ENG. However, this band will have some level of STL and ICR activity for the foreseeable future due to its long haul propagation characteristics.

The use of 2 GHz for ENG with its better propagation characteristics means stations have to install fewer ENG receive locations in their service area. Path lengths up to 50 miles can be operated reliably and under optimum conditions, including low humidity, path lengths up to 100 miles may be possible.

In many markets, there is intense competition for the seven primary 2 GHz channels (1.9 through 2.1 GHz) and for the 2 (+1 grandfather) channels at 2.5 GHz. The 2.5 GHz band is shared with other users such as the industrial, scientific, and medical (ISM), service and the private operational fixed microwave service. This factor has contributed to the rise in frequency coordinating committee formation and activity.

Stations having 2 GHz STLs have been, for the most part, relocating to 7 or 13 GHz for several reasons. First, they may themselves be involved in 2 GHz ENG. Second, a fixed link in this band has a high potential risk of interference from mobile operations. Since modern TV ENG portable equipment is frequency agile, and non technical personnel are more involved in field operations, this is a very real risk.

Coordination for ENG is being done more and more on a "real time" basis. Coverage of breaking news cannot be planned. Coupled with the limited number of 2 GHz channels, coordination will only be more difficult in the future.

SUGGESTED OPERATIONAL GUIDELINES FOR TV ENG OPERATIONS

1. Form a Microwave Subcommittee. Compile a list of persons responsible for ENG technical and operational decisions at each station. This list should contain telephone numbers providing access 24 hours a day, should be circulated to all stations involved in ENG operations, and should be updated as needed.
2. The Microwave Subcommittee should be a forum to devise a Home Channel Plan for the region. The purpose of this plan is to give each user a primary channel for his operation. Alternate polarization is assigned to each channel. Split channel operation should be the long range goal for the market. Every user is furnished with a copy of this plan for reference.
3. As part of this plan, each user should set a goal to become frequency, polarization, and power agile.
4. Once the Home Channel Plan has been developed, a method of coordinating this plan in real time is needed. This can be accomplished by a hard wired ring down network between ENG control points or by using a two-way radio system with base stations located at the control point of each ENG license.

   Each ENG control site should have a direct private phone line to which all ENG users have access as a minimal requirement. This has the disadvantages of requiring several phone calls to track down real time interference, or request use of time on a channel, but will satisfy minimum needs.
5. Each licensee should set a goal to equip the ENG operation at the following level:

   A. Mobile transmitters should be frequency agile.
   B. Each transmitter shall have continuously variable control of output power.
   C. Each mobile truck should ideally be equipped with an antenna with excellent sidelobe suppression of the "Silhouette" type.
   D. Each mobile truck should be capable of changing the polarity of their feed.
   E. Each truck should have a means of identifying its test bars, and ideally be able to identify its transmissions in the vertical interval. If this latter type of equipment is employed, the ID is viewed by unlocking the vertical hold control of a video monitor. (This signal must be stripped by a processing amplifier prior to on-air broadcast!)
   F. Use frequency agile ENG receive sites with remote steerable antennas.
   G. Employ multiple receive sites.
   H. Use steep-skirted channel filters ahead of receivers.

6. Truck crews are instructed never to light up until they receive permission from their control point, even on their home channel.
7. Truck crews should receive careful instruction on polarity settings, using only enough power for the path involved, and in the overall operational agreements with other stations engaged in ENG activity.
8. Stations normally stay on their home channel. They use the ENG control point communication system to request different channels for extra activity, to eliminate inevitable adjacent channel interference during some operations, or for paths that conflict on their home channel with Inter-City

Relay (ICR) links, or STLs. The request is made of the station which is assigned the desired channel as its Home Channel.

9. Remember, no one really "owns" a channel. Anyone might be called upon to share their channel on a real time coordination basis.

The plan must enjoy unequivocal support from all levels of management. It is imperative that this support be articulated and understood throughout the entire ENG operation, both in technical and non-technical areas, verbally and in writing.

All reasonable requests for temporary sharing of channels must be accommodated.

Spectrum use for all major events should be preplanned. When advance notice of a major event is given, a coordinator is assigned. Requests for channel assignment are solicited, operating channel assignments are made, and contingencies considered and addressed.

Examples of this would include community celebrations of a regional or national interest, a papal visit to a particular market, or the opening in New York of the United Nations General Assembly. On a larger scale, examples would include Olympic coverage or political conventions. The foregoing are documented examples of successful coordination.

The 7 GHz Band

The 6.875 to 7.125 GHz band of ten channels is typically used for STLs and ICRs. Some use for remote pickup (RPU) has taken place and it has proven to be very satisfactory. The bulk of all STLs throughout the country are in this band. There is some shared activity possible in this band with common carriers in the 6.425 and 6.525 GHz range.

The 13 GHz Band

The 12.7 to 13.25 GHz band with 44 channels (including offsets) is used also for ICR and STL activity. It is also being used more and more for low power "window" microwave to relay signals from isolated cameras in and out of the studio. (Fig. 1). This band is shared with the cable television relay service (CARS) and with private operational fixed service users on a co-equal basis. The chief liability of this band (and any microwave band at approximately 8 GHz or higher) is degradation due to rain and snow attenuation. Careful engineering is required to insure uninterrupted service, particularly for fixed links.

TV STL COORDINATION

Minimum Antenna Standards

TV STL systems licensed as of October 1, 1981 were given a ten year grandfather period to comply with minimum antenna standards established in FCC Docket 21505. Commission action in Gen. Docket 82–334 extended minimum antenna standards to the 2 GHz, 7 GHz, 18 GHz, and 31 GHz TV STL/ICR bands. Although October 1, 1991, would have been the compliance deadline, the FCC extended the deadline to April 1, 1992.

The minimum standards for "Category A" and "Category B" antennas are found in Section 74.641 of the Rules. The FCC had once proposed that Category A antennas be used in "congested areas." However, due to several difficulties, including the problem of defining a "congested area," the FCC abandoned this plan and, in September, 1991, decided not to define any geographic areas as being "congested." Thus, no stations will be required to employ Category A antennas. However, all stations, by April 1, 1992, must employ at least Category B antennas on all fixed microwave links.

Minimum Path Length

A second requirement for minimum path lengths adopted in 1987 in Gen. Docket 82–334 allows short paths at lower microwave frequencies as long as the effective isotropic radiated power (EIRP) be reduced in accordance with formulas stated in Section 74.644(a). After April 1, 1992, grandfathered links will become subject to the same minimum path length requirements that links licensed since 1987 have had to meet. These links must reduce their EIRP for paths shorter than 17 kilometers (10.6 miles) at 2 and 7 GHz.

If the path is shorter than 5 kilometers (3.1 miles) for 13 GHz, EIRP must also be reduced if a new licensee's operation would be hindered. There is no exclusion from this requirement for new licensees.

Power Limitations

Transmitter peak output for fixed stations should not be greater than necessary and should never exceed the power specified in Section 74.636.

Microwave Licensing Considerations

Form 313 is used to apply. Instructions are included with blank forms. A license is always required for an

STL or ICR. The FCC currently issues a "one step" Construction Permit (CP) and license. Contact with a local coordinating committee has not been made mandatory by the Commission.

Temporary Operation for TV Microwave RPU

As in the aural services, temporary operation away from a station's service area without a special license is permitted for up to 720 hours or 30 days per year under Section 74.24 of the Rules. As mentioned earlier in this chapter, the Coordinator Listing compiled and maintained by the SBE can make coordination for this type of operation less painful. The coordination burden is still on the licensee who is visiting not to cause interference to the local stations.

During this type of operation, visitors use their broadcast on-air call sign, not their Part 74 call sign. They should work closely with the local coordination group. Confirm all communications in writing.

A visiting broadcaster should also obtain an accurate database to determine existing cochannel and adjacent channel users. If such a database is not available through a local coordinator, it is incumbent on the temporary user to accurately ascertain who would be affected.

It is important to notify existing co-channel and adjacent channel users of the intended link giving transmitter power output, dates and times of operation, and antenna type and gain information. Exchange names, addresses, and 24-hour telephone numbers.

An engineering study of the path should be performed. This should include detailed path calculations. Several computer programs using accepted path consideration algorithms are available from a number of sources, including the SBE National Frequency Coordination Committee.

A field spectrum analysis is a valuable tool for engineering any link, fixed or temporary. It may uncover licensees who have not been entered in the database, newly authorized construction that may interfere with the path, temporary users who have not notified affected licensees or the local coordination group, Section 74.24 users, or multipath from co-channel links on different paths.

This rule is primarily designed to cover special events and should not be substituted for filing licenses.

Major Event Frequency Coordination for RF Equipment

The FCC has traditionally recognized ad-hoc coordination groups for many years for events such as the national political conventions, major sporting events such as the Olympic Games and the America's Cup races, and news events like NASA Shuttle launches and landings.

Such events require a great deal of planning and hard work. Preparation for the national conventions typically begin 24 to 18 months in advance, although no substantive work can commence until the city sites are announced.

The FCC's normal course of action for such events is to suspend Section 74.24 of the Rules for a period before and during the event. This has the effect of requiring all Part 73 licensees wanting to use RF equipment of any type at the event to contact and coordinate with other users via the ad-hoc coordination group.

The Society of Broadcast Engineers, through its Washington, D.C., attorney will assist local groups with making the proper request and showing to the FCC for such a waiver to be issued for an event.

If an event takes place in an enclosed venue, it may be possible to use channels in use by local broadcasters outside the venue. Using very low power transmitters is an excellent way to allow a number of users to coexist inside such a venue. A large number of handheld transceivers can often be used in adjacent channels by the simple expedient of removing the "rubber duck" antenna and substituting a 50 ohm termination resistor. TV microwave transmitters should be cut back or attenuated to 50-11 milliwatts. If all users cooperate, receivers in the various bands being used will be quite happy, and the needs of all users will be met with little or no interference.

Weekend events may make it possible to use TV and radio ENG channels only used during weekdays. Compatible sharing should take place in the spirit of good cooperation between engineers.

Assuring all equipment used for such events is working properly is an important consideration. While this is the responsibility of the licensee, the coordinating body can sometimes help them deal with this burden. Various techniques have proven to be effective. For example, the FCC usually sends one of its sophisticated trucks to the major political conventions to look for spurious and unauthorized emissions. NASA and the United States Air Force usually check all equipment as it comes into Edwards Air Force Base for Shuttle landings. NASA requires everyone to participate in a "full light up test" two hours before each landing. For smaller events, local groups commonly borrow or rent a spectrum analyzer as a service to guest broadcasters.

If it is not possible to accommodate all users within the existing Part 74 bands for major events, the FCC has granted waivers in the past for one or more unused TV UHF channels, usually for two-way dispatch. This is not possible in all markets. When this spectrum is finally allocated, this option will no longer be available.

Whatever the event, the primary goals of special event coordination are:

1. Protect the existing base of local users.
2. Accommodate itinerant users to the greatest extent possible.
3. Be present at the event to help unsnarl the inevitable "glitches" that will happen.
4. Report to the industry and the FCC after the event so all can learn for the future.

The Benefits of Coordination for Microwave Licensees

As in the case of all Part 74 coordination, committees exist to help new and existing licensees share very limited amounts of spectrum. The move to frequency agility has made real time coordination possible for mobile operations. It mandates cooperation and sharing. In return, it allows licensees to operate their field ENG equipment and STLs with reduced risk of interference.

The Risks and Penalties of Not Coordinating

Failure to coordinate can be an expensive proposition for those who do not participate in this voluntary process. Uncoordinated mobile and fixed links have been taken off the air and re-engineered when they interfered with licensees operating under rules and procedures they agreed to abide by along with other broadcasters in the market. Precedent has been set for FCC support of local agreements where consensus is evident.

Expensive recrystalling, reprogramming, and retuning, antenna and site changes may be the only way to correct interference problems, most of which could have been avoided by communication with the coordinating committee and other users prior to their installation.

Because the broadcasting and cable industries are not monolithically structured, frequency coordination techniques cannot be identical in each market. Only general suggestions can be given as to what each manager or news director can do to participate in and support the coordination process. However, it is clear that coordination cannot succeed without the active support of general managers and news directors at whatever level is practical in a given situation.

INTERFERENCE AND THE PART 74 LICENSEE

Interference to a Part 74 licensee's operations may come from almost any source of RF one cares to mention. Radiation from unshielded computer cables has interfered with wireless microphone operation, for instance. Channel interference from other broadcasters can be thought of as a problem that can be solved by additional attempts at coordination, followed, if necessary, by mediation by a neutral party.

Locating the source of spurious emissions can be a real challenge. The committee can offer some advice and support when a suspected case of interference from an out-of-channel source is reported. Quite often, other stations in the market can make spectrum analyzers available to eliminate the possibility of a mixing product that is actually generated in the front end of the receiver due to an overload condition. This type of problem is common for both voice and video equipment.

Older solid state receivers are sometimes quite prone to front end overload. When an overload-prone receiver is operating at a common site with an appreciable amount of adjacent channel activity, the receiver may be rendered useless. Filtering and attenuator pads can sometimes be suggested as cures. Video microwave receivers operating with preamplifiers can overload easily as a result of proper adjacent channel operation. In such cases, a suggestion to provide a bypass switch is in order.

Committees should encourage licensees to use call letters and unit identifiers for all voice transmissions. All video ENG trucks should be able to transmit bars with ID, and ideally should be able to place ID in the vertical interval as well as for identification during program transmission.

Tracking unidentified interference is not unlike detective work. For video, tuning through the on-air signals may provide a clue. If bars with no ID are seen at an ENG receive location, triangulation may be possible if the interference can be seen by two other locations equipped with steerable dishes. Trucks have been identified by reading street signs that appear in shots. Talent on other stations can sometimes be a good means of identification.

Interference to aural links can be very challenging to trace. If call letters are not being used, anything heard then becomes a clue. If a street address is mentioned, a newsroom "criss-cross" telephone directory can be used to find a telephone number at or near the address. A call to the number identifying yourself, your reason for calling, and if a taxicab or delivery truck has been there (or will be there) often works wonders.

Land mobile transmitters are sometimes designed so the final has power applied to it at all times. Any instability in the final can start it oscillating. These transmitters can sometimes migrate through many megahertz of spectrum, almost at random. When their exciters are keyed, they return to their proper channel. Sometimes only a spectrum analyzer and a lot of patience can trace this type of problem.

Inexpensive direction finding equipment is available for VHF and UHF tracking. Some units work with any hand-held portable. For unmodulated carriers and other types of interference that are present for long periods of time, direction finding can be a very effective (though time consuming and expensive) process.

If the licensee(s) involved, even with committee guidance, are unable to locate the interference, a call to the FCC may be in order. You will be asked for all pertinent information, such as time the interference occurs, its nature, duration, and any other details you might have learned. They generally will not take interference complaints unless you can supply this information. Remember that coordinating committees and their members are never to act as police in such matters.

Curing Interference

Dealing with the broad topic of interference cures is beyond the scope of this chapter. When committees are working to solve such problems, creativity is definitely an asset. For instance, in a case where an aural STL on an adjacent channel on a parallel path was causing interference, the cure that was tried and worked involved installing a larger dish at the transmitter. The dish was aimed slightly off azimuth from its receiver so that the receive site being interfered with appeared in a deep null of the interfering transmit antenna.

MORE INFORMATION

For more information on frequency coordination, including a subscription to the SBE National Frequency Coordinators' Listing, or information on starting a local coordinating committee, contact the Society of Broadcast Engineers, P.O. Box 20450, Indianapolis, Indiana 46220. (317) 842-0836.

1.4 Frequency Allocations for Broadcasting and the Broadcast Auxiliary Services

William R. Meintel
Datel Corporation, Arlington, Virginia

INTRODUCTION

This chapter provides an overview of frequency allocations[1] and a listing of the frequencies available for AM, FM, and TV broadcast stations as well as for the auxiliary broadcast services that support broadcasting operations. Necessarily, such an overview needs to include a description of the decisionmaking process that is involved in allocating a frequency band for a specific purpose.

This complex subject of allocations involves more than just the location of the service in the frequency spectrum; it includes decisions as to the number and width of channels, power and antenna limitations, as well as decisions concerning the technical standards that define how the spectrum will be shared with other users. Because each broadcast service presents unique service and interference objectives, the allocation process has been and will continue to be different for each of these services.

Here it is only possible to provide a brief description of the allocation process before turning to the current situation for each of the services. Where appropriate, the discussion will touch on changes expected in the foreseeable future.

HOW SPECTRUM IS ALLOCATED

It is a fundamental characteristic of radio wave propagation that radio waves follow the laws of physics and thus ignore political or geographic boundaries. As a result, decisions concerning radio frequency allocations cannot be made solely at the local level but must take into account their anticipated impact outside the station's coverage area. Recognizing that coordination in the allocation and use of spectrum is essential, an international mechanism has been established to perform this function, and in the United States, a parallel coordination system has been established at the federal level.

International Allocation

At the international level, frequency allocation decisions are made by the International Telecommunication Union (ITU), a specialized agency of the United Nations, headquartered in Geneva, Switzerland. Like the United Nations, the ITU is a consortium of more than 160 governments, whose purposes are to propose, develop, revise, and administer worldwide frequency allocation plans. Clearly international cooperation will minimize interference and maximize use of the spectrum.

Worldwide allocations for radio services are made through international conferences called World Administrative Radio Conferences, or WARCs. Through a process of give and take, the WARCs make decisions on how to allocate spectrum. General WARCs that encompass the use of the entire radio frequency spectrum are held at roughly 20-year intervals; the last such general WARC took place in 1979, and considered over 15,000 individual proposals dealing with numerous aspects of world telecommunications. Other WARCs are also held as necessary to consider more specific topics of concern on a worldwide basis.

The ITU also convenes Regional Administrative Radio Conferences (RARCs) to consider questions that are unique to a specific ITU Region. Often these RARCs consider implementation of decisions made at an earlier WARC.

Technical Submissions

In addition to allocation proposals and related submissions by ITU member countries, technical input for WARCs and RARCs comes from the International Radio Consultative Committee (CCIR). The CCIR is the arm of the ITU that develops recommendations and provides reports dealing with technical standards and operating procedures. Its work is conducted through 12 study groups,[2] each of which is devoted to a particular radio communication service or specific technical issue.[3]

Overall coordination for the work of the CCIR is provided by its director, elected by the ITU members, who functions at the ITU headquarters in Geneva. The work of two study groups is relevant to broadcasting: Study Group 10 (sound broadcasting) and Study Group 11 (television broadcasting). Under both of these study groups, there are subgroups to deal with specific areas of interest. There also are joint study groups that deal with questions that are of relevance to more than one study group. Each study group has an international chairperson and one or more vice chairpersons who are provided by interested participating administrations (participating governments).

ITU and CCIR work is carried out not only by the members of the ITU, but also by recognized users and standard setting groups such as the European Broadcasting Union and the U.S. broadcasting networks. Within individual administrations, organized structures often are created to provide input for the administration to submit to the CCIR.

In the United States, this activity is chartered by and operates under the Department of State (DOS). There is a U.S. national chairman appointed by DOS, two national vice chairmen from the Federal Communications Commission (FCC), and one from the National Telecommunications and Information Administration (NTIA). DOS also appoints a U.S. national chairman for each of the individual study groups. Each is responsible for the work of the group and heads the U.S. delegation to international study group meetings. In the United States, CCIR activities are open to participation by the public. Contributions to CCIR work in the United States come mainly from the private sector. Elsewhere in the world, CCIR work is performed primarily by government employees.

In addition to providing technical input timed to coincide with scheduled WARCs and RARCs, the CCIR's basic work is carried out in four-year cycles. Three international CCIR meetings are normally held; the first two meetings, usually held at the 18- and 36-month points, are for the individual study groups and are referred to as the *interim* and *final* meetings of the study group. The four-year cycle concludes with a combined meeting of all the study groups, referred to as the plenary meeting. At the plenary meeting, all documents from the study groups are submitted for approval; an outline of work for the next cycle is produced, and the CCIR director and study group chairmen for the next cycle are elected. In addition to these meetings, provision is made for extraordinary meetings to address issues of critical importance that cannot be resolved during the regular study group meetings.

Administrations may suggest any matter of interest for study that is within the purview of the CCIR, but priority is given to issues that are relevant to a scheduled WARC or RARC.

The cumulative recommendations and reports of the CCIR are updated and published at the end of each four-year cycle in books commonly referred to as the Green Books. These contain a great deal of information and recommendations.[4] The material relates not only to spectrum allocation but includes related information concerning measurement procedures and standards for audio and video recording equipment used for the exchange of broadcast programming.

The Allocation Process

The allocation of radio frequency spectrum occurs as a result of a series of interrelated decisions. On the first, most basic level, blocks of frequencies are allocated on a worldwide basis by the ITU WARC process. Exactly which blocks of frequencies are allocated to particular services is determined by evaluating the many specific proposals submitted to the WARC for each frequency band. Technical input is obtained from propagation studies and other engineering analyses undertaken as part of the CCIR process and from the submissions of individual administrations. Frequently, blocks of spectrum are allocated for the same purpose on a worldwide basis, but may also be allocated for different purposes on a regional basis.

Member nations theoretically retain the sovereign right to domestic use of the spectrum so long as such use is not in contravention of the International Radio Regulations or the international agreements to which that administration is a party. However, as a practical matter, the flexibility of administrations to use the spectrum is limited by the worldwide allocation system and the need to avoid harmful interference.

Unlike the FCC, the ITU does not license users of the spectrum. Instead, it operates only as a coordinator, maintaining a Master International Frequency Register (MIFR or Master Register) of radio stations worldwide. The agency within the ITU responsible for that activity is the International Frequency Registration Board (IFRB). Member administrations have agreed to provide notifications to the IFRB of the new stations or modifications in existing stations operating within their respective countries. The IFRB studies these notifications for compliance with the existing world or regional agreements and provides the results of its studies to the member nations. Only those notifications that comply with the existing agreements are placed in the Master Register of stations. Once a station has been placed in the Master Register, the member nations are obliged to provide it with the internationally agreed level of interference protection.

Because the WARC and RARC agreement texts provide only a general framework, many specific matters are left to individual nations to resolve and implement. In the U.S., the FCC and NTIA share the responsibility for implementing agreements to which the U.S. has assented, including the bilateral or multilateral agreements negotiated with our neighbors.

There are differences in the treatment of the various broadcast services. Because AM signals propagate over great distances, international decisions have a much greater impact on AM broadcasting than FM and television, whose VHF or UHF propagation is much more limited. This means that the restrictions on FM and TV allocations imposed by international agreements are usually applied only to areas near the borders. However, international agreement on technical transmission standards often is desired in order to foster the absence of interference and the worldwide free flow of communication.

Domestic Allocation Process

Regulation of spectrum began with the U.S. Department of Commerce in the early 1920s, when the Secretary of Commerce granted the first AM broadcasting licenses. By 1927, the number of AM stations had increased to 733, and over six million radio receivers had been manufactured. However, because of an unfortunate court decision that precluded the Secretary of Commerce from dealing with the specific choice of location, power, and operating frequency, these matters were left largely to the discretion of the broadcaster. This led to a chaotic use of the spectrum, with widespread interference, a situation that led to the creation of the Federal Radio Commission in 1927. Seven years later the Federal Radio Commission was replaced by the Federal Communications Commission (FCC), formed pursuant to the Communications Act of 1934. Ever since, anyone desiring to operate a broadcast station, or most any kind of radio transmitting device, must apply to the FCC and be granted a license before commencing operation. Today, a broadcast license sets forth all essential technical parameters of station operation.

The NTIA performs a similar function and coordinates the spectrum used by government agencies. The FCC works with the NTIA where there is a need for coordination between government and private uses of the spectrum.

Spectrum for domestic use must be allocated by FCC rule making proceedings. The FCC can initiate domestic allocation rule making proceedings on its own motion or in response to requests from the public, but in so doing it must not contravene international agreements to which the United States is a party. The FCC rule making process is a complex subject in its own right, but for present purposes, only a brief description is required. Rule making proceedings are based on a public record developed through responses to the issuance of a Notice of Proposed Rule Making that are filed by interested parties. In addition to filing comments on the FCC's proposal, the public may reply to the comments of other parties. After the Commission evaluates the responses to its Notice, it may decide to either adopt the proposal as originally set forth, modify it, based on the comments received, or possibly reject the proposal.[5]

Many FCC proceedings are controversial in nature. Allocations proceedings may be especially controversial, since a particular communication industry's livelihood may depend in part on how much spectrum is allocated. Thus, FCC allocation decision making is not simply a matter of technical evaluation but must be seen as part of the political process as well, as happens when entire industries compete for a limited amount of spectrum. Where the number of users in a particular frequency band is expected to be relatively small or their use sporadic, the FCC may propose sharing of this spectrum with other users. Such proposals may also be controversial, since sharing spectrum with a dissimilar service invites the possibility of interference and difficulties in coordinating the use of the frequencies. Because of these and other factors, FCC allocations proceedings consume a great deal of its time and energy and can impose burdens on the organizations that participate in them.

From time to time, alternative methods have been proposed for allocating spectrum. These ideas usually envision the removal of the FCC as the arbiter of mutually exclusive requests for spectrum and instead substituting marketplace forces. Under a market allocation system, frequencies would become used by entities who would pay for them; noneconomic, social, or public policy factors would not be considered. The Commission's role would be reduced to that of a technical "traffic cop" of the airwaves. To date, this approach has not been significantly implemented.

AM BROADCASTING FREQUENCY ALLOCATION

In the United States, amplitude modulated (AM) stations operate with carrier frequencies in the center of 10 kHz channel bandwidths. Until recently, most people thought of the AM band as including 107 channels in the band from 535–1605 kHz, as has long been the case in the United States. However, the frequency band allocated to AM broadcasting actually includes a total 118 channels, each 10 kHz wide, in the band 525–1705 kHz, as shown in Fig. 1. As of this writing, the lowest channel (530 kHz) is not used for conventional broadcasting in the United States but is used solely for Travelers Information Stations (TIS). A recent FCC Rule Making has made the 10 channels from 1605 kHz to 1705 kHz available for use in the very near future.

Currently, there are over 4,800 commercial and noncommercial AM stations operating in the United States. These stations operate with various powers levels, up to a maximum of 50 kilowatts. About half of these stations use multitower directional antennas to restrict radiation in certain directions, for the purpose of controlling interference or maximizing radio service in particular directions.

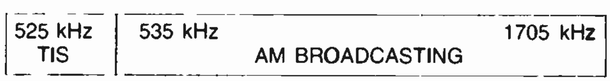

Figure 1. AM broadcasting band, including the Travelers Information Service (TIS).

Allocation decisions for the AM broadcast band are the most complex of the broadcast services. Since propagation varies with time of day, geographic latitude, and frequency, the engineering analyses necessary to establish interference protection for other stations can be quite complicated. Engineers, the FCC, and the IFRB have sophisticated computer programs that analyze the input of a new or modified AM station proposal. Before going into the details of the AM broadcast allotment system currently in place in the United States, it is necessary to provide a brief history of recent AM broadcasting allocations.

From the beginning, the countries in the North American area recognized the need to cooperate in the use of AM frequencies, and in 1937 they reached agreement on how to proceed. Soon, however, this agreement was found to be inadequate. Negotiations began on a new agreement. Although the North American Regional Broadcasting Agreement (NARBA) was signed on November 15, 1950, it did not go into effect until 10 years later, on April 16, 1960. Signatories to NARBA include the United States, Canada, Cuba, the Dominican Republic, and the United Kingdom on behalf of Jamaica and the Bahama Islands. Mexico, an earlier participant, removed itself from these negotiations, and a bilateral agreement between the U.S. and Mexico was reached in 1957. It was superseded by a new U.S.-Mexican agreement in 1968.

These international agreements became necessary principally because nighttime AM propagation has the potential for causing widespread interference to neighboring countries unless mutual allocations criteria and related technical standards could be agreed upon and implemented. To this end, NARBA provided for a partitioning of AM broadcast channels into three basic classes. The first of these are the so-called *clear* channels, whose high-powered stations would have primary access to the frequency. Other stations could use the channel subject to providing full protection to the clear channel's dominant station(s). Clear channel dominant stations were designed to provide service over extensive areas by means of skywave as well as ground wave signals. NARBA set aside 60 of the 107 channels then available for clear channel use. Each NARBA country, except Jamaica, received a priority on one or more clear channels, with the U.S. receiving a major portion of available priorities. NARBA countries without a priority on a given clear channel could still assign stations on that channel, provided that these stations protected the area-wide service of the dominant station in the country with the NARBA priority.

The second class of channels were called *regional* channels, and these occupied an additional 41 channels. Unlike clear channels, these channels were shared on a equal basis by all the NARBA countries. Stations operating on these channels were intended to provide service to a considerable area, but, unlike the clear channel stations that received protection for their skywave as well as groundwave service, only the groundwave service provided by the regional stations was protected.

The remaining six frequencies were the *local* channels that provide an even more limited type of groundwave service. Only limited interference protection was provided to these relatively low power operations.

Recognizing the need for updating these agreements and for developing more efficient coordination throughout ITU Region 2 (North and South America), the 1979 General WARC called for a conference to be held in Region 2 to address AM broadcasting and sharing criteria. That conference was held in two sessions in 1980 and 1981 and resulted in the adoption of an agreement among most of the countries of the hemisphere. Included as part of that agreement, referred to as the 1981 Rio Agreement[6] (for Rio de Janeiro, the location of the second conference session), was a list of all of the operating stations in the hemisphere along with information indicating whether or not the stations were receiving or causing harmful interference according to the technical criteria set forth in the agreement. Stations not causing interference were placed in the IFRB Master Register and accorded protection from interference as defined by the agreement. In situations where interference already existed, the countries involved were asked to meet and work out mutually satisfactory solutions.

Because the general framework of the Rio Agreement did not deal with the particular needs and desires of the United States, Canada and Mexico, separate new bilateral agreements have been negotiated which incorporate the required additional items concerning coordination and technical parameters. Although the Rio Agreement applies throughout most of Region 2, as of this writing, relations with the Bahamas and the Dominican Republic continue to be governed by NARBA, as neither country has taken the necessary steps to replace the NARBA provisions with the Rio 1981 Agreement. Relations with Cuba regarding the 535–1605 kHz band are governed solely by the international Radio Regulations rather than by agreement.

The 1981 Rio Agreement changed the NARBA station classifications. No longer are the channels themselves classified. Stations are now classified without regard to the channel on which they operate. Stations providing wide-area service, both groundwave and skywave, are now designated Class A stations, while stations providing the equivalent of the regional and local services are designated as Class B and C respectively. The new agreement permits any class of station to operate on any channel so long as it provides protection to other stations based on their classification.

Over the years, there have been many changes in the nature of AM broadcasting in the United States. In early years, clear channel stations provided the only service available in many areas of the U.S., but with the end of World War II, demand increased greatly and many AM stations were established in all areas of the country. Because of its early development of AM radio service, the U.S. experience has been used as a model for the regional and bilateral agreements. Figs. 2, 3, and 4 show the classification system that exists today. Until 1990, for domestic purposes, the U.S. continued to use the old method classification of stations based on frequency, rather than the new system adopted in the Rio Agreement. In 1990, the FCC proposed to align the U.S. domestic classification system for AM stations with the 1981 Rio Agreement system. The current status of AM station classification is contained in Section 73.21 of the FCC Rules and Regulations.

The AM broadcasting system in the United States has continued to evolve as the demand for more stations has grown. One result of the demand for facilities is the increased use of directional antennas to provide required interference protection while enhancing coverage in other directions.

Another post-war development was a large increase in the number of daytime-only stations. These are stations authorized to operate only during daylight hours. Since propagation conditions during these daylight hours do not normally support significant skywave transmission, there are many locations where a station can operate during the daytime without causing harmful interference to other stations. Based on this concept, the FCC over the years licensed approximately 2,500 stations for daytime-only operation.

Recognizing that daytime-only stations (and even some full-time stations that operate with restrictive directional antenna patterns during the night) are unable to provide effective service during early morning hours, the FCC originally allowed these stations to operate during this period so long as no interference complaint had been received. Ultimately, this proved to be unworkable, and a more formalized approach was adopted. The FCC began granting Presunrise Authorizations (PSRAs), permitting many of these stations to operate with their daytime facilities with powers up to 500 watts during the presunrise period between 6:00 AM and local sunrise. While some interference occurred, the FCC believed the interference was balanced by the public's need for local informational services during this very important morning time period.

While presunrise operation did provide some relief, it did not end the economic problems many stations faced in effectively competing with full-time stations. The FCC was pressed to provide relief in the form of post sunset operation for daytime-only stations. With the removal of international impediments, the FCC did provide such relief.

International classes of AM stations	Corresponding U. S. classes prior to 1990	Classes of Channels available in U.S. for each class
Class A	I-A	Clear channels
	I-B	"
	I-N	"

1550 kHz	II	1560 kHz	I-B		

* In addition to the Class I-A or Class I-B stations that can be assigned to the above channels, various Class II stations may also be assigned.

Regional Channels

(Class III or III-S stations are assigned to these channels)
550, 560, 570, 580, 590, 600, 610, 620, 630, 790, 910, 920, 930, 950, 960, 970, 980, 1150, 1250, 1260, 1270, 1280, 1290, 1300, 1310, 1320, 1330, 1350, 1360, 1370, 1380, 1390, 1410, 1420, 1430, 1440, 1460, 1470, 1480, 1590, and 1600 kHz

Local Channels

(Class IV stations are assigned to these channels)
1230, 1240, 1340, 1400, 1450, and 1490 kHz

Figure 3. Channel utilization in the United States prior to 1990.

Class of Station Prior to 1990	Power in kW Daytime hours Minimum	Maximum	Power in kW Nighttime hours Minimum	Maximum
I-A	10.0	50.0	10.0	50.0
I-B	10.0	50.0	10.0	50.0
I-N	10.0	50.0	10.0	50.0
II	10.0	50.0	10.0	50.0
II-A	10.0	50.0	10.0	50.0
II-B	0.25	50.0	0.25	50.0
II-C	0.25	50.0	0.25	1.0
II-D	0.25	50.0	Daytime only	Daytime only
II-S	0.25	50.0	less than 0.25	
III	0.25	5.0	0.25	5.0
III-S	0.25	5.0	less than 0.25	
IV	0.10	1.0	0.10	1.0

Figure 4. Power limitations by class of station.

Once again, taking into consideration the need for more service of a local nature, and recognizing the changing nature of propagation conditions in which full nighttime conditions do not exist until several hours after sunset, the FCC granted Post Sunset Authorizations (PSSA) for most of the daytime only stations. These authorizations permit operation for periods of up to two hours past sunset with power reduced to prevent interference. The FCC also changed its rules concerning the minimum power at which a station is permitted to operate. This, in turn, led to a subsequent decision allowing many PSSA stations to operate throughout the night, albeit with reduced power.[7]

Still another change that has occurred pertained to the use of the Class I-A clear channels. At one time, only a single station was permitted to operate on these channels at night, but in two FCC decisions, first some and now all of these channels have been broken down to permit the authorization of additional nighttime operations. Clear channel stations that at one time provided service for a major portion of the country during nighttime hours now are protected only out to a distance averaging 750 miles.

Use of the Expanded Band

The FCC has issued a rule making to implement the results of the expanded band Regional Administrative Radio Conference sessions held in 1986 and 1988. At that conference, participating administrations reached agreement on the criteria for expanding the AM band in Region 2 by the adding ten new channels from 1605 kHz to 1705 kHz. Although the Regional agreement established specific technical criteria for the implementation of the new channels, (including the granting of priority usage of certain channels) the United States still retained considerable latitude in its domestic implementation. In a large country like the U.S., the use of the channels is unrestricted except in the relatively few areas near the borders with our neighbors.

The basic criteria set forth in the Regional Agreement are as follows: stations may operate with 1 kW of power with a nondirectional antenna height of 90°; or stations may operate with a power not in excess of 10 kW by employing a directional antenna to provide equivalent protection to stations in other countries. The channels allotted to the United States in the border areas vary from location to location, but, as noted, over a large portion of the U.S. all ten of the channels may be used. Nonallotted channels are not precluded from use, but the allotted channels in the other countries must remain fully protected.

Persons seeking an authorization for a new AM broadcast station may do so by filing an application with the FCC. Such application must provide documentation that the proposed operation will comply with all applicable FCC Rules as well as the appropriate international regulations. The details and methodology for allocating AM radio stations along with basic design specifications for AM directional antennas can be found in FCC Rules at Sections 73.14 to 73.190. A reader interested in further details regarding AM allocations criteria is referred to these sections of the FCC's Rules.

FM BROADCASTING FREQUENCY ALLOCATION

The frequency band 88 MHz to 108 MHz is allocated for FM broadcasting in Region 2 and, with some exceptions, the same is true in Regions 1 and 3 as well. However, unlike AM, FM broadcast allotments are largely a domestic matter, especially in large countries such as the United States, due to the limited nature of signal propagation at these frequencies. Although there are some international regulations regarding FM broadcasting, there is no region-wide FM agreement in Region 2. Instead, there are bilateral agreements between the U.S. and Canada and between the U.S. and Mexico. Both regulate the use of FM Channels in the border areas and specify technical standards in order to insure system compatibility.

The basic plan of the FM broadcast band is shown in Fig. 5. The band is divided into 100 channels, each 200 kHz wide. In the United States, the lower 20 channels, located between 88 MHz and 92 MHz, have been reserved for noncommercial broadcasting, but some of these stations operate on the upper 80 channels as well. In addition, although it is part of television channel 6, the frequency 87.9 MHz can be used for low power noncommercial FM stations, but its use is severely restricted.

As with AM broadcasting, there are different classes of FM stations designed to provide different types of service. In recent years, the number of different classes of stations has grown considerably as the demand for more stations increased. In response to this demand, the FCC has significantly modified the criteria concerning the use of the frequencies. In June 1983, the FCC concluded a lengthy rule making proceeding and modified the domestic allotment criteria for FM broadcasting. Prior to this action, there were three classes of stations on the 80 commercial channels. Twenty of these channels were used for lower power Class A stations having a maximum effective radiated power (ERP) of 3 kW and a maximum antenna height-above-average-terrain (HAAT) of 300 feet. Class A stations have a 1 mV/m service radius of about 15 miles. Higher power Class B or C stations operated on the remaining 60 channels. Whether a station was

82–MHz CHANNEL 6	88 MHz–92 MHz U.S. Noncommercial	92 MHz–108 MHz U.S. Commercial
TELEVISION	FM BROADCASTING	

Figure 5. FM broadcasting band. The FM sound carrier for TV channel 6 is 87.75 MHz or 15 kHz below the first FM broadcast channel (220 at 87.9 MHz).

designated Class B or C depended on where in the U.S. it was located.[8] A Class B station is located in Zone I or I-A. Zone I is the northeast U.S., extending south to the Virginia-North Carolina border and west to the Mississippi River. Zone I-A is all but the northernmost portion of California, plus Puerto Rico and the Virgin Islands. Class C stations operate elsewhere in the country, which is referred to as Zone II.

Class B stations operate with a maximum ERP of 50 kW at 500 feet HAAT and have a service radius of about 33 miles. Class C stations operate with a maximum power of 100 kW at 2000 feet HAAT, for a service radius of approximately 57 miles. FM stations in each of these classes may elect to operate at a HAAT above the maximum, but in such cases they are required to make a compensatory reduction in ERP as noted in FCC Rules and Regulations Section 73.211.

This system was changed drastically in 1983.[9] The FCC:

1. Permitted Class A stations to operate on channels previously reserved for Class B or C stations.
2. Created three new classes of FM stations. Class B1 stations are permitted to operate in Zones I and I-A with a maximum ERP of 25 kW at 100 meters (328 feet HAAT); Class C1 and Class C2 stations are permitted to operate in Zone II. Class C1 stations are permitted a maximum ERP of 100 kW at 300 meters (984 feet) HAAT, and Class C2 stations are permitted a maximum ERP of 50 kW at 150 meters (492 feet) HAAT.
3. Required stations that were previously licensed as a Class B or C, and were not operating at the minimum level specified for their class under the new rules, to upgrade their facilities within three years. Otherwise, the under-minimum facilities would be reclassified to the appropriate lower class based on the facilities they used.
4. Increased the maximum antenna HAAT for Class A stations to 100 meters (328 feet).

In 1989 the FCC further modified the rules to permit Class A stations to operate with an ERP of 6 kW and a HAAT of 100 meters, and added an additional classification (C3) that permits operation in Zone II with a maximum of 25 kW at 100 meters HAAT. In addition, there also are Class D stations that operate as noncommercial educational stations with power not in excess of 10 watts. However, applications for this class of station are no longer accepted.[10] A complete list of the station classes and a summary of FM allotment standards can be found in Figs. 6A and 6B.

Unlike AM broadcasting, where a new station may be applied for at any location where it can meet applicable criteria, the use of commercial FM channels (channels 221–300) is governed by the FM "Table of Allotments" found in Section 73.202 of the FCC's Rules. This table lists all FM channel allotments that have been made available for use. Most are already in use. If the Table does not list a vacant channel in the desired community, the prospective applicant must file a rule making petition with the FCC seeking to add such a channel for the community. The rule making petition proposing such addition must provide a showing that the proposal meets the separation requirements that are applicable to the class of station being proposed. A complete list of the spacing requirements, including those that pertain to stations located in Canada and Mexico, is provided in Figs. 7, 8, 9, and 10. Alternatively, a petitioner can propose to modify the Table by deleting a vacant existing allotment or by changing the frequencies of an existing station and thereby achieve compliance with these spacing requirements.

Station class	Maximum ERP	Maximum HAAT in Meters (ft.)	Expected service radius
A	6 kW	100 (328)	28 km
B1	25 kW	100 (328)	39 km
B	50 kW	150 (492)	52 km
C3	25 kW	100 (328)	39 km
C2	50 kW	150 (328)	52 km
C1	100 kW	299 (981)	72 km
C	100 kW	600 (1968)	92 km

Station class	Maximum ERP	Maximum HAAT in Meters (ft.)	Expected service radius
A	6 kW	240 (787)	42 km
B1	25 kW	150 (328)	46 km
B	50 kW	472 (1549)	78 km

Figure 6B. Standards for FM Allotments in Puerto Rico and the Virgin Islands.

Once a location has been added to the Table of Allotments, the FCC will announce a period of time called a *window* when it will accept applications for the location. If, as often is the case, there are multiple applicants, the winning applicant will be determined by a comparative hearing. It also should be noted, that in cases where it is not possible to locate a transmitter site that meets the mileage separation requirements, the FCC does permit the use of reduced power and/or antenna height, as well as directional antennas, in order to provide equivalent protection to other stations. However, this only applies to the filing of an application for a location that is already in the Table of Allotments. The FCC will not accept a proposal to modify the Table unless it is shown to meet applicable separation requirements.

Assignment of stations on the noncommercial educational channels (200–220) is accomplished more in the manner that is followed in AM, where an application includes a showing that interference will not be caused to other stations. In addition, for proposals to use Channels 218, 219, and 220, compliance with applicable separation requirements to any allotments on higher, adjacent commercial channels is required.

In addition to the regular FM broadcast stations, there are two other types of stations that are permitted to operate in the FM band on a secondary basis. These

Relation	Co-channel	200 kHz	400/600 kHz	10.6/10.8 MHz

are FM translator stations and FM booster stations. An FM booster station retransmits the signal of a primary station on the primary station's channel in order to serve areas where the primary station's signal is inadequate. An FM translator station is similar to an FM booster station, except that the signal is not retransmitted on the same channel but instead is translated to a different channel. These stations are authorized in accordance with Part 74, Subpart L of the FCC Rules which, among other things, requires that such stations provide protection from interference to all regular FM Broadcast Stations.

TELEVISION BROADCASTING FREQUENCY ALLOCATION

There are several different frequency bands used for television broadcasting within the United States. The plan as shown in Fig. 11 includes the low-VHF band TV channels 2 to 4 (54 MHz to 72 MHz) as well as channels 5 and 6 (76 MHz to 88 MHz), the high-VHF band channels 7 through 13 (174 MHz to 216 MHz), and the UHF band channels 14 through 69 (470 MHz through 806 MHz). The greater portion of all of these bands is allocated for broadcasting throughout the world; but this allocation is not uniform and in many areas other uses such as land mobile are permitted on a secondary basis. This is also the case in the U.S., where certain UHF television channels are now used for radio services in some major cities. In general, due to the limited extent of radio wave propagation in the television band, TV allocations, like FM, are basically a domestic matter, with few international regulations. Although no regional agreement exists, the United States does have agreements with both Canada and Mexico concerning television allocation.

Like FM broadcasting, TV allocations in the United States are governed by a Table of Frequency Allotments. This Table, which can be found in Section 73.606 of the FCC Rules, contains all commercial as well as noncommercial allotments (the latter are

54–72 MHz	76–88 MHz	174–216 MHz	470–806 MHz
TV Channels 2–4	TV Channels 5–6	TV Channels 7–13	TV Channels 14–69

Figure 11. TV broadcasting bands.

identified by an asterisk). The Table is based on the separation criteria contained in Sections 73.610 and 73.698 of the FCC Rules. As can be seen in Figs. 12 and 13, there are different requirements for different zones or areas of the country. Zone I is the northeast U.S. extending south to the Virginia-North Carolina border and west to the Mississippi River. Zone II consists of that portion of the United States that is not in Zone I or Zone III, along with Puerto Rico, Alaska, the Hawaiian Islands and the Virgin Islands. Zone III is that portion of the southeast United States extending from the east coast of Georgia westward to the Mexican border. An exact description of the zones is contained in Section 73.609 of the FCC Rules.[11] As with FM, the zones reflect the differing population densities in various parts of the country. In addition, differences in propagation conditions were also considered. The closer spacings in Zone I recognize the fact that in the Northeast portion of the United States there are many large population centers needing stations of their own, which are close enough to one another to lessen the need for wide area service. Zone II is characterized by fewer population centers, usually smaller and further apart. For them, wide-area service is a necessity. Finally, because the area of the country along the Gulf Coast (Zone III) is susceptible to high levels of tropospheric propagation, stations in that area need to be spaced further apart so as not to interfere with one another. Although there are differences in the power levels authorized for low-VHF, high-VHF, and UHF stations, unlike AM and FM broadcasting, there are no class designations as such in television. The differing power limitations reflect the differences in signal propagation for low-VHF, high-VHF and UHF.

In addition to the above constraints, there are others on UHF channels due to various types of problems caused by the mixing, in TV receivers, of the signals of stations operating on different channels. A complete table of these restrictions referred to as the "UHF Taboos" is contained in Section 73.698 of the FCC Rules.

To obtain authority to operate a television station, an application is filed with the FCC. The applicant may request authority to operate a station on any of the allotments that are not already in use. Alternatively,

Minimum co-channel television separation distances in kilometers (miles)

ZONE	CHANNELS 2–13	CHANNELS 14–69
I	272.7 (169.5 miles)	248.6 (154.5 miles)
II	304.9 (189.5 miles)	280.8 (174.5 miles)
III	353.2 (219.5 miles)	329.0 (204.5 miles)

Minimum adjacent channel separation distances

Channels 2-13	95.7 kilometers (59.5 miles)
Channels 14-69	87.7 kilometers (54.5 miles)

Figure 12. Minimum co-channel and adjacent channel television separation distances.

a petition for rule making may be filed with the FCC seeking to modify the Table to include a new allotment. Such petitions must provide a showing that the proposal complies with applicable separation criteria that serve to prevent mutual interference. Generally speaking, few, if any, VHF allotments are available, but there are a number of vacant UHF channels remaining in scattered areas of the U.S.

In addition to the regular television broadcast stations, there are three other types of stations that are permitted to operate in the television bands with low power, on a secondary basis. These are low-power television stations (LPTV), TV booster stations, and TV translator stations. Low-power television stations may retransmit the signals of another station or they may originate programming. A TV booster station retransmits the signal of a primary station on the primary station's channel in order to serve areas where the primary station's signal is inadequate. A TV translator station is similar to a TV booster station, except that the signal is not retransmitted on the same channel but instead is translated to a different channel. All of these stations are authorized in accordance with Part 74, Subpart G of the FCC Rules, which requires full protection from interference to all regular television broadcast stations. In addition, these stations are not accorded any protection from the operation of regular television broadcast stations.

Aside from establishment of the LPTV service, there has been little change in the allocation of television broadcast stations over the past several years. The last major change was the reallocation of channels 70 through 83 (806 MHz to 890 MHz) from TV to the land mobile radio services in the early 1970s. At that time, sharing of UHF channels 14 to 20 (470 MHz to 512 MHz) with land mobile radio services also was permitted in certain major markets. As the demand for radio spectrum continues to grow, land mobile interests may press for further changes of this type, which broadcasters are likely to oppose.

Currently, studies are underway at the FCC and elsewhere looking toward a new type of high definition television system (HDTV) capable of providing greatly enhanced picture and sound quality. As of this writing, it appears the implementation of this new type of service will initially require stations to operate two separate systems. One would continue to provide service for existing television receivers and the second would provide the new service on a second channel. In view of this, it appears that the opportunity for any new stations will be extremely limited because of spectrum requirements to accommodate the existing station expansion into the new system.

AUXILIARY BROADCAST SERVICES FREQUENCY ALLOCATION

Although all auxiliary broadcast services share a common role in support of AM, FM, or TV broadcast operations, there are important differences between them. The nature of the service they provide varies as does the frequency band in which they operate. For these reasons, the allotments available for each auxiliary service needs to be discussed separately. However, before turning to a specific discussion of each service, some general comments are necessary.

The steady growth in the number of AM, FM, and TV stations, as well as their desire to use more advanced technology in every aspect of their operation, has greatly increased demand for spectrum in all auxiliary services. Because of the continuing demand for spectrum from a multitude of other broadcast and nonbroadcast activities, it has been difficult for the FCC to allocate more spectrum to alleviate the congestion faced by the auxiliary services. At the same time, some relief has come through changes in the FCC Rules to facilitate the use of newer, more spectrum-efficient, technology. In using this material, the reader should be aware that additional changes may take place. Accordingly, the careful reader should check the current regulations governing that particular radio service.

Recognizing that available spectrum is limited, it is imperative for broadcasters to use it efficiently. To do this, it is first necessary to understand what spectrum is allocated, how it may be used and what advantages or disadvantages, if any, may be involved in the use of a particular band, for each of the auxiliary services discussed below.

Remote Pickup Broadcast Stations (RPUs)

Remote pickup stations are mobile or portable facilities used to transmit live on-the-air programming from a temporary remote location, such as a shopping center or football game, to the station's studio facilities. This material can be taped for later rebroadcast, or it can be incorporated into actual on-going live broadcasts. Radio stations typically have several RPUs that may be licensed to one or more frequencies.

In November 1984, the FCC significantly revised its radio broadcast auxiliary frequency allocations to permit operational use of narrow band technologies in the Broadcast Remote Pickup Service. The Commission's goal was to foster spectrum efficiency in a flexible manner. Broadcasters and equipment manufacturers who wanted to operate narrow band equipment, the Commission believed, should not be precluded from doing so by rigid FCC Rules. However, these changes have not yet been formally implemented by the FCC due to delays in setting up the mechanism to handle the expected applications, but formal implementation is expected in the near future. In the meantime, the FCC will accept applications based on this revised allocation, which is detailed below.

The following are the frequency allocations for radio broadcast remote pickup stations.

1. 25.67–26.47 MHz: There are a total of 25 frequencies available in this band for use by remote pickup broadcast stations. Bandwidth is limited to 20 kHz except between 25.87 MHz and 26.03 MHz where 40 kHz is permitted. Please note that the use of the frequencies between 25.87 and 26.09 is subject to the condition that no harmful interference is caused to broadcast stations sharing this band. It is also noted that the frequencies between 26.100 and 26.175 have been allocated on a worldwide basis to the Maritime Mobile Services. Although this service has not yet been implemented, at such time as the maritime service is implemented, these frequencies may no longer be available for use by remote pickup stations. It is further noted that the frequencies between 26.175 and 26.47 are allocated on a worldwide basis for use by various types of fixed and mobile operations. Hence, in selecting a frequency in this band for remote pickup use, the implications of the above restrictions should be taken into consideration.
2. 152.875–153.3625 MHz: There are a total of 54 frequencies available in this band for use by remote pickup broadcast stations. Each channel is 5 kHz wide, and channels may be stacked to form a single channel with a maximum bandwidth of 30 kHz. This band is shared with the Private Land Mobile Radio Service and the Maritime Service, and operation of remote pickup stations is subject to the condition that no harmful interference is caused to these other services. Please note that these frequencies are not available to networks entities or for use on board aircraft unless they were previously licensed for such purpose.
3. 160.8625–161.3975 MHz: There are a total of 30 frequencies available in this band for use by remote pickup broadcast stations in Puerto Rico or the Virgin Islands where they are shared with the Public Safety and Land Transportation Radio Services. Each channel is 5 kHz wide and channels may be stacked to form a single channel with a maximum bandwidth of 30 kHz.
4. 161.6275–161.7725 MHz: There are a total of 102 frequencies available in this band for use by remote pickup broadcast stations. Each channel is 5 kHz wide and channels may be stacked to form a single channel with a maximum bandwidth of 30 kHz. These frequencies are not available to network entities and are not available for use in Puerto Rico or the Virgin Island. Also, Public Safety and Land Transportation Radio Service stations may continue to operate on these frequencies on a noninterference basis.

5. 166.25 and 170.15 MHz: These frequencies may be used by remote pickup stations with a maximum bandwidth of 25 kHz; however, the area in which they may be used is restricted. A description of the area in which they may be used is found in FCC Rule Section 74.402.
6. 450.01, 450.02, 450.98, 450.99, 455.01, 455.02, 455.98, and 455.99 MHz: These frequencies may be used by remote pickup stations only for the transmission of operational communications, including tones for signaling and for remote control and automatic transmission system control and telemetry. Bandwidth is limited to a maximum of 10 kHz.
7. 450.0275–455.6225 MHz: There are a total of 240 frequencies available in this band for use by remote pickup broadcast stations. Each channel is 5 kHz wide, and channels may be stacked to form a single channel with a maximum bandwidth of 50 kHz.
8. 450.6375–455.8625 MHz: There are a total of 20 frequencies available in this band for use by remote pickup broadcast stations. Each channel is 25 kHz wide, and channels may be stacked to form a single channel with a maximum bandwidth of 50 kHz. Users committed to 50 kHz bandwidths to transmit program material will have primary use of these channels.
9. 450.900, 450.950, 455.900, and 455.950 MHz: These frequencies are available for use by remote pickup broadcast stations. Each channel is 50 kHz wide, and channels may be stacked to form a single channel with a maximum bandwidth of 100 kHz. Users committed to 100 kHz bandwidths to transmit program material will have primary use of these channels.

Aural Broadcast Auxiliary Stations

Aural broadcast auxiliary stations include studio-transmitter link (STL), intercity relay (ICR), and microwave booster stations used by radio broadcast stations. STL stations are fixed stations used for transmitting program material between the studio and the transmitter of a broadcasting station. ICR stations are fixed stations used for the transmission of program material between broadcasting stations, except international, for simultaneous or delayed broadcast. Microwave booster stations are used to relay the signals of a STL or ICR station over a path that cannot be covered with a single station. They receive and transmit on the same frequency. One or more microwave booster stations may be authorized to licensees of STLs or ICRs. It should be noted that stations in the aural broadcast auxiliary service may be authorized on a secondary noninterference basis to licensees of TV broadcast stations to transmit aural material.

The following frequencies are available for assignment to STL, ICR, and microwave booster stations:

1. 942.5, 943.0, 943.5, and 944 MHz: These frequencies are available for use in Puerto Rico and the Virgin Islands. Also, stations licensed in other parts of the United States prior to November 21, 1984 may continue to operate on a co-equal primary basis in this band.
2. 944–952 MHz: There are 320 channels 25 kHz wide available in this band. The channels may be stacked to form a single channel up to 300 kHz wide. Separately, stations also may be authorized additional 25 kHz channels up to a grand total of 20 channels. The use of these frequencies by ICR stations is subject to the condition that no harmful interference is caused to other classes of stations.
3. 18760–18820 MHz and 19100–19160 MHz: There are 24 channels, each 5 MHz wide, available in these bands. These frequencies are shared on a co-primary basis with other fixed services and their use is subject to the rigorous coordination requirements of FCC Rule Section 21.100(d).

Part 94 Operational Fixed Services

Although not strictly broadcast auxiliary frequency bands, the Operational Fixed Services frequencies, particularly those above 21200 MHz and the 6425–6525 MHz band, in fact are available to broadcasters and may be less congested than the typical auxiliary frequencies. However, some of them are subject to significant limitations. Accordingly, licensees interested in making use of these frequencies should refer to the provisions applicable to the band in question. Applications and instructions are available from the Land Mobile and Microwave Division in the FCC's Private Radio Bureau. Suitable equipment is available from several microwave equipment manufacturers.

Television Broadcast Auxiliary Stations

The demand for the spectrum allocated for television auxiliary services is significantly greater than the spectrum allocated for radio broadcasting services. In addition to the extensive local demand, network remote units travel extensively and compete with local broadcasters for available frequencies, resulting in increased spectrum congestion. Finally, it is also important to recognize that the variety of activities undertaken by television broadcasters usually requires more complex auxiliary systems than is the case in the radio industry.

The following are the types of television broadcast auxiliary stations: TV pickup stations, TV STL stations (studio transmitter link), TV relay stations, TV translator relay stations, and TV microwave booster stations.

TV pickup stations are land mobile stations used for the transmission of TV program material and related communications from the scenes of events to TV broadcast or low power TV (LPTV) stations.

TV STL stations are fixed stations used for the transmission of program material and related communications from the studio to the transmitter of a TV broadcast or LPTV station.

TV relay stations are fixed stations used for transmitting visual program material between TV broadcast or LPTV stations or for the relay of transmissions from a remote pickup station to a single TV station.

TV translator relay stations are fixed stations used for relaying programs and signals of TV broadcast stations to LPTV stations or TV translator stations.

TV microwave booster stations are fixed stations used to receive and amplify signals of TV pickup, TV STL, TV relay, or TV translator relay stations and retransmit them on the same frequency. These stations are used to transmit signals over a path that cannot be covered by a single transmitter.

The following are available for assignment to TV pickup stations.

1. 1990–2110 MHz: Seven channels are available in this band which is also available for assignment to all the other types of television broadcast auxiliary stations.
2. 2450–2483.5 MHz: Two channels are available in this band which is also available for assignment to all the other types of television broadcast auxiliary stations. This band is not available for use by network entities.
3. 6425–6525 MHz: The channels available in this band are co-equally shared with mobile stations licensed under Parts 21, 78, and 94 for the FCC Rules. The available channel bandwidth varies from 1 MHz to 25 MHz and Section 73.602 of the FCC Rules contains further explanation concerning the usage of this band.
4. 6875–7125 MHz: Ten channels, each 25 MHz wide, are available in this band which is also available for assignment to all the other types of television broadcast auxiliary stations.
5. 12700–13250 MHz: This band contains 43 channels; however, the channels overlap and therefore, if use of this band is contemplated, Section 73.602 of the FCC Rules should be consulted for a more complete understanding of their usage. This band is also available for assignment to all the other types of television broadcast auxiliary station.
6. 38.6–40 GHz: This band is available without channel bandwidth limitation on a secondary basis to fixed stations.

The following are available for assignment to TV STL, TV relay, or TV translator relay stations.

1. 1990–2110 MHz: Seven channels are available in this band which is also available for assignment to TV pickup stations.
2. 2450–2483.5 MHz: Two channels are available in this band which is also available for assignment to TV pickup stations.
3. 6875–7125 MHz: Ten channels, 25 MHz wide, are available in this band which is also available for assignment to TV pickup stations.
4. 12700–13250 MHz: This band contains 43 channels; however, the channels overlap and therefore, if use of this band is contemplated, Section 73.602 of the FCC Rules should be consulted for a more complete understanding of their usage. This band is also available for assignment to TV pickup stations. In addition, the channels between 13150 MHz and 13200 MHz are not available within 50 km of the top 100 markets.
5. 17700–19700 MHz: Frequencies in this band are shared on a co-equal basis with stations in the fixed service authorized by Parts 21, 78, and 94 of the FCC Rules. The available channel bandwidth varies from 2 MHz to 80 MHz and Section 73.602 of the FCC Rules contains further explanation concerning the usage of this band.
6. 31.0–31.3 GHz: Frequencies in this band are shared on a co-equal basis with stations in the fixed service authorized by Parts 21, 78, and 94 of the FCC Rules. The available channel bandwidth varies from 25 MHz to 50 MHz and Section 73.602 of the FCC Rules contains further explanation concerning the usage of this band.

In addition to the above frequencies, TV STL and TV relay stations also may be authorized to use UHF-TV channels 14–69 on a secondary basis provided no interference is caused to TV and LPTV stations operating in this band.

Furthermore, the aural portion of television broadcast program material may be transmitted over an aural broadcast STL or ICR station on a secondary, noninterference basis. Likewise, remote pickup stations may be used to transmit the aural portion of television program material.

CONCLUSION

As can be seen from the material contained in this chapter, frequency allocation is a very complex matter and is subject to frequent changes. Therefore, the reader is advised to consult the FCC Rules and Regulations for a complete description of the current allocation situation, including the procedures and policies now being applied by the FCC concerning a particular band.

ENDNOTES

1. Technically the term "allocation" refers to the process by which a frequency band is made available for a specific purpose. However, it is used here in a broader sense that includes the *allotment* of frequencies within a band, and the *assignment* of individual stations.
2. A complete list of the 12 CCIR study groups is contained in Appendix 1.
3. A sister technical committee, the CCITT, performs similar functions for wireline telephone and telegraph communications.
4. Copies of the Green Books may be purchased from:
   International Telecommunication Union
   General Secretariat, Sales Service
   Place des Nations
   CH-1211 Geneva 20
   Switzerland

5. The nature of the Commission's rule making process is described in greater detail in Chapter 1.1 "FCC Organization and Administrative Procedures" of this handbook.
6. Copies of the 1981 Rio Agreement may be purchased from:
   International Telecommunication Union
   General Secretariat, Sales Service
   Place des Nations
   CH-1211 Geneva 20
   Switzerland
7. The rules pertaining to PSSA and PSRA are contained in FCC Rules and Regulations Section 73.99.
8. The concept of allowing different classes of stations in different areas or zones is based on the population density of the areas. The Commission has assumed that there is less need for wide areas of service in areas of dense population. A map depicting Zone I is contained in Appendix 2.
9. See FCC Rules Sections 73.210 and 73.211 for a discussion of station classes.
10. Section 73.512(c) FCC Rules and Regulations.
11. Maps depicting zones I and III are contained in Appendix B.

APPENDIX A

CCIR Study Groups

Study Group Subjects

1. Spectrum utilization and monitoring.
2. Space research and radioastronomy.
3. Fixed service at frequencies below about 30 MHz.
4. Fixed service using communications satellites.
5. Propagation in nonionized media.
6. Ionospheric propagation.
7. Standard frequency and time-signal services.
8. Mobile services.
9. Fixed service using radio relay systems. Coordination and frequency sharing between systems in the fixed satellite service and terrestrial radiorely systems (subjects common to study groups 4 and 9).
10. Broadcasting service (sound) including audio recording and satellite applications.
11. Broadcasting service (television) including video recording and satellite applications.
12. Cross-service spectrum sharing issues. (This group was created in 1990. It does not originate any studies but is given specific tasks by the CCIR Director. Its usefulness will be evaluated at the end of the four year cycle and a decision made as to whether it should continue to exist.)

MARCH 1957

APPENDIX B

1.5 Environmental Concerns

Warren P. Happel
Brecksville, Ohio

INTRODUCTION

We work in a world of regulations. Regulations can easily exist today which are not known but which must be followed. As broadcasters we are well aware of the Federal Communications Commission (FCC) and Federal Aviation Administration (FAA) rules which companion our day-to-day business activities. What is not as apparent are the federal Environmental Protection Agency (EPA) and Occupational Safety and Health Administration (OSHA) rules which affect broadcasters as well as other business firms. Most states, many cities, and some counties have parallel rules which often contain additional requirements. Meeting all federal requirements does not necessarily mean all state and local rules have been met. Fines can be imposed for rule violations, even though the rules may not be well publicized and therefore unknown. Penalties can be from federal, state, or local agencies.

This overview will alert you to rules, agencies, dates of compliance, and where to find more information. In comparison to the multitude of pages which have been written about each of the subjects discussed herein, this alert is brief and not exhaustive. The purpose is to guide you to seek more information relative to the regulations that apply to your operation.

The EPA and/or OSHA have rules, regulations and guidelines which affect broadcasters covering:

- Air Contaminants
- Asbestos
- Drinking Water Coolers
- Electromagnetic Radiation
- Hazard Communications Standard
- Lockout/Tagout
- Occupational Noise Exposure
- Polychlorinated Biphenyls (PCBs)
- Protection of Stratospheric Ozone
- Radon
- Underground Storage Tanks

The goal of the OSHA Occupational and Health Standards is to make the workplace safe, and the EPA rules are designed to protect the environment. These rules are not specifically aimed at the Broadcaster, but are for industry/business in general. The EPA and OSHA have not gone out of their way to inform individual business operations. For example, consider PCBs. The EPA rules name power and food industries as PCB users but no mention is made within the rules of the broadcast industry. It wasn't until a PCB transformer was broken open in Oregon, that broadcasters became aware of the PCB problem. Funding, specifically for notification, may be part of the problem, considering there are so many businesses affected and not enough staff available for the purpose of informing and enforcing. To help spread the word, broadcasters and newspapers will continue to receive requests to report OSHA and EPA penalties which have been imposed for rule violations.

INFORMATION SOURCES

Information sources are available that publish the EPA and OSHA Rules, but they are not generally distributed and usually must be bought. Obviously the rules will not even be sought if it is not known that they exist. As an excellent secondary source, the National Association of Broadcasters (NAB) has provided member stations with useful information concerning underground storage tanks (USTs), asbestos, polychlorinated biphenyls (PCBs), and electromagnetic radiation (EMR). Some law firms are now notifying their clients of compliance requirements. Newspapers also serve as a secondary source, but since the articles are usually written to provide general information it is easy to miss what isn't specifically directed toward the broadcast industry. Not knowing that rules exist will not prevent being fined if a penalty is applicable.

The primary source of the OSHA and EPA rules is the Code of Federal Regulations (CFR) which is the general and permanent collection of rules published by the Federal Register (FR). The Code is divided into 50 titles (e.g., title 29 for Labor), each title is divided into volumes (e.g., title 29 has eight volumes), each volume is divided into chapters which usually bear the name of the issuing agency (e.g., Chapter XVI Occupational Safety and Health Administration, Department of Labor) and each chapter is further subdivided into numbered parts (e.g., volume 5 is title 29, contains parts 1900 to 1910 and is all Chapter XVII).

Each volume of the Code is revised at least once each calendar year. In order to stay current on FCC Regulations, one may subscribe to a service that sends FCC updates, learn of major changes from NAB, subscribe to the Federal Register (FR), or some combination of the above.

And so it is with the EPA and OSHA rules. It is not sufficient to buy "Title 29 Parts 1900 to 1910," revised as of July 1, 1991, because just as with the FCC Regulations, changes must necessarily continue with the EPA and OSHA rules.

To be aware of changes made to the Code, one can subscribe to the "List of CFR Sections Affected" (LSA), without subscribing to the FR. (The LSA is included with a subscription to the FR.) Upon learning from the LSA that a regulation change has been made, it would be necessary to pursue the change in the FR. Some local libraries subscribe to the Federal Register.

At the end of each topic discussed herein, references and contacts are listed so that the reader may pursue more sources for information. It is necessary to keep alert and question any hint that a compliance requirement applies to some aspect of the business.

For additional information about the Federal Register and CFRs, contact the Superintendent of Documents, Government Printing Office, Washington, D.C. 20402–9371, (202) 783–3238 or U.S. Government Printing Office Bookstores located in Atlanta, Birmingham, Boston, Chicago, Cleveland, Columbus OH, Dallas, Denver, Detroit, Houston, Jacksonville FL, Kansas City, Los Angles, Milwaukee, New York, Philadelphia, Pittsburgh, Pueblo CO, San Francisco, Seattle, Washington D.C. (3), and Laurel MD.

Additionally, informational booklets are often available through state agencies, such as Department of Transportation, Department of Occupational Safety and Health, and Department of Environmental Regulation, to mention just three departments which are defined in some states.

AIR CONTAMINANTS

Air contaminants are defined by OSHA in a final rule (651 pages), and this rule became effective March 1, 1989 with a compliance date of September 1, 1989. This rule modifies many of the existing permissible exposure limits (PELS) of substances, establishes PELS for substances for which no previous exposure limits exist and includes short-term exposure limits (STEL) to complement the 8-hour time weighted average (TWA) limits. There are 428 substances listed in the rule which include such items as wood dust and carbon tetrachloride. It is estimated that every 20 minutes a new and potentially toxic chemical is introduced into industry. Thus, one can expect this list of 428 substances to be increased as substance studies continue on new and existing substances. For example, the PELS for fibrous glass and mineral wool, two popular insulation materials, were not given in the original 428 substance list. They are named as having their PELS delayed.

This current revised rule on air contaminants should not have a significant impact on the broadcasting industry since there would not normally be exposure to many of the substances listed or at least in amounts to trigger concern. However, the only way to be sure is to review the list of 428 substances and determine if a substance is being used in significant amounts. As an example, wood dust is listed as causing respiratory effects and carries a TWA of five milligrams per cubic meter. This TWA can be met with proper ventilation. More serious are those substances which can cause cancer, kidney or liver effects, and other long term physiological concerns. It is obviously beyond the scope of this review to list the 428 substances listed and their health effects. Under the Hazard Communications Standard, discussed herein later, one should already be aware of hazardous substances being used in the workplace.

In 1987, the EPA was asked to consider indoor air pollution. While there is not now an EPA or OSHA standard for indoor air pollution (other than the PELS established for the 428 substances) the American Society for Heating, Refrigeration and Air Conditioning Engineers (ASHRAE) has recommended standards for indoor ventilation requirements. Additionally, some states have established ventilation requirements. Air contaminants such as mold (which can build-up in ventilation systems), smoke, carbon dioxide, and gasses emanating from building materials can cause some severe reactions in people. Complaints of fatigue, dizziness, eye irritation, headache, nausea, and skin irritation can be caused by ventilation problems rather than a cold, the flu, or allergies.

There are companies which specialize in the measurement of indoor air contamination and make recommendations for the solution to indoor air problems. A building's air should be checked for contaminants if a ventilation problem is suspected.

Copies of the Air Contaminants document may be obtained from the OSHA Publications Office Rm. N-3101, U.S. Department of Labor, 200 Constitution

Avenue, N.W., Washington, DC 20210, (202) 523-9667, or any OSHA regional or area office.

ASBESTOS

Asbestos removal and disposal are regulated by the EPA, and OSHA regulates the exposure to asbestos in the workplace. The National Emissions Standards for Hazardous Air Pollutants (NESHAPS) requires that asbestos material must be removed when it is friable, that is, crumbled or in any form which could free it into the air. By EPA definition, "Friable asbestos material means any material containing more than one (1) percent asbestos. . . . that, when dry can be crumbled, pulverized, or reduced to powder by hand pressure." Asbestos is one of eight known naturally occurring carcinogens.

Asbestos is not required to be removed if it is enclosed or encapsulated. However, eventually asbestos may need to be removed and some property sales are being conditioned on "no asbestos present." Discussion continues as to whether there is more risk involved in the removal of asbestos which is totally encapsulated rather than leaving it in place.

Asbestos was used commercially as fire-proofing as early as the 1890s, as insulation in early 1900s, and at the height of its popularity in more than 3,000 items, including such widely distributed products as brake linings and hair dryers. Although one can easily identify some material forms of asbestos, by color and consistency, final identification should be done by a lab which can also measure the quantity in a sample. Removal of asbestos should be handled by a licensed contractor, and it is expensive. One should deal with contractors who are experienced, have certified trained workers and supervisors, carry proper insurance, and have submitted a satisfactory work plan. The air needs to be monitored during removal. It is also a good idea to have occurrence type liability insurance for asbestos related work.

The asbestos abatement contractor must certify that the asbestos removed has been disposed of properly in an EPA licensed landfill. Under the EPA published NESHAP revisions of November 20, 1990, the owner or operator of an asbestos removal site is considered the asbestos waste generator. The employer must inform employees of asbestos removal and post signs. Employee notification is required under the OSHA Hazard Communication rules. No smoking is permitted in areas where asbestos removal is taking place. Smoking severely increases the chance of cancer if asbestos lodges in the lungs.

The rules do not end at the federal level. Some states had regulations before the EPA or OSHA did. Not handling asbestos abatement properly can result in a health hazard, the delay of job completion, and fines. The OSHA asbestos standard states that medical surveillance must be provided to any employee exposed to an airborne concentration of asbestos in excess of 0.1 fiber per cubic centimeter of air calculated as an eight-hour time-weighted average. Further, medical records on employees exposed must be maintained by the employer, indefinitely if necessary, even after employment ends.

DRINKING WATER COOLERS

Drinking water coolers that are not lead free was the subject of an EPA final and proposed list of drinking water coolers which was published in the FR January 18, 1990. The EPA believes that the most serious cooler contamination problems are associated with water coolers which have water reservoir tanks lined with lead materials. On October 31, 1988, the Lead Contamination Control Act of 1988 was enacted. Its major provisions include a mandate for the Consumer Product Safety Commission to order the repair, replacement, or recall and refund of drinking water coolers that EPA has identified as containing lead-lined water tanks and a ban on the manufacture or sale of water coolers which are not lead free.

HAZARD COMMUNICATIONS STANDARD

The OSHA hazard communications standard is a rule which required compliance as of May 23, 1988. It applies to nonmanufacturing industries and can even apply to white collar offices with a copy machine that uses a chemical which is listed among the more than 400 substances considered to be hazardous. Because of the disaster at Bhopal, India, Congress enacted Title III, the Community Right To Know Law under the Superfund Amendment and Authorization Act (SARA) of 1986. SARA was originated to cover the clean-up of hazardous waste sites under the Comprehensive Environmental Response, Compensation and Liability Act, (CERCLA). The EPA is also involved since it lists the CERCLA-defined hazardous substances and, among other things, also generates reporting forms. If all of this seems confusing, it is. It is not apparent that there is any effort to consolidate or communicate all of the necessary reporting requirements to the millions of businesses which are affected. Most do not know they need to comply, or how. To comply, an employer must develop and maintain a written Hazard Communications Program, which explains and accomplishes the following:

1. Identify and list all of the hazardous chemicals in the workplace.
2. Obtain, (usually from whom one bought the product) the material safety data sheet (MSDS). Any manufacturer who manufactures a product which contains one or more of the chemicals listed by CERCLA and EPA must prepare an MSDS. (The Office of Management and Budget under the paper work reduction act has exempted drugs regulated by the FDA in the nonmanufacturing sector.)
3. Make the MSDS sheets available to the employees.
4. Identify those workers who should be trained and provide training to include the dangers of the substance and the correct and safe use.
5. Know what to do if there is a spill, fire, or personal contact.
6. All substances must be properly labeled and stored.
7. Appoint someone in charge of the program.
8. Any company required to have available MSDSs must submit copies of the MSDSs, or a list of MSDS chemicals to the State Emergency Response Commission, the Community Emergency Planning Commission, and the local fire department. Under some instances, an EPA-designed inventory report form must also be sent to the before mentioned three entities. Those were due March 1, 1988.

There was for a period of time a consumers product exemption which suspended the above reporting requirements if a product was not used differently in a business than in a home. This exemption has, at the time of this writing, been eliminated by the Third Circuit Court.

Most states now have OSHA-approved state hazard communication rules. These state regulations, as do the federal regulations, define the financial penalties which can be imposed for rule infractions.

Effective May 20, 1990, it became no longer permitted to distribute hexavalent chromium water treatment chemicals for use in comfort cooling towers. After May 18, 1990, it could no longer be used by owners and operators. The purpose of the rule is to prevent unreasonable risks associated with human exposure to air emissions of hexavalent chromium.

LOCKOUT/TAGOUT

On September 1, 1989, OSHA published the standard for the control of hazardous energy, known as the "Lockout/Tagout" rule, 29 CFR 1910.147. This rule became effective January 2, 1990. The rule describes lockout/tagout procedures to follow in order to disable machinery/equipment and prevent the release of hazardous energy (mechanical) while maintaining/servicing equipment. While lockout/tagout is for the purpose of controlling the electrical source to prevent machine operation and injury, this lockout/tagout rule does not cover exposure to electrical hazards (shock/electrocution). Electrical hazards are addressed under the later rule, "Electrical Safety-Related Work Practices" (ESWP), OSHA 29 CFR 1910.333.

The lockout/tagout rules apply to general industry and requires employers to implement the procedures which are specified in 1910.147, based on the workplace hazards that are encountered. The potential hazards at a broadcast facility under this rule would include, for example, heating/ventilation/air-conditioning (HVAC), moveable satellite antennas, blower motors (especially in transmitters), television commercial spot players, and elevators in buildings and on towers.

Of this group, HVACs and elevators are generally serviced by outside contractors who would be responsible for the lockout/tagout of those items. This is covered under 1910.147(f)(2) Outside Contractors. Under some conditions, the place-of-business may want to place a secondary lock/tag on the equipment being serviced by others if employees are also working or potentially involved by being on/near the locked-out/tagged-out equipment. Employers are required to become familiar with the lockout/tagout procedures used by the contractor.

Under 1910.147, a lockout/tagout program must now be in effect, and those individuals who have the responsibility/authority to lock/tag equipment must be instructed/trained concerning the procedure. One may include the lockout/tagout requirements of 1910.333, (as permitted by OSHA page 32002, FR, August 6, 1990), with those of 1910.147.

The ESWP standard covers electrical safety related work practices of employees who work on, near, or with electric circuits and equipment. Training is required for all qualified persons. A qualified person is someone who is well acquainted with and thoroughly conversant with the electrical/electronic equipment and the electrical hazards involved in the work being performed. Electrical/electronic technicians and engineers are defined as qualified persons by the rules.

As discussed under History, the rule requires the lockout/tagout of electrical/electronic equipment to prevent injury. Lockout/tagout does not apply to equipment which is normally bench maintained and electrically connected with a power cord.

The ESWP rule became effective December 4, 1990 with the training requirement of Section 1910.332, training became effective August 6, 1991. The rules should be available for employees to review.

One must have appropriate OSHA approved tags and locks. The tags and locks are available through a number of sources, catalog and local suppliers.

OCCUPATIONAL NOISE EXPOSURE

The occupational noise exposure rules became effective in 1983. A disc jockey probably won't turn down his headphone volume to be in compliance with the rules, even though the sound level exceeds the limit. If someone does listen to sound levels which exceed the OSHA levels, it would be a good idea to limit the power available to the headphones. A broadcaster who is asked to set up an earth-shaking PA system may want to become familiar with CFR 29 Part 1910.95. While normally operating audio systems would not be in violation, it is important to know that the rules exist and what the limits are.

Exposure to noise levels exceeding the permissible limits listed in CFR 29 Part 1910.95, can occur with the operation of some lawn equipment and chain saws. Under such circumstances, proper ear protection should be worn.

For additional information see:

"Occupational Noise Exposure," OSHA, 29 CFR 1910.95

POLYCHLORINATED BIPHENYLS (PCBs)

PCBs are listed by the EPA as toxic and persistent. Based on animal data, the EPA concludes that in addition to chloracne, PCBs may cause reproductive effects, developmental toxicity, and tumors (oncogenicity) in humans. PCBs do not biodegrade rapidly and accumulate in fatty animal tissue.

Should a capacitor explode all over the inside of a transmitter, the spill must be cleaned up, all of the cleanup material disposed of properly, and the site must be certified or sampled depending on the quantity of the spill. A broadcaster could be off the air during cleanup if an uncontaminated standby facility is not available. And if PCBs are in a fire, the use of the building could be lost. In transformers, PCBs are usually mixed with tri-chlorobenzene (TCB) to alter the viscosity of the PCB material. During a fire, dibenzofuran and dioxin which are more toxic that PCBs and TCBs can be generated.

The EPA can impose severe fines for not following the rules under the Toxic Substances Control Act (TCA) which was passed by Congress in 1976. Any authority not granted to the EPA under TCA is given under the Resource Conservation and Recovery Act, (RICRA).

The final EPA transformer rule was published July 19, 1988, in the Federal Register. The owners of PCB transformers which are in or near a commercial building need to take action. As of February 25, 1991, all radial and network PCB transformers and those with secondary voltages below 480 volts, not located in sidewalk vaults, must be equipped with electrical protection to prevent high current faults. By October 1993, all transformers below 480 volts in sidewalk vaults in use near commercial buildings must be removed from service.

The use of PCB transformers and capacitors is still permitted in TV and radio transmitters if the PCBs would be contained, should a leak occur, and there is no reasonable risk of injury to health and the environment. However, as stated earlier, there is risk in using items containing PCBs, and as time goes on it may become more difficult and costly to dispose of PCB items. The revised EPA Penalty Policy became effective April 9, 1990. The revised policy incorporates the enforcement related provisions of all PCB rules and policies to date, including the Notification and Manifesting Rule. The Policy will be used to calculate all penalties in all administrative actions concerning PCBs regardless of the date of the violation. For a copy of the Policy, contact: Environmental Assistance Division (TS-799), EPA, 401 M St. SW, Washington, DC 20460, (202) 554–1404.

On February 5, 1990, the EPA amendments to the disposal and storage regulations for PCBs became effective. Under this Rule, the EPA expanded the meaning of "generator of PCB waste" to include the owner of the PCB material at the time of disposal. Items unregulated for disposal, such as small capacitors (by EPA definition) are not included within this expanded meaning.

A generator of PCB waste must obtain an EPA identification (ID) number before turning the PCBs over to commercial storers, transporters, and disposers of PCBs who must also have an EPA ID number. An ID number can be obtained by filling out the required "Notification of PCB Activity," EPA form number 7710–53. Additionally, a manifest, EPA form 8700–22 must be prepared by the generator to accompany a PCB shipment. The generator must track the PCB waste under the EPA defined time requirements until the PCB waste is finally destroyed. Any deviations from the manifest and time requirements from day of shipment to disposal must be reported by the generator to the EPA Regional Administrator for the region in which the waste originated.

Generators of PCB waste do not relieve their potential for PCB disposal violations by entering into contracts with disposers. Also, any state or local requirements are not preempted by meeting the EPA requirements. Additionally, items exempted from notification by the EPA, may be required for notification under local or state regulations.

Many articles have been published concerning the extensive rules pertaining to PCBs. By this time the identification and labeling of PCB items should have been completed along with the required record keeping and monitoring. Therefore, rather than repeat the extensive PCB information here, please refer to those published articles which are identified below, since they are readily available.

PROTECTION OF STRATOSPHERIC OZONE

The protection of stratospheric ozone has been receiving attention because of the suspected environmental effects. From the Federal Register, April 17, 1989, page 15228, Background, first paragraph:

> "The threat of depletion of the ozone layer from chlorine released chloroflorocarbons (CFCs) was first raised well over a decade ago by the scientific community. (Molina and Rowland 1974). The initial theory suggested that because CFCs are relatively inert, emissions of these chemicals would not break down in the lower atmosphere, but would instead slowly migrate to the stratosphere where they would break apart releasing chlorine. Once freed in the stratosphere, the chlorine would catalytically destroy ozone. From a health and environmental perspective, depletion of the ozone layer would allow more harmful ultraviolet radiation to penetrate the atmosphere and strike the earth's surface. This would increase the incidence of skin cancers and cataracts, suppress the human immune system, damage crops, forests, and aquatic systems, accelerate weathering of certain plastics, and increase the formation of ground level (tropospheric) ozone or smog."

On August 12, 1988, the EPA issued its final rule (53 FR 30566) implementing the Montreal Protocol, an international treaty to limit the worldwide production of CFCs and halons. On April 17, 1989, the EPA in a Notice of Proposed Rule Making considered the possibility of adding carbon tetrachloride to the list of ozone depleting chemicals.

The producers of CFCs and halon are required to decrease the production of these chemicals, and users will pay higher prices and will need to use alternate substances such as HCFC-123. However, the use of HCFC-123 is only an interim solution since its production is scheduled to cease by the year 2015. And the use of HCFC-123 requires equipment modifications and reduces the efficiency of the system. Manufactures are seeking replacements for CFCs, HCFCs, and halon.

For those who are using halon fire suppression systems, it is not too early to begin planning for a substitute for halon fire suppression. It is also likely the use of carbon tetrachloride will be curtailed and substitute solvents will need to be used.

In order to keep presently operating CFC refrigeration systems operating as the supply of CFCs diminishes and becomes much more expensive, it will be necessary to reclaim CFCs from both operating and abandoned refrigeration systems. Present air conditioning systems which release refrigerant into the atmosphere with required moisture purges will need to have CFC recovery units installed. Refrigeration systems which must be emptied of refrigerant for repair will need to have the CFC saved by pumping down the system rather than dumping into the environment. If the company that services one's air conditioning equipment has not approached one about reducing the loss of CFCs, one should initiate the CFC recovery conversation and perhaps if there is no interest, one should discuss it with another service company.

RADON

Radon is a radioactive gaseous element which occurs in nature as a result of the natural disintegration of radium. It is a colorless, odorless gas and is found in various levels of concentrations in the ground and ground water. Levels vary in different parts of the United States. Radon can accumulate in basements and buildings by seeping through porous or cracked floors/foundations. Concentrations of radon in structures can expected to be higher if there is insufficient outside air exchange, sometimes referred to as the tight building syndrome. In homes especially, levels of radon can be expected to be higher in the winter.

Concentrations of radon gas are considered to be a health hazard. There does not seem to be agreement regarding the level of radon to be considered dangerous. The EPA presently warns that radon levels exceeding 4 picocuries per liter of air pose a health threat. In Canada, action to reduce levels is not considered necessary until the level exceeds 20 picocuries. The average outdoor level is 0.2 picocuries.

Some states are beginning to pass legislation which requires a buyer or lessee to be notified of the possible threat of radon gas, and some states are passing laws to regulate and license radon testers and mitigators.

Testing for radon gas can be accomplished by placing radon testing canisters in areas where concentrations may be anticipated. The results can vary drastically, depending on the season of the year and the location(s) selected for measurement. If one is placing the canisters oneself rather than having a recognized testing service perform the task, it is suggested that in addition to the test canisters placed within the area of interest, a test control canister be placed outdoors as a calibration check.

To reduce radon concentrations, cracks in foundations and floors must be sealed, and drains must be checked for potential gas leakage. Porous foundation surfaces (such as concrete block) and floors must be sealed.

UNDERGROUND STORAGE TANK REGULATIONS (USTs)

The underground storage tank regulations were published in final rule form September 23, 1988, in 165 pages of the Federal Register. An EPA Form 7530–1 or a similar State Certificate of Notification should already be filed with the environmental agency of the state. Beginning December 22, 1988, the owner/operator of an underground storage tank (UST) needed to begin keeping records which include the date and nature of inspections, repairs, and replacement of USTs in use. Within a ten year period of December 22, 1988, depending on the age of the tank, the USTs must be made corrosion resistant. Since October 24, 1988, any person who sells a tank to be used as an underground storage tank must notify the purchaser of the requirement to report bringing the tank into use.

An underground storage tank is defined as a tank and piping which has at least 10% of its volume underground. There are a few EPA exclusions (not necessarily state exclusions) to the definition of USTs, which at least presently include:

1. Farm or residential tanks of 1,100 gallons or less capacity, storing motor fuel for noncommercial purposes.
2. Tanks storing heating oil for use on the premises where stored.
3. Septic tanks.
4. Storage tanks situated on or above the floor in basements.
5. Tanks that have a capacity of less than 110 gallons (not excluded in the Ohio State regulations for example).

The UST rules define new tank design, construction, and installation. Also defined are the requirements for leak detection, spill prevention, record keeping, reporting, tank closure, and the corrective action for spills. Under the Superfund Amendments and Reauthorization Act of 1986 (SARA), the EPA is given authority to clean up petroleum releases or to require owners or operators to do so. If the EPA cleans it up, do not expect them to seek a low bid and do expect an invoice and a fine.

An EPA study indicated that 42% of the tanks which were 15 to 20 years old and 30% of the 10 to 15 year old tanks were leaking. Release detection at existing UST systems must be added. Older tanks which are unprotected from corrosion must have release detection as of December 22, 1989, with new tanks that are protected from corrosion to have release detection within five years. A protected tank is one with proper cathodic protection or a tank made of an acceptable material, such as fiberglass over steel. Periodic tank tightness testing every five years combined with monthly inventory control is allowed at new tank installations for ten years after installation, but after ten years, monthly release detection is required. Monitor wells are a method of leak detection and are required by some states and may be in addition to whatever other method is used. The above are federal regulations. Many states have requirements which are more stringent.

Tank owners and operators must report actual and suspected releases. Owners and operators of leaking UST systems must follow measures for corrective action. Cleanup levels will be established on a site-by-site basis as approved by the implementing agency. Tanks over ten years of age must be either internally inspected or lined to meet upgrade requirements. This procedure may not be practical for small tanks. It may be more practical to replace an older tank with a new protected one. When a new tank is installed, the installer must certify that the UST system was installed according to the rules. All substandard existing UST systems must be closed, replaced, or retrofitted with corrosion protection within ten years of December 22, 1988 which are also the years of grace before adding overfill protection to all tanks. The required overfill protection leaves much to the discretion of the operator but to wait ten years before installing protection burdens the environment, and could burden the operator financially if there is a spill. Overfill protection can be as simple as automatic supply shut-off when the tank is 95% full. At some locations overspill protection, such as a retaining basin, may be appropriate. If more than 25 gallons are spilled, the spill must be reported. No exceptions here. Failing to report a spill can result in very large fines. In all cases, the spill or overfill must be cleaned up immediately, and if not, even spills under 25 gallons must be reported.

This is only a small sample of the regulations. In addition to the EPA rules, there are state/city regulations which additionally may impose requirements not contained in the EPA rules. Many states had rules which were in effect before the EPA wrote theirs. For example, although tanks associated with emergency generators are currently deferred from release detection by the EPA, they are not deferred in Florida. It really is not wise to defer meeting the requirements of the rules since the consequences of a spill or leak can be severe to both the environment and the bottom line. The cost to replace a 1,000 gallon storage tank in Cleveland, including monitor wells, is around $12,000. If it would be necessary to remove tons of contaminated soil, the costs could be unaffordable.

If a tank is leaking, it must be replaced and any contaminated soil removed. It may be a better choice to replace aged tanks rather than wait until a leak starts. If a tank is buried and not leaking and its removal would be too expensive or not practical, it may be emptied by removing liquid and sludge, and then filled with inert solid material. The choice of inert fill material is not specified. The EPA accepts sand and concrete, some states do not accept both. However, concrete could cause a future construction problem. Many states will dispatch an inspector to review a tank installation before the tank may be filled. The state often requires drilled soil samples in the area of the tank before filing is permitted.

Civil fines for violation of the regulations can be up to $10,000 a day with criminal fines topping $25,000 a day. Corporate officials face fines up to $250,000 and up to 15 years in prison, with corporate fines running to $1 million. Additionally, the clean-up costs of an underground water system could be astronomical.

The EPA addressed financial responsibility in the October 26, 1988, issue of the Federal Register. All UST owners and/or operators, including owners of USTs that are used to store fuel for generators, must be in compliance. This responsibility requires owners, such as broadcasters, to maintain financial assurance of at least $500,000 per occurrence, $1 million aggregate, to insure that damage resulting from a leak will be paid for by the owner.

Some states have established financial assurance funds which require UST owners to file a yearly statement along with an assessment fee.

For the list of agencies designated to receive notifications, refer to the January 1989, NAB UST Info-Pak.

On April 9, 1990, the National Oil and Hazardous Substances Pollution Plan became effective. The 200-page document was printed in the Federal Register March 8, 1990. The purpose of this National Contingency Plan (NCP) is to provide the organizational structure and procedures for preparing for and responding to discharges of oil and releases of hazardous substances, pollutants, and contaminants. The NCP would apply in cases of the discharge of oil into or upon navigable waters of the United States and releases into the environment of substances which may present an imminent and substantial danger to public health and welfare. Thus under certain conditions, an oil spill could fall under the NCP.

Contact:

RCRA/Superfund hotline (800) 424-9346 and in D.C., (202) 382-3000.

In summary, this brief collection of information and reference materials has been pulled together to alert the broadcaster to the EPA and OSHA rules which affect the industry and are of an environmental concern. This information is far from complete. Lengthy seminars are often given on just a single subject. There are companies whose main business is the preparation of materials for compliance with the various regulations. Other companies are in the business of meeting environmental clean-up needs. Further rule changes can be expected as well as additions to the rules.

1.6
Consultant Services: When and How to Use Them

Warren M. Powis, P.E.
Cohen, Dippell and Everist, P.C., Washington, District of Columbia
(Chapter based on material prepared by Alan E. Gearing, P.E. and John F.X. Browne, P.E.)
Association of Federal Communications Consulting Engineers (AFCCE)[1]
Washington, District of Columbia

RANGE OF CONSULTING SERVICES

Broadcast applicants and licensees employ the services of consultants to assist with various aspects of the conduct of their business such as engineering, financial, legal, marketing, personnel, and programming areas. The need for these services may arise for many reasons including the unavailability of staff, the need for expertise not found in-house, or the need for additional manpower to ensure timely completion of a project. Broadcasters selecting engineering or technical consultants may be unfamiliar with the variety of services normally offered by consultants or with the procedures for selecting and engaging a consultant.

Services offered by consultants ranges from evaluation and recommendation, to supervision of installation, to complete turnkey responsibilities. The types of consultants range from those handling transmission and general broadcast engineering matters to those specializing in narrowly defined areas. Examples of the latter include experts in broadcast building design and acoustics, tower design and maintenance, and telephone system planning.

Tables 1, 2, and 3 contain a partial listing of the types of services provided. Table 1 includes services applicable to all types of broadcast facilities. Services specific to AM broadcast stations are listed in Table 2, and Table 3 lists services mainly applicable to FM and TV broadcast stations.

Many consultants offer services of the types listed in the tables for other communications activities in which some broadcasters may also be involved, such as:

- Instructional Television Fixed Service Systems
- Multichannel Multipoint Distribution Systems
- Satellite Up Link, Down Link, and Space Facilities
- Microwave Relay Systems
- Paging Systems
- Land Mobile Systems
- Cellular Radio Systems
- International Broadcast (Shortwave) Facilities
- Subcarrier Services
- LPTV and Translator Systems
- Remote Pickup and other Auxiliary Systems
- Fiber Optic Systems

QUALIFICATIONS, REGISTRATION, AND CERTIFICATION

Some of the activities engaged in by consultants may affect the public in matters of health, safety, and welfare, such as radio frequency power density computations and measurements. Therefore, various means have been used to provide some assurance to the public that practitioners have at least threshold qualifications. For example, the states and some professional organizations have established minimum qualifications for persons acting in certain professional capacities including the practice of engineering. All fifty states and the District of Columbia have engineering registration laws.

The practice of broadcast and telecommunications consulting engineering is, with few exceptions, a professional field in which most states require the practitioner to be registered as a *professional engineer* or "PE". In most cases, in fact, registration is required by law in order to represent oneself as a consulting engineer or to provide professional engineering services.

Professional engineers are registered or licensed through a process involving verification of educational credentials (e.g., a degree in engineering or related science), the attainment of specific engineering experience (usually a minimum of four years, post graduation), and passing an examination gauging the applicant's mastery of engineering fundamentals and his or her specific field of engineering practice (usually a two-day, 16-hour written exam).

The services listed in the Tables at the end of this chapter include both those which fall within the realm of the professional engineer and those which may not require such certification. While the guidelines for selecting a consultant, contained in this chapter, refer to the professional engineer or consulting engineer, they can, and should, be used as a general guide in the selection of any type of consultant service.

CODE OF ETHICS

Professional Engineers usually subscribe to a code-of-ethics such as those adopted by the National Society of Professional Engineers (NSPE) and the Association of Federal Communications Consulting Engineers (AFCCE). Many engineering societies representing the various engineering disciplines also support ethical codes for their members.

These codes require a standard of professional conduct which govern the consultant's activites and his relationship with clients in areas such as:

- Advertising
- Solicitation of clients
- Conflicts of interest
- Confidentiality of client activities
- Practice in field of expertise
- Use of the work of other engineers

Copies of these representative codes of ethics may be obtained free-of-charge from the National Society of Professional Engineers, 1420 King Street, Alexandria, Virginia, 22314 and the Association of Federal Communications Consulting Engineers, P.O. Box 19333, 20th Street Station, Washington, D.C., 20036.

SELECTING A CONSULTING ENGINEER

Selection of a consulting engineer does not have to be a confusing formal process. Initial contacts with prospective consulting engineers are often made by referral from communications attorneys or on the recommendations of other broadcasters. Additionally, "professional cards" in trade publications or referrals by engineering societies are sources of listings on professional practitioners.

When selecting a consulting engineer the broadcaster should, as a minimum, discuss the following topics with the candidate consultant:

- Professional qualifications and registrations
- Knowledge of FCC Rules and Regulations and international agreements
- Expertise in the particular area of interest
- Recent experience
- Availability of professional staff, time, and facilities
- Estimated time for completion
- Estimated fees or fee structure

1. Seek names of recommended individuals or firms from people within industry.
2. Review professional cards in magazines.
3. Obtain copy of AFCCE Membership Directory.
4. Select several candidates and discuss your requirements with each. Determine with each discussion if that individual/firm is experienced in providing services required by your project and can work in the desired time frame. If considering a firm, obtain the name of an assistant who can be contacted in the event that the prime contact is unavailable.
5. For portions of work not requiring a consultant, obtain from the consultant recommendations of companies who he believes provide that work.
6. Determine the consultant's hours. Are they compatible with your schedule? Do they have facsimile (fax), answering systems, etc., if the need arises to contact them at irregular hours?

Figure 1. Selecting a consultant.

WORKING WITH A CONSULTING ENGINEER

Once a consulting engineer has been selected for a specific project, an agreement regarding the scope of work, timetables, and fees is normally executed. In its simplest form this may merely be an exchange of informal letters; on complex projects, particularly those involving large scale construction, there may be a need for formalized contractual documents. A retainer fee to be applied against initial work may also be required.

There should be a clear understanding between the parties as to the scope of work and responsibilities of each party, particularly if the client (broadcaster) desires to perform part of the engineering work in-house or plans to employ other consultants for portions of the project. There is a great potential for both duplicative efforts and omissions in these arrangements when areas of responsibility are not clearly defined. While the initial objective may have been to minimize the consulting engineer's time (and fees) the result could very well be the opposite.

To assist the consulting engineer in the performance of his work, the client should provide any and all background material as well as earlier engineering documentation that may have been developed on the project. It is important that the client recognize that the use of such information is at the discretion of the consultant, and that a fee quoted on the basis of the validity and applicability of such data to a new project may have to be adjusted if the data is found to be unsuitable or inaccurate. In some contexts, such as FCC filings, the consultant must attest to the accuracy of the data being presented and, therefore, he must have a high level of confidence in data which he did

1. Establish rapport with the consultant and discuss your goals and requirements.
2. You can provide items which will assist the consultant. Prompt site selection is desirable, and information provided should include the following details:

- Property boundaries of proposed site
- Address(es) of proposed site
- Coverage goals if a broadcast station
- If using an existing tower, pertinent structure information including transmit and receive frequencies, and location of other antennas (including manufacturer and model numbers)
- Availability of power
- Site accessibility

Figure 2. Using your consultant wisely.

not personally generate in order to incorporate it. There may also be legal or ethical problems associated with incorporating the engineering work product of other engineers, especially that prepared by non-registered or unqualified practitioners.

Changes in technical details which may appear to be minor to the client often have major impact on the work completed by the consulting engineer. A transmitter site relocation of only a mile, for example, may involve recomputation of service areas, operating parameters, interference protections or separations, or aeronautical impact. For these reasons the client should attempt to finalize such details—with guidance from the consulting engineer—as early as possible, but especially before authorizing the completion of final reports or applications.

FCC Applications

In many cases FCC applications must be filed before certain dates which are established by processing procedures or mandated in FCC docket actions. Since the preparation of these filings can be a rather lengthy, the client should give the consulting engineer sufficient advance notice of such filing deadlines.

In the absence of formal arrangements to the contrary, consulting engineers do not generally assume the responsibility of monitoring FCC actions on behalf of present or former clients, to note activities (such as competitive filings, notices, or grants) which could have an impact on a client's existing or proposed facility. Such monitoring is often performed by the station's legal counsel and is also available directly from some of the computer database firms serving the broadcast industry. One way in which consulting engineers do provide such monitoring, relative to potential engineering impact, is through retainer agreements in which the client employs the consultant's services under an ongoing arrangement. The agreement usually specifies the level of services, such as FCC monitoring, that will be provided and the method of reporting to be used. In some cases, such agreements also specify that the consultant will make available a specified minimum amount of staff time which may be used over the course of the agreement to respond to the client's needs as they arise.

Data Rights

The client should have an understanding with the consultant regarding ownership of documentation produced by the consultant. It is common practice for the consulting engineer to retain all rights to files, drawings, reports, and other work products. The consultant grants to the client permission to use such data for specified FCC filings and for retention as part of the station's files. Normally, the data cannot be transferred to another party, or copied and used as part of another filing, or incorporated as part of a design for another project or facility without the express consent of all parties.

There are some consultants offering services which are oriented to field projects, such as equipment installation, construction, and measurements. These persons or firms operate as extensions of the broadcaster's staff and usually can bring a wealth of practical experience and additional manpower that the broadcaster may not have in-house. Professional engineering certifications may not be required for these services, but the possession of an appropriate FCC Commercial Operator's license may be required if transmitter related services are performed. Any measurements made by these consultants, which will ultimately be used in connection with FCC filings, should be collected, assembled, and presented (including certifications) in an acceptable form. Coordination of these activities with the station's consulting engineer may be desirable. References concerning the qualifications and capabilities of such consultants may be obtained from the station's consulting engineer or the other referral sources listed earlier.

TABLE 1

Services applicable to all types of broadcast facilities.

Engineering Allocation Studies and Applications

- Allocation studies to determine the feasibility of establishing new stations at specified communities.
- Allocation studies to determine the feasibility of improving existing facilities.
- Determination of appropriate areas for transmitting facilities to be located.
- Consideration of air hazard aspects and preparation of notice to FAA of proposed construction.
- Preparation of engineering portions of applications to the FCC for construction permits and licenses.
- Review of engineering proposals by other stations or applicants
- Engineering in support of petitions to deny or replies to petitions to deny.
- Provision of expert testimony in FCC hearings or court proceedings or local authority hearings.

- Population and area service analyses.
- Determination of existing and proposed services in a particular area
- Environmental and Electromagnetic Compatibility
- Environmental impact studies.
- Electromagnetic interference studies to determine whether a proposed new or improved facility would cause interference to an existing station or to another proposed new or improved facility.
- Electromagnetic radiation power density level computations and measurements.

Transmission Systems

- Preparation of specifications for transmitting systems.
- Transmitter plant design and construction.
- Measurement and adjustment of transmission systems to establish proper operation and compliance with FCC Rules.
- Analysis and design of special-purpose antennas, waveguides, transmission lines, cavity resonators, and other electromagnetic devices.
- Antenna tower planning, including placement of antennas, intermodulation studies, and multicoupler and filter requirements to avoid interference.
- Tower design, erection, and maintenance.
- Structural analysis of towers and antennas.

Studio Systems

- Evaluation and recommendation of equipment for studios, newsrooms, remotes, and automation.
- Studio design and construction including proper acoustics, sound proofing, lighting, heating and air conditioning.
- Design and installation of in-house telephone systems.

Miscellaneous Services and Systems

- Appraisals and on-site inspections of facilities for buyers, sellers, and brokers.
- Mock station inspections to check compliance with FCC Rules and Regulations.
- Field review of station facilities to determine compliance with FCC Rules and to determine the general condition of station facilities.
- Development of operational and monitoring procedures, including specification of test equipment.
- Evaluation of manufacturer's equipment bids.
- Design and installation of equipment for lightning protection.
- Training of technical personnel.
- Preparation of specifications for, installation of, and maintenance of computer systems.

TABLE 2

Services applicable to medium frequency AM broadcast stations (530 to 1700 kHz).

- Measurements of RF field strength relative to allocation matters.
- Design of directional antenna systems.
- Design of phasing and coupling equipment for directional antenna systems.
- Adjustment of directional antenna systems (proof of performance).
- Investigation of effects of reradiating obstacles (buildings, power lines, water towers, utility poles, irregular terrain, nearby antennas and arrays) upon antenna performance.
- Design of matching systems for multiple operations into a single vertical radiator.
- Design of special filters or detuning networks which may be required.
- Investigation of electromagnetic effects of guy wires upon AM broadcast antennas and arrays.

TABLE 3

Services applicable to FM and TV broadcast stations.

- Study of feasibility of adding allotments to FCC Table of Allotments.
- Engineering support for petition for rulemaking.
- Review of engineering aspects of comments and providing engineering support for reply comments.
- Study of and recommendations for optimum antenna height, radiated power, tower location, and vertical and horizontal radiation pattern characteristics.
- Propagation studies, including use of alternate models and accounting for actual terrain features.
- Field strength and signal quality surveys of existing facilities.
- Preparation of specifications for antenna systems including review of manufacturer's range test results.
- Investigation of electromagnetic effects of support towers and guy wires upon TV and FM broadcast antenna.

ENDNOTE

1. Full members of AFCCE are registered professional engineers who subscribe to the Code of Ethics for engineers as adopted by the National Society of Professional Engineers. A directory listing of AFCCE full members and individual firms is available upon request.

INTRODUCTION

The purpose of this chapter is to provide an easily accessible guide to organizations whose activities affect the work of broadcast engineers. This includes government agencies, trade and professional associations, and private companies.

FEDERAL GOVERNMENT

Department of Agriculture

14th and Independence Avenue, Southwest
Washington, D.C. 20250
(202) 447-2791

The Department of Agriculture (USDA) Forest Service oversees the use of 190 million acres of land under the domain of the National Forest System. More often than not, the use of a mountaintop transmitter site is controlled by the Forest Service. Land use permits are obtained from the forest supervisor for the particular forest of interest. The forest supervisor has detailed policy directives for permissible uses and fee structures of forest land.

Department of Commerce

National Institute of Standards and Technology (NIST)

Gaithersburg, MD 20899
(202) 921-1000

The National Institute of Standards and Technology of the Department of Commerce has been authorized by Congress to undertake the following functions: "The custody, maintenance, and development of the national standards of measurements and the provisions of means and methods for making measurements consistent with those standards, including the comparison of standards used in scientific investigations, engineering, manufacturing, commerce, and educational institutions, with the standards adopted or recognized by the Government."

Time and Frequency Division. The Time and Frequency Division, located in Boulder, Colorado, is the part of the NIST that carries out the above functions which relate to time and frequency. This division is responsible for distributing the standards and for finding new and improved methods of dissemination. The dissemination services for time and frequency are presently available from stations WWV and WWVB in Fort Collins, Colorado, and from WWVH in Kauai, Hawaii. In addition, services using network television and satellite signals are also available. Correspondence pertaining to station operations may be addressed to: Engineer-in-Charge, NIST Radio Stations WWV and WWVB, 2000 East County Road 58, Fort Collins, CO, 80524, (303) 484-2372. Or, Engineer-in-Charge, NIST Radio Station WWVH, P.O. Box 417, Kekaha, Kauai, HI, 96752, (808) 335-4361.

National Telecommunications and Information Administration

14th Street and Constitution Avenue N.W.
Washington, D.C. 20230
(202) 337-1551

The National Telecommunications and Information Administration develops policy for the executive branch; manages federal use of radio spectrum; conducts technical research on radio wave transmissions and other aspects of telecommunications; and serves as an information source for federal and state agencies on the efficient use of telecommunications resources.

Department of Interior

The Bureau of Land Management of the Department of Interior oversees the use of 360 million acres of "public domain" lands which are not under the domain of the USDA Forest Service. Broadcaster use of these lands for transmitter sites is coordinated by the State director of the Bureau of Land Management.

Topographic Maps

Topographic maps usually used in the prediction of coverage and other engineering studies, which require accurate information about the position and elevation of terrain features, may be obtained from the U.S. Geological Survey (USGS), a bureau of the U.S. Department of Interior. Standard topographic quadrangles on a scale of 1:24,000 (7.5 minutes) or 1:62,500 (15 minutes) are usually used, but other scale maps are available. To order free map indexes or to purchase maps, contact one of the following offices.

For areas east of the Mississippi River (including Minnesota, Puerto Rico, and The Virgin Islands): Eastern Distribution Branch, U.S. Geological Survey, 1200 South Eads Street, Arlington, VA, 22202.

For areas west of the Mississippi River (including Alaska, Hawaii, Louisiana, Guam, and Samoa): Western Distribution Branch, U.S. Geological Survey, Box 25286, Federal Center, Denver, CO, 80225.

Department of Labor

200 Constitution Ave., N.W.
Washington, DC 20210
(202) 523-6666

Broadcast engineers should be aware that two federal laws, the Federal Labor Standards Act and Occupational Safety and Health Act, empower the Department of Labor (DOL) to regulate work place safety standards and the wages and hours of employment for broadcast employees. Occupational safety standards are enforced by OSHA, the Occupational Safety and Health Administration of DOL, while the minimum wage and hours of employment are enforced by DOL's Wage and Hour Division.

Applicability of OSHA and Wage and Hour Division regulations depend upon many factors; such as the station's geographic location, the number of station employees, and the type of work they perform. Broadcast engineers should consult their station's attorney to determine what regulations apply to them and how to abide by them.

Department of Transportation

Federal Aviation Administration
400 7th Street, S.W.
Washington, D.C. 20590
(202) 426-4000

When construction of a new broadcast tower or a change in height of an existing tower is proposed, the Federal Aviation Administration (FAA) becomes involved by studying the potential impact that the proposed structure may have on navigable airspace. Broadcasters are required to notify the FAA of proposals for new or modified tower structures. The FAA applies its obstruction standards (FAA Rules Part 77) to determine whether or not the tower constitutes a hazard to air navigation. Broadcasters may need to accommodate an adverse finding by the FAA with a modified tower location and or tower height. When the proposal is granted by the FCC and the FAA, the license will contain specifications for marking and lighting the structure, if it is required. The FAA must receive notice immediately should any tower lighting systems fail.

Environmental Protection Agency

401 M Street, S.W.
Washington, D.C. 20460
(202) 382-2090

When broadcasters construct station facilities such as antenna towers or large satellite earth stations they should be aware that these activities may fall under the scope of the National Environmental Protection Act (NEPA). NEPA grants the Environmental Protection Agency (EPA) authority to regulate activities which may affect the "quality of the human environment." The FCC cooperates with EPA in enforcing provisions of NEPA that relate to telecommunication licensees.

The FCC monitors construction of telecommunications facilities and requires information about the operation of transmitters and other broadcast equipment. For example, the FCC, with the assistance of EPA, monitors the level of employee and general public exposure to nonionizing radiation emitted from the equipment. Generally, licensees who propose to construct such facilities must file studies of the potential environmental consequences with the FCC and may be required to take steps to minimize possible environmental hazards.

Federal Communications Commission

1919 M Street N.W.
Washington, D.C. 20554

For information on the Federal Communications Commission, see Chapter 1.1, "FCC Organization and Administrative Procedures," and Chapter 1.2, "FCC Field Operations Bureau."

Every station should have a current copy of the FCC's broadcast rules. There are two ways to obtain them:

1. Order a set of the Code of Federal Regulations (CFR) issued annually by the U.S. Government Printing Office. Call them at (202) 783-3238 and order "47 CFR Parts 0–19" for the Tower Regulations in part 17 and "47 CFR Parts 70–79" for the Broadcast Rules Part 73 and Broadcast Auxiliary Rules Part 74.

The CFRs may also be ordered by writing the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402.

2. For a continuously updated subscription, call the Rules Service Company at (301) 424-9402. Parts 17,73 and 74 in loose-leaf form (updated quarterly). Or write to them at: 7658 Standish Place, Suite 106, Rockville, MD 20855.

National Labor Relations Board

1717 Pennsylvania Avenue, N.W.
Washington, D.C. 20570
(202) 254-9044

Broadcast engineers should be aware that the National Labor Relations Act (NLRA) protects the right of station employees to bargain collectively with management over the "terms and condition of employment." The National Labor Relations Board (NLRB), an independent federal agency, was established to enforce the right of workers to organize and engage in "concerted activity." As with the Department of Labor regulations, the extent of these rights depends upon many factors such as the type and the number of employees involved.

STATE AND LOCAL GOVERNMENTS

A number of aspects of a broadcast engineer's job are affected or controlled by state or local government agencies. It is important for the engineer to have some familiarity with the laws, codes, and zoning ordinances governing such matters as building construction, electrical wiring, and fire safety. Regulations may vary from one community to another, even within the same state or county.

While there are model national codes, these codes may or may not be adopted by a state or local government. If adopted, there may be some changes from the national model. The only way to determine this is to check with the local agency or agencies having jurisdiction over the matter in question. For more information on state or local regulations see the following:

- The broadcast station's local lawyer
- The county or city business licensing office
- The county or city building inspector, fire marshall
- A licensed local contractor who does the type of work in question

TRADE ASSOCIATIONS

Association of Federal Communications Consulting Engineers (AFCCE)

P.O. Box 19333
20th Street Station
Washington, DC 20036–0333

The AFCCE is a professional association of communications engineers practicing before the Federal Communications Commission. Engineering for broadcast stations in the AM, FM, and TV services, for microwave, cellular radio, paging systems, and for satellite facilities are some of the areas in which AFCCE members offer their professional services. Full members of the AFCCE are registered Professional Engineers in the jurisdictions where they practice. For more information on AFCCE and consultants, in general, see Chapter 1.6, "Consultant Services: When and How to Use Them."

Association for Maximum Service Television (MSTV)

1400 16th Street, N.W.
Suite 610
Washington, DC 20036
(202) 462-4351

The purpose of MSTV is to assure the maintenance and development of an effective nationwide system of free over-the-air television based on local broadcast stations providing service of high technical quality. MSTV seeks to meet both the present and future needs of developing an effective nationwide VHF and UHF system; to provide free over-the-air broadcasting; to develop local stations to reflect the needs and interests of local communities; to safeguard against broadcast of only a few purely national voices; and to protect against interference and degradation of the public's broadcast service. MSTV develops and preserves opportunities for local stations to use new technologies.

Advanced Television Systems Committee

1776 K Street, N.W.
Suite 300
Washington, DC 20006
(202) 828-3130

The Advanced Television Systems Committee (ATSC) was established in 1983 to develop and coordinate voluntary national technical standards for advanced television systems, and to recommend to the U.S. Department of State positions for the United States within international standards organizations such as the International Radio Consultative Committee (CCIR).

The ATSC is composed of fifty member companies, all of which are major factors within the United States television industry. These members include broadcast networks and stations, cable television companies, program producers, professional and consumer equipment manufacturers, and satellite communications companies.

Cable Television Laboratories Inc. (CableLabs)

1050 Walnut Street
Suite 500
Boulder, Colorado 80302
(303) 939-8500

CableLabs is a research and development consortium of cable television system operators representing more than 85% of the cable subscribers in the United States.

Committee for Digital Radio Broadcasting (CDRB)

c/o Society of Broadcast Engineers
P.O. Box 20450
Indianapolis, IN 46220
(317) 253-1640

The role of the CDRB is to support the development of a digital radio broadcast system in the United States. A viable system should provide radio broadcasts with a sound quality comparable to compact discs in a cost effective manner. This technology could be used to augment the current distribution system of radio broadcasting via the FM and AM bands in the United States. The CDRB will:

1. Sponsor demonstrations of digital radio broadcast technology in the U.S.
2. Analyze current developments in digital radio broadcasting.
3. Analyze legal and practical implications of a system on the existing U.S. radio broadcast industry.
4. Determine what elements are needed to identify appropriate spectrum and implement a viable system in the U.S.
5. Promote and support research and development of digital radio broadcasting in the U.S.
6. Advocate spectrum allocation.
7. Serve as industry liaison to the government, consumer electronics industry, and international organizations.
8. Promote industry consensus on digital radio broadcast standards.

Participation in committee activities is open to all interested parties with a direct interest in the development of digital radio broadcasting in the United States, including broadcasters, manufacturers, associations, and laboratories.

Electronic Industries Association (EIA)

2001 Eye Street, N.W.
Washington, DC 20006
(202) 457-4900

The Electronic Industries Association is a trade association representing the manufacturers of telecommunications; industrial and consumer equipment; components (parts, tubes, and solid state products); and equipment and systems for the government. Their engineering activity includes the publication of voluntary standards. Those of interest to broadcasters are standards covering transmitters, towers, microwave transmission systems, and tape cartridges. The standards work is primarily done in the Broadcast Television Systems Committee (BTSC), the National Radio Systems Committee (NRSC), and standing engineering committees. The BTSC and NRSC are joint engineering committees with the National Association of Broadcasters (NAB). The catalog of standards and engineering publications may be obtained from: Standard Sales Department, Electronic Industries Association, 2001 Eye Street, N.W., Washington, D.C., 20006, (202) 457-4966.

A selection of EIA voluntary standards of interest to broadcast engineers is given below along with the date of acceptance or reaffirmation. Interested readers should contact EIA for a current listing and prices.

EIA-189-A Encoded Color Bar Signal. 1976.

EIA-200-A Circular Waveguides. 1975.

EIA-211-D Processed Analog Disc Records and Reproducing Equipment. 1981.

EIA-215 Basic Requirements for Broadcast Microphone Cables. 1958.

EIA-219 Audio Facilities for Radio Broadcasting. 1959.

EIA-221-A Polarity or Phase of Microphones for Broadcasting, Recording and Sound Reinforcement. 1979.

EIA-222-D Structural Standards for Steel Antenna Towers and Antenna Supporting Structures. 1987.

EIA-225 Rigid Coaxial Transmission Lines. 1975.

EIA-232-D Interface Between Data Terminal Equipment and Data Circuit Terminating Equipment Employing Serial Binary Data Interchange. 1986.

EIA-238-B Standards for Stylus Tips Used for Disc Phonograph Record Reproducing. 1981.

EIA-250-C Electrical Performance Standards for Television Relay Facilities. 1977.

EIA-258 Semi-flexible Air Dielectric Coaxial Cables and Connectors. 1962.

EIA-261-B Rectangular Waveguides. 1979.

EIA-264 Magnetic Recording Tape Cartridge Dimensions. 1962.

EIA-288 Audio Magnetic Playback Characteristic at 7½ IPS. 1963.

EIA-295 Disc Recording Characteristic. 1982.

EIA-297-A Cable Connectors for Audio Facilities for Radio Broadcasting. 1970.

EIA-355 Standard dimension for Unrecorded Magnetic Sound Recording Tape. 1974.

EIA-386 Recommended Measurement Method for Phonographic Rumble. 1978.

EIA-455 now has about 100 sections dealing with broadcasting.

EIA-462 Electrical Performance Standards for Television Broadcast Demodulators. 1979.

EIA-508 Electrical Performance Standards for Television Broadcast Transmitters. 1987.

EIA-549 NRSC AM Pre-emphasis/De-emphasis and Broadcast Audio Transmission Bandwidth Specifications. 1990.

EIA-560 Standard Method of Measurement for Compact Disc Players. 1989.

TR-101-A Electrical Performance Standards for Standard Broadcast Transmitters. 1948.

TR-107 Electrical Performance Standards for FM Broadcast Transmitters. 1949.

TR-117 Antennas and Combination of Antennas for FM Broadcasting Stations. 1949.

National Association of Broadcasters (NAB)

1771 N Street, N.W.
Washington, D.C. 20036–2891
(202) 429-5300

The NAB represents the broadcasting industry before Congress, the courts, regulatory agencies, at the White House, and before the general public. They serve a membership of over 5,100 radio station and approximately 1,000 television stations. The NAB department of Science and Technology represents the industry before the FCC and other agencies on issues affecting spectrum management and technical regulations. The department fosters and promotes research and development of new broadcast technologies, in part, by using the resources of NAB's engineering laboratory.

The department provides timely, useful, and accurate technical information for NAB members in Radio & TV TechCheck (a weekly technical news fax), and through other NAB publications. Other engineering publications are: Broadcast Engineering Conference Proceedings and HDTV World Proceedings (published annually at the conferences); Broadcast and Audio System Test CD I and II; NAB Test Record; "Engineering Technical Standards"; "Guide to Advanced Television Systems II"; "A Broadcaster's Guide to FCC RF Radiation Regulation Compliance"; and "Radio and Television Towers: Maintaining, Modifying, and Leasing."

NAB publications may be ordered by calling (800) 368-5644.

National Cable Television Association (NCTA)

1724 Massachusetts Avenue N.W.
Washington, D.C. 20036
(202) 775-3550

The National Cable Television Association (NCTA) is the major trade association for the cable industry. They represent the cable television industry before Congress and Federal Agencies, in the courts, and before state regulatory agencies. Members comprise over 400 cable operating companies and over 600 equipment manufacturers, programmers, and service companies.

Telecommunications Industry Association (TIA)

1722 Eye Street, N.W.
Suite 440
Washington, DC 20006
(202) 457-4936

The Telecommunications Industry Association is the result of a merger between the Electronic Industries Association (EIA) and the United States Telecommunications Suppliers Association (USTSA). The TIA represents U.S. suppliers of telecommunications equipment before Congress, the courts, regulatory agencies, at the White House, and before the general public. TIA is a provider of product-oriented standards. The standards programs presently operate under the accreditation awarded to the EIA Engineering Department by the American National Standards Institute (ANSI).

PROFESSIONAL ASSOCIATIONS

Broadcast Technology Society

Institute of Electrical and Electronic Engineers (IEEE) 345 East 47th Street
New York, New York 10017
(212) 705-7900

Members of the IEEE include engineers and scientists in electrical engineering, electronics, and allied fields as well as over 30,000 students. The IEEE holds numerous meetings and special technical conferences, conducts lecture courses at the local level on topics of current engineering and scientific interest, assists student groups, and awards medals, prizes, and scholarships for outstanding technical achievement. Along with other societies, they support the Engineering Societies' Library in New York City.

Publications of the IEEE include the Proceedings (monthly), Spectrum (monthly), and Directory (annually). The Societies and councils publish journals, magazines, and conference proceedings.

Society of Broadcast Engineers (SBE)

8445 Keystone Crossing, Ste. 140
Indianapolis, Indiana 46240
(317) 253-1640

The SBE is the largest national organization for broadcast engineers. It is devoted to the professional development of its members. The SBE promotes communication between SBE members, and provides national representation for those members before federal and state regulatory agencies, the courts, manufacturers, and the general public. The SBE through its 100 plus local chapters holds periodic meetings and technical conferences.

There are five levels of membership in the society.

- Honorary Member
- Fellow
- Senior Member
- Member
- Associate and Student

The SBE administers a certification program, recognizing four levels of engineering achievement.

- Broadcast Technologist
- Broadcast Engineer
- Senior Broadcast Engineer
- SBE Professional Broadcast Engineer

Frequency Coordination

The SBE National Frequency Coordinating Committee (NFCC) was established in 1982 when the FCC asked the broadcast industry to identify local contacts for Part 74 frequency coordination. The SBE formed the NFCC to develop local data bases of frequencies and users to assist the FCC and Part 74 users. Voluntary frequency coordination is handled on a local basis by SBE coordinators.

For additional information on SBE frequency coordination, see Chapter 1.3, "Frequency Coordination."

Ennes Foundation

The Ennes Educational Foundation was incorporated in 1986 as the educational arm of the SBE.

Each year the Foundation awards scholarships and grants for entry level training as well as continuing education in broadcast technology.

Society of Motion Picture and Television Engineers (SMPTE)

595 West Hartsdale Avenue
White Plains, New York 10607
(914) 761-1100

The membership of SMPTE is comprised of professional engineers and technicians in motion pictures, television, and allied arts and sciences. The Society advances engineering technology, disseminates scientific information, and sponsors lectures, exhibitions, and conferences to advance the theory and practice of motion picture and television engineering. As an accredited standards developer under the American National Standards Institute, they develop national standards for motion pictures, television, and sound associated with motion picture and television images. The Society also develops Recommended Practices and Engineering Guidelines. For copies of SMPTE engineering documents, contact their Standards Department.

SMPTE also makes available picture and sound test films for use as standardized measuring tools, serves as administrator of the Secretariat of ISO Technical Committee 36 on Cinematography, and of the U.S. Technical Advisory Groups for ISO TC36 and IEC SC60B on Video Recording. The Society sponsors technical courses at universities on such subjects as sound techniques, laboratory processing, special effects, and lighting for technicians and students. The Society presents nine annual awards for outstanding contributions to motion picture and television engineering.

SMPTE engineering committees include: Audio Recording and Reproduction Technology; Film Technology; Laboratory Services Technology; Projection Technology; Video Recording and Reproduction Technology; Television Technology; and New Television Technology. Publications of the Society include the monthly Journal, a yearly book of papers presented at the Society's annual Television Conference, and other books on motion picture and television technology.

RELATED ORGANIZATIONS

American National Standards Institute (ANSI)

655 15th Street N.W.
Suite 300
Washington, D.C. 20005
(202) 639-4090

Members include industrial firms, trade associations, technical societies, labor organizations, consumer organizations, and government agencies. ANSI serves as the clearinghouse for nationally-coordinated voluntary safety, engineering, and industrial standards. The institute gives status as American National Standards to standards developed by agreement from all groups concerned, in such areas as: definitions, terminology, symbols and abbreviations; materials; performance characteristics; procedure and methods of rating; methods of testing and analysis; size, weight, volume, and rating; practice; and safety, health, and building construction. They also provide information on foreign standards, and represent United States' interests in international standardization work. The ANSI committee is Certification. The Councils are: Company Member, Consumer, Executive Standards, International Standards, and Organizational Member. Publications of the institute are the Reporter (biweekly), Standards Action (biweekly), and Catalog of Standards (annually).

American Radio Relay League (ARRL)

225 Main Street
Newington, CT 06111
(203) 666-1541

Members are licensed amateur radio operators in the U.S. and Canada, and others interested in amateur radio, communication, and experimentation. The league operates a nationwide message handling network: the National Traffic System. Its members serve as official relay stations, observers, phone stations, emergency coordinators, experimental stations, and bulletin stations. They operate an experimental equipment laboratory and maintain the Museum of Amateur Radio. They also sponsor contests and present awards for operating proficiency. ARRL serves as secretariat for International Amateur Radio Union. Publications include QST (monthly) and Radio Amateur's Handbook (annually), as well as special booklets for beginners, and others on antennas, mobile, and radio fundamentals.

Association for Broadcast Engineering Standards (ABES)

2000 M Street, N.W.
Suite 600
Washington, D.C. 20036
(202) 331-0606

An independent, nongovernmental, voluntary organization of licensees and permitees of U.S. radio broadcast stations "united to assist the appropriate government authorities and the industry in assuring optimum radio service for the people of the United States and to follow the intent of Congress in the Communications Act of 1934, as amended." Objectives include: "rejecting and opposing proposals which would decrease, impair, or destroy the radio service now available to the American people; and supporting the adoption of legislature and Federal Communications Commission policies that encourage sound technical standards upon which optimum radio service may be obtained." The association analyzes proposed broadcast legislation, FCC proposals for rule making, and industry proposals filed with the FCC that will, directly or indirectly, affect the public interest in optimum radio service. The association formulates and conducts short and long range programs of technical research to assist governmental and industrial groups in maintaining sound technical standards.

Audio Engineering Society (AES)

60 East 42nd Street
Room 449
New York, NY 10017
(212) 661-8528

Members include engineers, administrators, and technicians who design or operate recording and reproducing equipment for radio, television, motion picture, and recording studios, or who produce, install, and operate disc, magnetic tape, and sound amplifying equipment; educators who use recording in teaching, or who teach acoustics, electronics, and other sciences basic to the recording and reproducing of sound; and administrators, sales engineers, and technicians in the sound industry and related fields.

Broadcast Education Association (BEA)

1771 N Street, N.W.
Washington, D.C. 20036
(202) 429-5355

Primarily directed by those in the academic community, its orientation is toward exploring new trends, ideas, and opportunities in broadcasting. The BEA publishes the Journal of Broadcasting and Electronic Media and Feedback. It also administers the Patterson Radio Scholarship and the Harold E. Fellows Memorial Scholarship.

Illumination Engineering Society of North America (IES)

345 East 47th Street
New York, NY 10017
(202) 705-7926

This is a technical society whose members include engineers, architects, designers, educators, students, contractors, distributors, utility personnel, scientists, and manufacturers dealing with the art or science of illumination. They provide assistance with technical problems, reference help, and speakers. They maintain liaison with schools and colleges and offer basic and advanced IES Lighting Courses through local sections and in cooperation with other organizations.

Underwriters Laboratories (UL)

333 Pfingsten Road
Northbrook, Illinois 60062
(312) 272-8800

A testing laboratory that maintains additional laboratories in Melville, New York; Santa Clara, California; and Tampa, Florida. UL seeks "by scientific investigation, study, experiments, and tests to determine the relation of various materials, devices, products, equipment, constructions, methods and systems to hazards appurtenant thereto or to the use thereof affecting life and property, and to ascertain, define and publish standards, classifications, and specifications for materials, devices, products, equipment, construction, methods, and systems affecting such hazards, and other information tending to reduce loss of life and property from such hazards."

2.1 Design, Erection, and Maintenance of Antenna Structures

John Windle, P.E.
Stainless, Inc., North Wales, Pennsylvania

Tower Lighting Section by:
Lewis Wetzel
EG&G Electro-Optics Division, Salem, Massachusetts

INTRODUCTION

The purpose of this section is to provide broadcast engineers and managers information concerning the design, erection, and maintenance of antenna structures. While fundamental principles of the design and behavior of these structures will be discussed, this section is not intended to enable readers to design and build their own tower, but provides instead a basic understanding of these unique structures to facilitate planning, modifying, and maintaining broadcast facilities.

TOWER CHARACTERISTICS

Types

All towers may be classified in one of the two basic groups: guyed or self-supporting. As their names imply, guyed towers depend on cables running to anchors located some distances from the tower base for their structural integrity, while self-supporting towers rely solely on their own construction as a cantilevered space truss.

With only a few exceptions, the cost of the actual tower structure and foundations is considerably less for a guyed tower than for one that is self-supporting. The advantage of the self-supporting tower is the relatively small land area required. Therefore, the choice between guyed or self-supporting depends to a large degree on the availability and cost of real estate.

A self-supporting tower requires a nearly square plot of land with equal sides that are 8% to 20% of the tower's height.

The amount of land required for a guyed tower depends on the distance between the tower base and the guy anchors. This distance is preferably between 70% and 80% of the height, which would require a rectangular plot having sides equal to 125% and 145% of the height.

Because of the great flexibility in guyed tower design, it is possible to reduce the anchor distance to as little as 35% of height, thereby requiring a much smaller land area. However, the cost of the tower increases as the anchor distance decreases. The approximate relationship of cost to anchor distance for a representative 1,200 feet television broadcast tower is shown in Fig. 1.

It is often possible to position a guyed tower on an irregularly shaped plot or to obtain long term lease

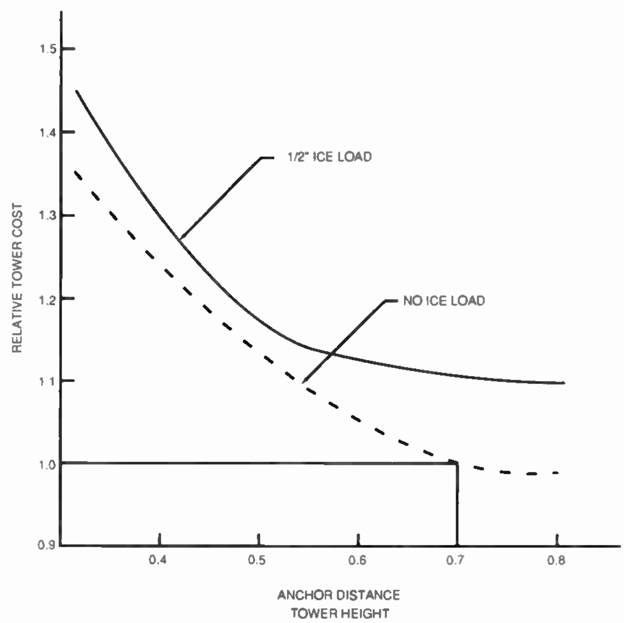

Figure 1. Effects of anchor distance on cost of a 1,200 foot guyed TV broadcast tower using ANSI/EIA/TIA Standard 222-E-1991.

agreements or easements for guy paths and anchor locations in order to minimize the tower cost without obtaining large, rectangular land areas.

Configurations

Self-Supporting Towers

Self-supporting towers may be either square or triangular in cross section. While it is usually more economical to use a triangular cross section, there are situations where a square cross section is a better choice. The principal structural elements are the legs, the web bracing in each face, and if required for stability, horizontal diaphragm bracing. The legs are usually sloped (tapered) to provide adequate strength and stability as the height increases. The degree of slope is an option of the designer to suit the equipment supported, the required rigidity, and the available land area. The slope is sometimes varied within a tower to maintain a desirable balance between the costs of leg members and bracing, or to reduce the foundation loads. Frequently the legs in the top section of the tower will be parallel to simplify the mounting of equipment.

There are several different configurations of bracing members for the individual truss panels. The choice is influenced by the width of the panel, the magnitude of the wind and ice loads imposed, the location of equipment, and required stability. Continuity in transferring the applied loads through the structure without significant eccentricity is essential regardless of the configuration used.

Guyed Towers

Guyed towers are almost always of triangular cross section although there are a few unique conditions for microwave and panel type FM and TV antenna supports where a square cross section is advantageous. The principal structural elements are the legs, the web bracing in each face, and the guy support systems. Except for sections at the tower base and locations where the width changes, the legs are parallel. The width of the tower is usually constant throughout the height of the tower with the exception of sections supporting antennas requiring a specific width of support structure. The base section is often tapered to a single point to provide a pivot support to eliminate large bending and torsional moments.

Theoretically, there are an infinite number of arrangements of guy cables to support a tower. The most common arrangement is three cables spaced at 120° with one attached to each leg, as shown in Fig. 2A. This is the minimum number of cables that can be used. When the tower supports equipment which imposes large twisting moments (torques), it is necessary to provide six cables at a level to maintain torsional stability. If the torque is localized, the guys at the location may be attached to triangular frames as shown in Fig. 2B. If the torques occur throughout the height, it may be desirable to double-guy the tower at every level as shown in Fig. 2C.

The number of levels of guy cables to support the tower is dependent on a number of factors including the height of the tower, width, location of equipment, and the environmental loading conditions. Because the tower is an axially compressed column, its strength is a function of its slenderness. While design codes permit slenderness ratios resulting in triangular towers having a span-to-width ratio as great as 49, it is usually economical to limit the ratio to a maximum of 30. While there is no upper limit to the number of guy levels imposed by any code, a practical limit for economical design is ten.

The position of equipment on the tower is an important factor in determining the location of guy levels. Preferably, guy attachments should not be located

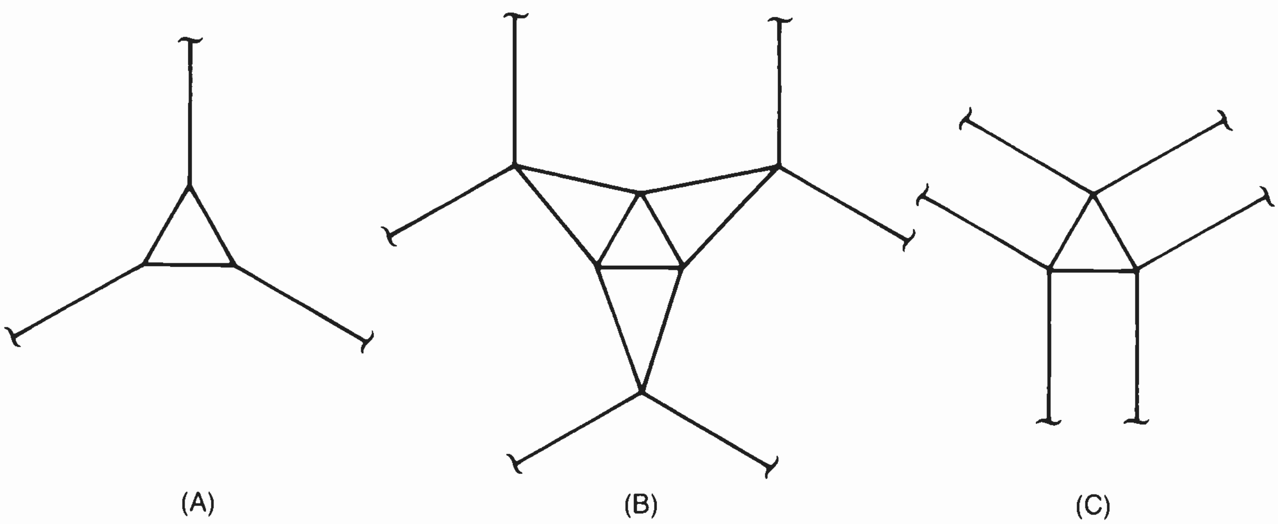

Figure 2. Typical guy arrangements.

within the apertures of side mounted TV and FM broadcast antennas. Equipment producing large localized wind loads, such as microwave antennas or clusters of two-way radio cabinets and antennas, should not be positioned near the center of a span between guys.

If the tower will be subjected to ice loading, it is desirable to reduce the number of guy levels to minimize loads imposed on the tower by ice accumulation on the guy cables.

The number of anchors in each guy direction is dependent on several factors including the number of guy levels, the soil conditions, topography, and obstacles. As a general guideline, it is desirable to limit the number of guy levels attached to a single anchor to five. However, there is nothing absolute about this number, and other conditions may dictate using an anchor for a greater number. There are some soil conditions where it may be economical to provide two or more smaller anchors, while in another instance the use of one large anchor might be desirable. If minimizing the area within which the tower would fall in the event of a collapse is a consideration, a minimum of two anchors should be used in each direction. Where the elevations of the anchors differ from the tower base, it is desirable to vary the distance of the anchors from the tower base to maintain nearly equal initial tensions in the guy cables. Anchors higher than the tower base should be moved toward the tower; and anchors that are lower, away from the tower. The amount of movement should be specified by the designer.

Materials

Tower Structures

Nearly all broadcast towers are made from steel because it provides the most economical structure. The selection of the grade and shape of steel is obviously an important design consideration.

Steels used for towers commonly have low carbon content with yield strengths in the range of 36,000 psi to 60,000 psi. These materials have good ductility and are suitable for welding. Some towers have been built using higher grade materials with yield strengths up to 100,000 psi, but the savings in weight are more than offset by higher base prices and increased fabrication costs. Regardless of the grade of material, the steel's physical and chemical properties should be certified by the producing mill to ensure that it conforms to the design requirements.

The shape of the material as well as its size and strength affects the tower's load carrying capacity. The shape also has a significant effect on the magnitude of loads produced by wind. Design standards permit a reduced wind load on round members as little as 57% of the wind load for flat or angular members of the same width. For this reason, solid round bars, round structural tubes, and pipe are often used. This advantage in wind load is offset somewhat by increased fabrication costs, due to the necessity of welding plates to connect the various members.

There is no one grade or shape of material that is best. The choice depends to a large degree on the preference of the designer and the type of fabricating facilities available.

A factor equally as important as the selection of the grade and shape of the structural steel is the design of the connections. For shop welded connections, the compatibility of the base and filler metals and required preheat temperatures must be considered. The procedures used must be qualified and the welders certified to use them. Inspection procedures should be compatible with the weld design.

Bolts for field assembly may be of various types. Usually those for the main load carrying members are high strength. If positive resistance to slippage of the connections is required, they should be designed as friction connections.

Guys

The most common material for tower guys is galvanized steel strand. This material has excellent strength and durability. Its "structural" elongation due to the seating of the individual wires in the strand is small and can be almost entirely eliminated by prestressing the strand to 50% of its breaking strength at the factory. This should be done for guys on tall towers with factory connected end fittings.

For guys on AM towers, and those close to FM and TV antenna apertures, a nonconductive material is sometimes desirable. Two such materials that have been used are Kevlar rope and fiberglass rods. When using these materials, careful attention must be given to protection against corona effects, fatigue, and deterioration from exposure to ultraviolet light. Also, their elongation characteristics under load must be evaluated. They require delicate handling at all times.

Just as for the tower structure, the connections for the guys are as important as the guy material itself. Some of the more common connections are as follows:

1. *Sockets* of forged or cast steel attached with molten zinc or epoxy resins develop the full strength of the guy. They are normally installed at the factory and proof loaded to 50% of the guy breaking strength. This type of fitting is most common for the larger guys used on tall towers.
2. *Dead end grips* are preformed spiral wire loops in the shape of a large hairpin. The two legs of the hairpin are wrapped around the guy with its closed end forming an eye. These grips are used for guys up to one inch in diameter and usually develop their full strength. They are easily installed in the field, but the ends must be completely snapped into place and a protective device installed to prevent ice from sliding down the guy and loosening the grip.
3. *Clips* used to clamp the ends of guys (when properly applied and tightened) develop 90% of the guys' strength for sizes up to and including ⅞

inch and 80% for larger sizes. To install them it is necessary to bend the strand back on itself to form a loop; thus, the use of clips on large cables is difficult. The saddle of U-bolt type clips must be on the load side and not the dead end which provides another potential error in their installation.

4. *Swaged sleeves* develop between 85% to 100% of a guy's strength depending on the size of the guy and equipment used to squeeze the sleeve. These fittings are usually installed at the factory and can be proof loaded. They are advantageous for connecting closely spaced insulators where the length of dead end grips is unacceptable.
5. *Wedge Type Sockets* are available for guys up to 1¼-inch diameter and develop 100% of their strength. They are most advantageous for guys larger than those for which dead end grips are available.
6. A *serving* is a connection made by rolling the individual wires of a strand back on the strand itself. This method has for the most part been replaced with dead end grips, but it is advantageous for small guys with closely spaced insulators.

Insulators

Insulators in radio frequency applications must withstand mechanical and electrical stress in a varied, changing exterior environment. Selection of insulators should be made with these factors in mind. Insulators primarily designed for 60 Hz applications are unsuitable, particular at high RF powers.

The most common insulating material is a wet process porcelain which has excellent compressive strength and good insulating capabilities for frequencies up to 2 MHz. Synthetic materials are also used.

1. *Base insulators* for AM towers are made from porcelain with appropriate steel end plates or ferrous/nonferrous castings. For guyed towers, a rocking arrangement is provided in the form of a convex plate and pin at the top, or a pivot pin at the bottom of the assembly to hold the tower in place and relieve the porcelain from bending loads which could cause cracking. For self-supporting towers, the insulators are bolted between the tower leg and base pier, and are designed to sustain both uplift and download while keeping the porcelain in compression.
2. *Sectionalizing insulators* are sometimes required to isolate sections of a guyed tower. Where a compression load only is applied, a guyed tower base with minor modifications can be used. If a tension load is anticipated, a push-pull insulator similar to the type used for self-supporting towers is required. Under no circumstances should the porcelain be put in tension.
3. *Guy insulators* are available for primary insulation and for break-up purposes. Primary insulation (insulators next to the tower) should be selected to withstand the full voltage appearing at the guy attachment point. This is to ensure that sufficient insulation remains if all the break-up insulators in the guy line flash over. Break-up insulators, used to reduce reradiation, are selected to withstand the transmitter induced voltage and static voltage. Break-up insulators are usually low voltage types, sometimes protected from flashover and subsequent power arc by a static dissipation device. Guy insulators are available in many styles classified as either compression or tension types.

   A. *Compression* insulators are designed such that the porcelain element is in compression. Simple low voltage types are a single piece of porcelain placed between interlocking loops of the guy. Such insulators are available for mechanical working loads up to 40,000 lbs. For higher loads, oil filled and open types are used. The most common uses of compression insulators in broadcasting are for break-ups and as primary insulators (in groups of three or four) on low-power antennas.

   B. *Tension* insulators come in many forms, including porcelain rods (not permitted in structural applications), fiberglass rods, synthetic ropes, and oil filled safety core types. Tension insulators are used as primary insulators with corona rings to reduce the electrical field stress at the end fittings. One insulator is required at each guy attachment point. Since the voltage level is different at each point on the tower, different voltage ratings may be required for some insulators at certain guy attachment points. Tension insulators are available in a wide range of electrical and mechanical ratings to meet most needs.

Finishes

Corrosion Protection

Steel is susceptible to deterioration from atmospheric corrosion. To prevent deterioration, the tower members and hardware must be given a protective coating. This coating is usually zinc which has excellent resistance to corrosion, and, because it is higher in the electrochemical series of the periodic table of elements, it provides cathodic protection to exposed steel surfaces adjacent to it. Even though the zinc coating may be scraped or otherwise damaged, it continues to inhibit corrosion of these exposed areas, and rust will not develop beneath adjacent zinc coats.

There are several methods for applying the zinc including hot dip galvanizing, flame spraying electroplating, and painting. All must be applied to clean surfaces.

1. *Hot-dip galvanizing* consists of dipping the steel into a bath of molten zinc. A metallurgical bond develops between the steel and the zinc which

adheres to it. When galvanizing tubular members, it is necessary to provide holes in both ends to ensure that the inside surfaces are coated. Careful attention must be given to the type of base and welded metals used, as well as to the welding and forming procedures used in fabrication, to safeguard against possible embrittlement of the steel when galvanized. When properly applied, this process provides the most durable coating.
2. *Flame spraying* consists of spraying molten zinc at high pressure onto the steel surfaces. The bond in this process is mechanical rather than metallurgical. The coating produced is more porous and has less resistance to abrasion than the hot-dip galvanized coating. It cannot be used for the inside of hollow sections or other cavities where access is difficult.
3. *Electroplating*, while suitable for small objects, does not produce a coating thick enough to withstand a hostile exterior environment. This method is not recommended for tower parts or hardware.
4. *Zinc rich paint* consists of extremely finely divided zinc in an inorganic or organic vehicle. It is not a metal coating method, but rather a painting procedure. Its resistance to abrasion and durability are less than hot-dip galvanizing. This procedure is, however, useful for maintenance.

Aircraft Marking

When required by the FCC construction permit, towers must be marked as a hazard to air traffic. One such marking system requires a tower to be painted with contrasting colors of white and international orange in alternate bands. Selection of the paint materials must be compatible with the surfaces to which they will be applied. There are several manufacturers who have one-coat paint systems that can be applied directly to galvanized surfaces. Like all paint procedures, clean, dry surfaces and suitable temperatures are essential to obtaining satisfactory adherence.

Alternate sections of international orange (Federal Standard Number 12197) and aviation white (Federal Standard Number 17875) paint provide maximum visibility of an obstruction by contrast in colors. The chromaticity and luminance standards of aviation orange and white paint should conform to Federal Standard FED-STD-595. These paints meet the specific color requirements when freshly applied to a structure. However, all outdoor paints deteriorate with time. While it is not practical to give a maintenance schedule for all climates, surfaces should be repainted whenever the color changes noticeably, or its effectiveness is reduced by scaling, oxidation, or chipping. An orange color tolerance chart is available upon request from the FAA for determining when repainting is required. The color should be sampled on the upper half of the structure, where the weathering will be greater. This tolerance chart may be obtained from:

Manager, Flight Information and Obstruction Branch, ATO-210
Federal Aviation Administration
800 Independence Avenue, SW
Washington, DC 20591

When high intensity white lights are installed on the tower and are operated during daytime and twilight, the international orange and white paint may be omitted. When medium intensity white lights are operated on structures up to 500 feet in height, the international orange and white paint may also be omitted. See the section on, "Electrical Systems for Antenna Structures," below.

The cost of repainting an antenna structure depends on many variables such as accessibility, size, height, neighboring properties, weather, elevator availability, etc. A rough guideline for estimating the cost for repainting a structure is to multiply the face dimension in feet by the height in feet to get the cost in dollars. Due to the number of variables that have to be factored in, this formula will provide only a rough estimate.

Ice Prevention

Coatings are available to reduce the adherence of water to surfaces and subsequently the formation of ice on them. However, no reliable means exists to completely remove the risk of severe ice accretion.

Access Facilities

A tower must have some access facilities in order to maintain it and the equipment the tower supports. For small towers, the bracing members of the tower itself often serve as steps, or step bolts are attached to one leg or face.

Ladders

For taller broadcast towers, a fixed ladder inside the tower is desirable. The Occupational Safety and Health Administration (OSHA) standards for these ladders require a minimum clear width between side rails of 16 inches and a maximum rung spacing of 12 inches. OSHA also requires that any continuous ladder more than 20 feet in height be equipped with a safety device. This device consists of a continuous rail, either rigid or cable, running up the center of the ladder. A clamping device attached to the climber's safety belt rides along this rail. As long as the climber is in a normal position, the clamp slides freely; if he begins to fall, a cam actuated mechanism freezes the clamp to the rail and prevents his falling.

Elevators

For tall towers supporting multiple antennas, it is often desirable to install an elevator. Most tower elevators are of the power, cable driven type with a capacity of 500 pounds to 750 pounds and a speed between 80 feet and 100 feet per minute. They consist of a drive mechanism, car, guide rails, hoist cable with supporting sheaves, tension weights, electronic controls, and a two-way communications system.

Considerable attention must be given to elevator safety features. These should include limit switches to prevent travel beyond the upper and lower landings on the tower, an automatic brake on the driving mechanism that is activated by an interruption in power, a mechanism to automatically clamp the car to the rails in the event of a broken hoist cable, and interlocks to prevent operation with the car gate open. It is advisable to determine the applicable state or municipal government regulations that may apply, and whether permits, tests, and inspections are required before the tower and elevator system are designed.

The added wind and dead loads from an elevator system are substantial and must be considered in the tower design. Also, careful attention must be given to the positioning of the ladder, RF transmission lines, and electrical conduits in relationship to the elevator. The ladder must be positioned so it is accessible from the elevator car and can be used for an emergency descent. While the elevator hoist cables can be restrained in guides on the return side, they are free to move about under wind load on the lifting side. Therefore, the conduits and transmission lines must be protected from hoist cables striking and damaging them. If a side mounted TV or FM antenna produces a high RF field within the hoistway, protection must be provided to prevent arcing between the hoist cables, the tower structure, and other appurtenances.

Transmission Line Bridges

To allow for thermal expansion and contraction, it is necessary to locate broadcast towers some distance from the transmitter building. Unless the transmission line is placed underground, it is necessary to provide a structural support for it at a height compatible with the transmitter location in the building. The top of the support can be covered with steel grating or plate to protect the line from falling ice. The details of this structure can become quite involved for sites with multiple antennas, uneven terrain and roadways, or obstacles between the tower and building.

Stairways

The lower landing for a tall, guyed broadcast tower with an elevator is often 30 feet or more above ground level. A stairway may be desirable to permit easier access to the landing. This structure can be combined with the transmission line support bridge, or it may be completely separate. It may also be desirable to install a small capacity boom above the lower landing to lift radio cabinets or other equipment onto the landing.

DESIGNING ELECTRICAL SYSTEMS FOR ANTENNA STRUCTURES

Several types of electrical systems are commonly installed on towers to obtain the greatest utility from the structure. These include systems for tower lighting, antenna de-icers, utility circuits, and power for ENG, two way and other communication facilities. To ascertain overall requirements, the criteria and specifications for these systems should be determined, before the general specifications for the tower are completed.

Marking and Lighting Antenna Structures to Meet FAA/FCC Requirements

Since an antenna structure may be a hazard to air navigation, the Federal Aviation Administration (FAA) has established certain marking and lighting requirements for broadcast towers. In general, these requirements are spelled out in an advisory circular published by the FAA entitled "Standards for Marking and Lighting Obstructions to Air Navigation" (AC 70/7460–1). Prior to submission of an application for construction to the FCC, the various options for antenna structure marking and lighting should be carefully considered, and a preference for an option should be requested on the application.

New Certification Procedure For FAA Approved Lighting Equipment

Effective January 1, 1990, ETL Testing Laboratories, Inc., Industrial Park, Cortland, New York 13045 (607-753-6711), will be administering the certification process for airport and obstruction lighting equipment. Lighting equipment approved by the FAA prior to January 1, 1990, will be accepted for the ETL certification program without additional product qualification testing for a period of five years, provided sufficient documentation exists to support a certified status. The equipment covered by this clause will still be subject to ETL's quality control audit, site production testing, and inspection. Should the FAA revise a standard or specification, the applicable equipment must then be recertified and verified by ETL.

The FAA will continue to publish Advisory Circular 150/5345–1, "Approved Airport Equipment," listing all certified lighting equipment that ETL verifies as meeting the applicable FAA specifications.

When building or modifying an antenna structure which involves the purchase of obstruction lighting equipment, it would be wise to require a certificate of compliance from the manufacturer.

FCC Lighting Requirements

Temporary warning lights. During construction of an antenna structure, for which obstruction lighting is required, a temporary light is installed at the uppermost point of the structure. This light should be similar in type and intensity to the permanent light that is required for that level. In addition, as the height of the structure exceeds each level at which permanent obstruction lights will be required, another level of temporary lighting must be used. If practical, the permanent obstruction lights may be installed and operated at each required level as construction progresses.

Inspection of tower lights. The licensee of any radio or television station, which has an antenna structure requiring illumination, is required (FCC Rules Section 17.47 (a)) to do the following:

1. Make an observation of the antenna structure lights at least once each 24 hours, either visually or by observing a properly maintained automatic indicator designed to register any failure, to ensure that all such lights are functioning properly as required.

OR

2. Provide and properly maintain an automatic alarm system designed to detect any failure of such lights, and to provide indication of such failure to the licensee.
3. Inspect, at intervals not to exceed three months, all automatic or mechanical devices, indicators, and alarm systems associated with the antenna structure lighting to ensure that such apparatus is functioning properly.

Notification of extinguishment or improper functioning of lights. The licensee of any radio or television station which has an antenna structure requiring illumination is also required (FCC Rules Section 17.48 (a)) to:

1. Report immediately to the nearest Flight Service Station (FSS) or office of the FAA any observed or otherwise known extinguishment or improper functioning of any top steady burning light or any flashing obstruction light, regardless of its position on the antenna structure, not corrected in 30 minutes. Such reports must set forth the condition of the light or lights, the circumstances which caused the failure, and the probable date for restoration of service. Further notification must be given immediately upon resumption of normal operation of the light or lights.

An extinguishment or improper functioning of a steady burning intermediate sidelight or lights must be corrected as soon as possible, however, notification to the FAA of such extinguishment or improper functioning is not required.

Recording of antenna structure light inspections in the station log. The licensee of any radio or television station, which has an antenna structure requiring illumination, must make (FCC Rules Section 73.1820 (a) (1)) the following entries in the station log in the event of any observed or otherwise known extinguishment or improper functioning of an antenna structure light:

1. The nature of such extinguishment or improper functioning.
2. The date which such extinguishment or improper operation was observed or otherwise noted.
3. The date, time, and nature of adjustment, repairs, or replacements made.

Automatic monitoring for light failures. Although the FCC no longer requires daily logging of antenna structure lighting operation, the logging of a light failure is required along with notification to the FAA of the failure and the proposed schedule for resumption of normal operation. Automatic monitoring is available in accordance with FAA/FCC requirements to alert station personnel of a light failure. Computer compatible monitoring systems are available for use with remote logging systems.

In the electronic power supply that also performs the controller function in the high and medium intensity systems, a failure relay should be included to provide automatic monitoring of the system. From these contacts on the failure relay, a signal can alert the licensee of a failure.

Time when lights should be exhibited.

1. All red obstruction lighting must be exhibited from sunset to sunrise unless otherwise specified.
2. All medium and high intensity white obstruction lighting must be exhibited continuously unless otherwise specified.

Marking With Red Lights

Flashing red beacon (L-864). This is a flashing beacon which produces aviation red light. The peak effective intensity must be 2,000 candelas ±25% in red when measured at any horizontal angle. The flashing rate must not be more than 40 nor less than 20 flashes per minute. The beacon should be lit from one-half to two-thirds of the total cycle. The light intensity during the "off" period must be less than 10% of the peak effective intensity. A change in the latest revision of AC 70/7460–1(H) states, "Intermediate level flashing beacons (L-864) may be installed either within or outside the structure if the transmission cable or the tower legs do not have an effective diameter of more than three inches. If either is more than three inches, two beacons must be installed diametrically opposite each other and on the outside of the structure."

To ensure the proper light output, the operating voltage provided at the lamp socket should not vary by more than 3% from the rated voltage of the lamp. For instance, 3% low voltage results in a 10% drop in light output, and 3% high voltage results in a 30% reduction of the rated lamp life. The measurement of lamp socket voltage must be made while under normal station operating conditions.

Steady burning red lights (L-810). These obstruction lights consist of one or more steady burning lamps ranging from 45 watts to 116 watts per fixture. The intensity must not be less than 32.5 candelas at all horizontal angles. Three fixtures are required per level.

Cost considerations. The equipment cost plus installation for a red obstruction light group (one or two flashing beacons and three steady burning side lights) can vary from $2,000 to $6,000 depending on the size of the antenna structure, its location, and other local conditions affecting installation costs.

To estimate power costs, one must first add the number of lights required. Under the latest revision of AC 70/7460–1, the red obstruction lights are specified to be mounted on the structure in groups (one or two L-864 flashing beacon and one set of L-810 steady burning sidelights). One group consumes 1,175 watts to 2,000 watts of power if the flashing beacon is set to operate for ⅔ of the cycle. This assumes zero power consumption during the off portion of the flashing beacon cycle. Assuming electrical power costs of ten cents per kWh and a yearly average of 12 hours per day of red light operation, the yearly power costs per group is approximately $515 to $875.

Lamp replacement costs depend on the labor costs of riggers, if needed, but the interval can be estimated with the following guidelines. Steady burning sidelight lamps have a rated life of 6,000 hours. These lamps should be replaced after being operated for not more than 75% of their rated life. This allows for a yearly replacement schedule. However, many tower operators replace all lamps at the same time if early replacement of one lamp is necessary due to failure.

The 640 watt flashing beacon lamps have a rated life of 3,000 hours. Seventy-five percent of rated life is reached approximately every 6 months. A 700 watt lamp with a rated life of 6,000 hours is available. This lamp has the same light output as the 640 watt lamp that is normally specified. With the 700 watt lamps installed, the yearly power cost per group increases to approximately $565 to $975.

Marking With White Xenon Lights

The FAA allows the use of white xenon lights for marking antenna structures over 200 feet in height. Lighting with high and medium intensity white obstruction lights is done to provide a high degree of conspicuousness necessary to warn pilots on a potential collision course with a structure during both day and night.

The FAA spent several years looking for the best way to mark obstructions so they would be more visible during daytime. After trying different color painting ideas, and various lighting schemes, the white xenon lights proved to be the best solution. When more tests were conducted in the early 1980s to qualify the use of medium intensity on structures 200 feet to 500 feet tall, again the medium intensity white xenon lights proved to be better than international orange and white paint under all conditions except bright front-lit sunlight.

Effective intensity is probably the least understood term when it comes to the practical use of electronic strobe lighting equipment. The term *candela* is a unit of measurement of light output. *Effective candela* is specified by taking into account the so-called Blondel-Ray relationship.

The eye is able to integrate a light pulse with virtually no reciprocity failure for pulse lengths much shorter than the decay time constant for the eye which is approximately 0.2 seconds. Therefore, the eye is sensitive to the integrated value of the light pulse and not to the peak value, which for short pulses can be stated in impressively high but meaningless figures, as far as the eye is concerned.

The effective intensity can be determined from the Blondel-Ray relationship.

$$I_e = \frac{I_m(t + 1)}{t + 0.2}$$

where:

I_e = Effective intensity in candelas
I_m = Measured intensity in candle-seconds
t = Pulse width of the light pulse (usually between the ⅓ amplitude points) in seconds
0.2 = The decay time constant for the eye in seconds

For short light pulses, the effective intensity can approach five times that of a steady light source with the same candle-second intensity.

Factors Affecting Installation, Reliability, and Life

Power conversion. The power transformers that supply white xenon lights today are typically of the constant current/voltage regulating type. This type of transformer is very efficient when used to charge capacitors and is capable of supplying a near constant current from zero volts to full flash operating voltage on the capacitor. This type of transformer is not harmed if a flash capacitor develops a short, and is less likely to destroy the capacitor. Another feature of this type of transformer is its inherent immunity to voltage transients and spikes on the power line. Since the flash energy is proportional to the square of the flash voltage, capacitor safety margins are maintained and light output can be kept within the FAA specifications over the normal input power voltage fluctuations. To guard against lightning-induced voltages on the structure, the breakdown voltage from the primary to case and to other windings should be designed for at least 5.0 kV with insulation of high enough heat rating to hold up for the desired useful life of the light.

Energy storage. The energy storage capacitors should be properly derated for the operational voltage to provide long life. Operational deratings for capacitors in common use during the past 15 to 25 years have shown deratings to 60% as being safe and long-lived. New technology capacitors using state of the art dielectric materials have shown deratings to 80% as being safe and long-lived. Because of the significant energy levels used in these lights, energy storage capacitors using minimal deratings should have built-in protection devices to minimize the possibility of overheating, rupturing, and causing damage not only to themselves but to fixture interiors as well.

Flashlamp characteristics. In the nonionized state, a flashlamp has high impedance (tens of mega-ohms); therefore, all current from the power supply initially flows into the capacitor. As the voltage across the capacitor is increased, a point is reached, called the breakdown voltage, where xenon atoms are ionized and the impedance of the flashlamp starts to drop. In a short period of time, enough xenon atoms are ionized so that a low-impedance path is formed from anode to cathode, and current flows from the capacitor through the flashlamp. As this occurs, more xenon atoms are ionized; the arc impedance drops to the milliohm region; and the arc expands outward, eventually filling the bore of the flashlamp. Most of the energy stored in the capacitor is expended in a matter of microseconds so that, eventually, the current through the flashlamp drops to such a low level that the tube de-ionizes and stops conducting. At this point, the capacitor starts recharging. An inductor is placed in series with the flashlamp and the capacitor. The values of the inductance, the capacitance, and the charging voltage are chosen carefully so that the energy is transferred to the flashlamp in a critically damped pulse. To ensure long life, the flashlamp should be designed so that at maximum ratings its loading is not more than 6% of explosion energy.

Optical design. For environmental considerations, the optical design is very important. These lights are specifically designed to alert pilots to the presence of the structure. Stray light reaching inhabited areas on the ground may be minimized by using louvers to block the direct radiation from the flash tube and polyfocal parabolic reflectors to provide a very sharp cutoff on the lower side of the light beam. Because of the critical beam shaping, care must be taken in the initial adjustment of the lights, to give the local residents the protection available from the optical design.

Physical installation requirements. The size of the lighting fixture must be considered because of the wind loading that is added to the structure. The size and weight can also become a factor during maintenance procedures. Lighting fixtures must be manufactured with noncorrosive enclosures such as stainless steel or fiberglass material.

Medium Intensity Lights for 200 Foot to 500 Foot Towers

When to use medium intensity lights. Medium intensity white lights can be used to mark antenna structures with an overall height not exceeding 500 feet and eliminate the need for painting. The red light for nighttime marking is usually eliminated also; however, in some locations neighboring landowners have insisted on the use of red lights for nighttime. A change in the latest revision of AC 70/7460–1(H) states, "Intermediate level medium intensity beacons (L-865) may be installed either within or outside the structure if the transmission cable or the tower legs do not have an effective diameter of more than three inches. If either is more than three inches, two beacons must be installed diametrically opposite each other and on the outside of the structure."

Cost considerations. The equipment cost for medium intensity lighting is about $2,400 to $3,000 per beacon, and includes all installation material. Because of variables such as location, weather, other work being done on structure etc., the installation cost can vary from about $500 per beacon up.

Each beacon system operating 24 hours per day will consume about 920 kWh per year. Assuming a rate of ten cents per kWh, the yearly operational cost is approximately $92 per year.

Medium intensity systems warranties vary from one to two years on parts. One system manufactured is a self contained unit with the electronic power supply built into the beacon flashhead. All others manufactured have the electronic power supply in a separate cabinet which is usually installed at the base of the structure. Unless the beacon fails to operate properly, a scheduled yearly routine maintenance check of the electronic power supply is all that is necessary.

Optics designed to shield ground. Two types of medium intensity beacons are presently available. One type uses a Fresnel lens to form a beam and thus obtains a gain in the peak light output. The Fresnel lens redirects the light that would normally fall on the ground near the structure and up to the sky towards the horizontal. The other type uses three linear flash lamps with parabolic reflectors to control objectionable light radiated toward inhabitants near the structure.

High Intensity Lights for 200 Foot to 2,000 Foot Towers

When to use high intensity lights. The FAA will require high intensity lights on an antenna structure when its location and height are in the airspace normally used by visual flight rules (VFR) pilots. This includes four miles on either side of a vector airway, along natural flyways such as rivers, railroads, interstate highways, and areas near airports.

The licensee may choose to install high intensity light on an antenna structure over 500 feet because of the long term economic gains. The FAA must approve the request to use high intensity lights.

Cost considerations. A high intensity lighting system requires a level of lights to be installed every 350 feet or less. At least three lights are used at each level. The average cost per level for the lighting equipment is about $10,000. The cost of installation can vary widely due to structure location, height, and other variables.

Each level using three high intensity lights operating 24 hours per day consume about 3,942 kWh per year. Assuming a rate of ten cents per kWh, the yearly power cost is approximately $395.

High intensity system warranties vary from one to two years for parts and labor. In order to continue to meet the light output specification, the flashtubes should be changed approximately every two to three years. Unless there is a light failure, an annual routine maintenance check to perform preventative maintenance should keep the system in good working order.

Shielding the ground with louvers. A set of louvers can shield the ground from the light radiating from the flashtube directly toward the ground near the tower. The design of the reflector and other light controlling devices can also direct the light output so that a very small percentage of the light is radiated toward the ground.

Other Electrical Circuits to Consider in Antenna Structure Planning

Antenna Deicing Circuits

Antenna deicing circuits should be designed to be installed using the main electrical conduit. If a choice of deicer operating voltage is available, consider choosing the highest voltage under 600 volts in order to minimize wire size. In many cases a 208/240 volt deicer system is fed with 480 volts using a step down transformer to reduce the I^2 R losses incurred in the long runs feeding systems on tall towers. Deicing systems should be designed to provide no more than a 5% to 10% voltage drop to ensure the proper operation of the deicer since the available heating power is proportional to the square of the voltage. Most automatic deicer control circuits require a shielded triplet which may also be installed in the main electrical conduit.

AC Utility Circuits
An AC utility circuit to provide access to 120 volt power at several elevations on the structure will often save time during maintenance and repair work on the structure and associated systems.

Elevator Control Circuits
Wiring for the elevator control circuits, if needed, may also be installed in the main electrical conduit.

Sound-Powered Telephone
A sound-powered telephone system in a separate ½-inch conduit to provide communications with ground personnel from the various working platforms can likewise save time during maintenance and repairs.

Power at Platforms for Communications Systems
With the recent increase in two-way communications and cellular telephone activity, many tall tower installations have found it advantageous to provide several platforms with up to 150 amp, 120 volt service which will accommodate a large number of communication systems.

A separate conduit with 20 to 100 pair shielded cable is normally used to provide audio input for the two-way communications systems.

Design Criteria For Electrical Systems

The following criteria should be regarded as guidelines for tower and system design. Final designs must meet all applicable state and local regulations and codes.

Conduit Sizing
The size of the conduit is determined by the number and size of conductors that must go into the conduit. If all conductors are the same size, a table in the National Electrical Code (NEC) spells out the size of the conduit needed. However, in most cases the various electrical circuits on a tower require a large variety of conductor sizes. The following table from the NEC Handbook shows the maximum fill to be used when dealing with many sizes of conductors.

Percent of Cross Section of Conduit for Conductors

Number of Conductors	1	2	3 or more
All Conductor Types (Except lead covered)	53	31	40

In practice, most tower installations are specified for 30% or less conduit fill.

Junction and Pull Box Sizing
In straight pulls the length of the box should not be less than eight times the trade diameter of the largest conduit. Where angle or U pulls are made, the distance between each raceway entry inside the box and the opposite wall of the box should not be less than six times the trade diameter of the largest conduit.

Selecting Conductor Sizes
Each electrical circuit must be evaluated to determine the voltage drop that can be tolerated. With the voltage drop determined, the size of the conductors needed can be calculated. The following table is a guide for acceptable voltage drops for various antenna structure circuits:

Type of Circuit	Percent Voltage Drop
Red Lights	3
Strobe Lights	10
Deicer Circuits	10
Utility Circuits	10

Using boost transformers. Using boost transformers to make up for voltage drop in a circuit is a practice commonly used in the design of incandescent lighting for towers to allow for the use of smaller wire sizes. Fluctuations of the voltages in these circuits can shorten the life of the lamps.

Circuits for Isolated Antenna Structures
To connect a 60 Hz supply to an insulated antenna structure, a device to isolate the RF from the 60 Hz supply is required. The two methods commonly used are chokes with a very high RF impedance or isolation transformers. The lighting load and RF voltage at the antenna structure base must be considered during the selection process.

Chokes are relatively low cost and are suitable for low power applications. For high power and most directional arrays, where a high degree of tuning stability is required, ring isolation transformers offer a low fixed capacitance and high flashover capability.

DESIGN STANDARDS

Industry

The vast majority of towers in the United States have been designed in accordance with the Electronic Industries Association EIA-222, Structural Standards for Steel Antenna Towers and Antenna Supporting Structures. This standard has been used since 1959 when it replaced the Radio-Electronic-Television Manufacturers Association (RETMA) Standard TR-116. The current revision "E" of EIA-222 was issued in 1991. It is an approved American National Standard and carries the designation ANSI/EIA/TIA-222-E-1991.

This standard is intended to provide *minimum* criteria for specifying and designing steel antenna towers and antenna supporting structures. Unlike general specifications and building codes, it is applicable only to antenna towers and supporting structures. As such it contains criteria specific to these structures that are not readily available elsewhere. Therefore, it is always advisable to specify that your tower must conform to this standard.

"Appendix A: Purchase Checklist" of this standard is provided to alert the purchaser to the most common areas where site-specific data may be required to supplement the minimum criteria of the Standard.

Statutory

Most municipal and state governments have statutory codes regulating the design of structures. Many of these are patterned after or include one of several model codes. The most common of these are:

- Building Officials and Code Administrators International (BOCA) *Basic Building Code*
- International Conference of Building Officials (ICBO) *Uniform Building Code*
- Southern Building Code Congress (SBC) *Standard Building Code*.

These codes cover all types of structures and are directed primarily toward conventional types of buildings. As such, they do not contain all the criteria necessary to design broadcast towers. For example, none of them includes a recommended safety factor for guy cables.

The industry standard ANSI/EIA/TIA-222-E-1991 is compatible with these codes. In fact, its use for calculating and applying wind loads is required by the BOCA *Basic Building Code* and, as an approved American National Standard, is permitted by the ICBO *Uniform Building Code*.

Since it is necessary to comply with the applicable statutory requirements, it is important to determine what these requirements are and include them in the purchase specification for the tower.

LOADS, ANALYSIS, AND SAFETY FACTORS

Loads

In addition to a tower's own dead weight and the dead weight of the appurtenances and equipment it supports, the tower must withstand the forces of nature: wind, ice, temperature changes, and earthquakes.

Wind Load

Wind produces a principal load on tower structures. For design purposes it is represented as a horizontal static force.

Wind load is specified in terms of a basic wind speed at 10 meters (33 ft.) above ground level. The ANSI/EIA/TIA 222-E-91 Standard provides a tabulation of recommended minimum values for this speed for each county in the United States. This standard also gives specific procedures and factors for calculating wind loads considers the following:

1. Wind pressure is proportional to the square of wind speed.
2. Wind speed and, consequently, wind pressure vary with respect to the height above ground.
3. The effects of gusts of brief duration which exceed the fastest mile basic wind speed.
4. The effects of the configuration, size, proportions, shape and orientation with respect to the wind direction of the structural components of the tower and its appurtenances.

An example of wind load calculations for a typical broadcast tower is given in Fig. 3.

Since the wind may act from any direction it is necessary to apply the calculated wind loads in any horizontal direction to determine the maximum stresses produced in the structure. For a triangular tower, three directions must be considered; while for a square tower, two are sufficient. These are shown in Fig. 4.

In addition to this direct load in the direction of the wind (drag), there may also be a component of load perpendicular to the wind direction (lift). These lift components are calculated in a manner similar to that for drag forces using different shape coefficients that vary with respect to the angle of attack between the member's geometric axis and the wind direction. They are most significant for wind acting on guy cables, microwave antennas, and rectangular waveguides.

Ice Load

Ice accumulations have two effects on a tower. The weight of the ice acts directly on the structure in the same manner as the dead weight. The ice accumulation also increases the area exposed to the wind and consequently the load produced by the wind. This increase is substantial on small components such as guy cables, tension rods, ladders, small diameter transmission lines, and reflector screens for antennas. It is also possible for the ice accumulation to alter the aerodynamic shape of members, thereby requiring the use of a different coefficient in calculating the wind load. An example is a set of closely spaced parallel coaxial lines. Without ice each would be considered a round cylindrical member. With accumulated ice, they would present a large flat area to the wind requiring a different coefficient.

Ice produces an entirely different stress distribution in a tower than wind, so it is not reasonable to merely increase the design wind load to provide for ice accumulations. It is also a misconception that ice will break up and blow off the tower, and therefore, ice and wind need not be considered simultaneously. The

PROCEDURE

1. Determine basic wind speed V (mph). Minimum recommended values in Sect. 16
2. Calculate exposure coefficient $K_Z = \left(\frac{Z}{33}\right)^{2/7}$ where Z is the height (ft) above ground level to mid point of section. $1.0 \leq K_Z \leq 2.58$.
3. Calculate velocity pressure. $q_Z = 0.00256\, K_Z V^2$ (lbs/sq. ft).
4. Calculate gust response factor. $G_\mu = 0.65 + 0.60/(h/33)^{1/7}$ $1.0 \leq G_\mu \leq 1.25$ where h is the total height (ft) of the tower structure.
5. Calculate the projected areas A_F and A_R (sq. ft) of the flat and round structural components in one face including any linear appurtenances attached to a face and considered as structural components. Include the thickness of any ice load.
6. Calculate the solidity ratio $e = \frac{A_F + A_R}{A_G}$ where A_G is the gross area (sq. ft) of one tower face as if the face were solid.
7. Calculate the structure force coefficient
   $C_F = 3.4e^2 - 4.7e + 3.4$ (Triangular cross section)
   $C_F = 4.0e^2 - 5.9e + 4.0$ (Square cross section)
8. Calculate reduction factor for round structural components $R_R = 0.51e^2 + 0.57 \leq 1.0$
9. Determine direction factors D_F and D_R from Table 2 for the wind direction considered.
10. Calculate the effective projected area A_E (sq. ft) of the structural components.
    $A_E = D_F \cdot A_F + D_R \cdot R_Z \cdot A_R$
11. Calculate the projected area A_A (sq. ft) of each individual appurtenance not considered as a structural component.
12. Determine the appropriate force coefficient C_A from Table 3 for each individual appurtenance and sum the products $C_A \cdot A_R$ (sq. ft).
13. Calculate total wind force.
    $F = q_Z\, C_{TH}\, [C_F A_E + \Sigma\, C_A A_A]$ (lies)

EXAMPLE

1. V = 80 mph.
2. $K_Z = \left(\frac{600}{32}\right)^{2/7} = 2.29$
3. $q_Z = 0.00256(2.29)(50)^2 = 37.56$ lbs/sq. ft
4. $G_\mu = 0.65 + 0.60/(1200/33)^{1/7} = 1.009$
5.

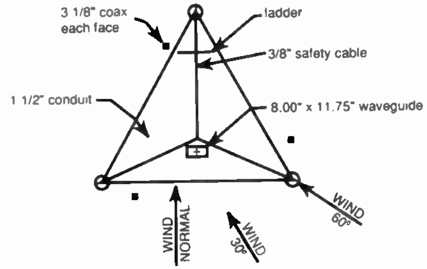
	Structural Component	A_F	A_R
Legs	$2 \times \frac{4}{12} \times 7.5$	—	5.00
Gusset P	$4 \times \frac{6 \times 8}{144}$	1.33	—
Horizontal	$\frac{2.5}{12} \times 8.67$	1.81	—
-Diagonals	$2 \times \frac{0.75}{12} \times 10.84$	—	1.36
3½" coaxes	$\frac{3.125}{12}\left(7.5 - \frac{2.5}{12} - \frac{2 \times 93}{12}\right)$		1.36
	Σ	3.14	8.22

6. $e = \frac{3.14 + 8.27}{10.33 - 7.5} = 0.147$
7. $C_F = 3.4(0.147)^2 - 4.7(0.147) + 3.4 = 2.78$
8. $R_R = 0.51(0.147)^2 + 0.57 = 0.58$
9. For wind normal $D_e = 1.0$, $D_R = 1.0$
10. $A_e = (1)(3.14) + (1)(0.58)(8.22) = 7.91$
11.

	Appurtenance	A_A	C_A	$C_A \cdot A_A$
Ladder rails	$\frac{2 \times 0.75}{12} \times 7.5$	0.74	1.2	1.13
Ladder rungs	$\frac{7 \times 0.75}{12} \times 1.33$	0.58	1.2	0.70
Safety cable	$\frac{0.375}{12} \times 7.5$	0.23	1.2	0.28
1½" Conouit	$\frac{1.9}{12} \times 7.5$	1.19	1.2	1.43
Waveguide	$\frac{11.75}{12} \times 7.5$	7.34	2.0	14.68

12. $\Sigma\, C_A \cdot A_A = 18.22$ Sq. ft
13. $F = (37.56)(1.009)[(2.73)(-.91) + 15.22] = 1524$ lbs.

$F = \frac{15.24}{7.5} = 203.1$ lbs/ft.



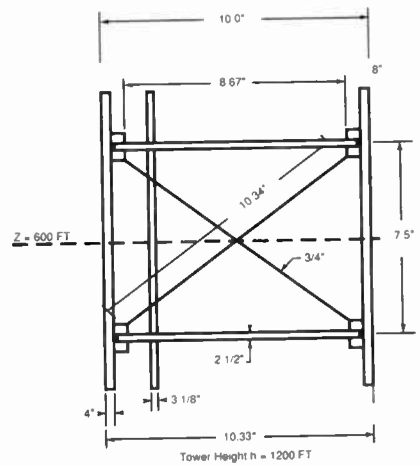


Figure 3. Wind force calculations for latticed towers using ANSI/EIA/TIA Standard 222-E-1991.

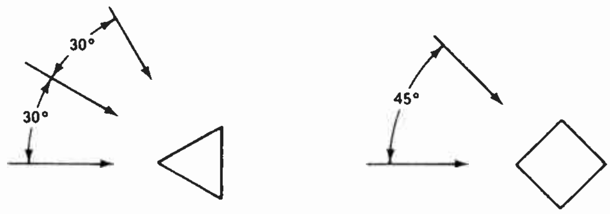

Figure 4. Wind directions to be considered.

ANSI/EIA/TIA-222-E-91 Standard states that unless otherwise specified by the purchaser, 75% of the windload shall be applied in combination with the ice load. This is equivalent to reducing the basic wind speed by a factor of 0.866. In areas where ice is likely to form, it is advisable to specify a basic wind speed to act concurrently with the ice load as well as the basic wind speed without ice, i.e., 70 mph with ice and 80 mph without ice.

While the 222-E Standard emphasizes the need to consider ice loads, it does not provide specific recommendations for the magnitude of the accumulation. This responsibility is left with the purchaser.

Temperature Changes

Changes in temperature have no significant load producing effects on self-supporting towers, but they can on guyed towers. Because of their differences in length, the guy cables expand and contract different amounts than the tower itself and thereby require elastic deformations from stress changes. The effects are greatest for those cables having the flattest angle with the ground. While the stresses produced are considerably less than those produced by wind and ice loads, they should be considered in the design of guyed towers.

Seismic Loads

Loads due to earthquakes are considered to act horizontally and are dependent on the mass and stiffness of the tower. They are usually less than those produced by wind but are distributed in a different manner. Procedures for calculating these loads are given in some of the design standards including ANSI A58.1, but not in ANSI/EIA/TIA-222-E-91. While a tower properly designed for wind loads is usually adequate for seismic forces, they cannot be neglected in areas with frequent and intense earthquake occurrences.

Structural Models and Analysis

A self-supporting tower may be described structurally as a cantilevered space frame or truss. Although it may have many different members, it is a relatively simple structure, and the determination of the forces in the individual members due to the applied static loads is easily done using fundamental principles of structural mechanics. The potential modes of failure are buckling of individual leg or bracing members under compressive loads, and shear or tension failures of the connections.

A guyed tower is a much more complex structure than a self-supporting tower. Whereas there is only one basic path through a self-supporting tower for the loads to be transferred to the ground, there are several for a guyed tower. The distribution of the loads among these paths is dependent upon the relative stiffnesses of guy systems and the tower shaft.

Each span of the tower has a stiffness with respect to relative deflections from axial and shear forces and bending and torsional moments. These stiffnesses are a function of several variables, including the geometric configuration, the mechanical properties, and the sizes of the individual members.

Each guy cable also has a stiffness with respect to movement of its attachment point to the tower that is a function of the amount of initial tension, the magnitude of ice load, and the magnitude and direction of wind load on the cables. By evaluating all of these, it is possible to simulate all the guys at a given level as a spring having a specific stiffness. Because of the nonlinearity of some of the relationships involved, the spring constant derived is only valid for a specific set of conditions and for a finite range of translation. Similarly, a torsional spring constant can be derived. It is interdependent with the translation stiffness and is also valid for only a finite range of translation.

Another difference between a guyed and self-supporting tower is the magnitude and significance of the axial load. For a self-supporting tower this is composed only of the gravity loads from the tower, its appurtenances, and any ice load. It is independent of wind load, and its effects on individual member loads are relatively small. The axial load for a guyed tower includes in addition to the gravity loads, the vertical components of the tensions in the various guys. Since these tensions are directly affected by the wind loads, the axial load is now dependent upon wind load, and its effects on the individual leg members are relatively large. Tension in the guy wires also produces an additional bending moment on the tower equal to the product of the axial load and the deflection of the tower.

Despite the complexity of the relationships involved, the availability and widespread use of computer systems permits accurate structural analysis of guyed towers. There are several different structural models that may be used.

One of the most commonly used idealizes the tower shaft as a continuous beam-column on nonlinear elastic supports (the guys) subjected to simultaneous transverse (wind and/or seismic) and axial (dead, ice, and vertical components of guy tensions) loads.

The modes of failure are buckling of individual leg or bracing members under compressive loads; rupture of bracing members, guys, or guy anchor arms under tensile loading; and shear or tension failures of the connections.

Dynamic Considerations

As previously mentioned, even though wind and earthquakes involve kinetic energy, their effects are simulated by equivalent static loads determined in accordance with the design standards. In recent years there have been more sophisticated efforts to investigate the actual response of tower structures to the dynamic aspects of wind gusts. A conclusion drawn from these studies is that the bending moments in the upper portions of tall guyed towers are considerably higher than those determined by the usual static analysis. Consequently, the loads imposed on the vertical legs and their splice connections would be amplified beyond safe limits indicating a potential failure condition. Considering the usual fundamental periods of tall guyed towers, it appears that towers taller than 1,200 feet to 1,300 feet should be investigated dynamically as well as statically.

There are two other phenomena related to the dynamics of wind that are important in guyed tower design. These are aeolian vibrations and "galloping," both of which involve periodic loading.

Aeolian vibrations are low amplitude, high frequency movements which occur in the tower guy cables due to a phenomenon known as vortex shedding. If they are not suppressed through the use of dampers, they can result in destruction of the filaments in the tower lights at the least, or fatigue failure of a guy cable and collapse of the tower at the worst. Dampers attached at one or both ends of the guy cables have proven effective in controlling these vibrations and should be considered for all tall guyed towers.

Galloping is a condition of instability involving large amplitude, low frequency movements. It is caused by the perpetual amplifications of periodic loads due to the motion of the body itself. The most dramatic and well-known example of galloping is the collapse of the Tacoma Narrows suspension bridge in 1940.

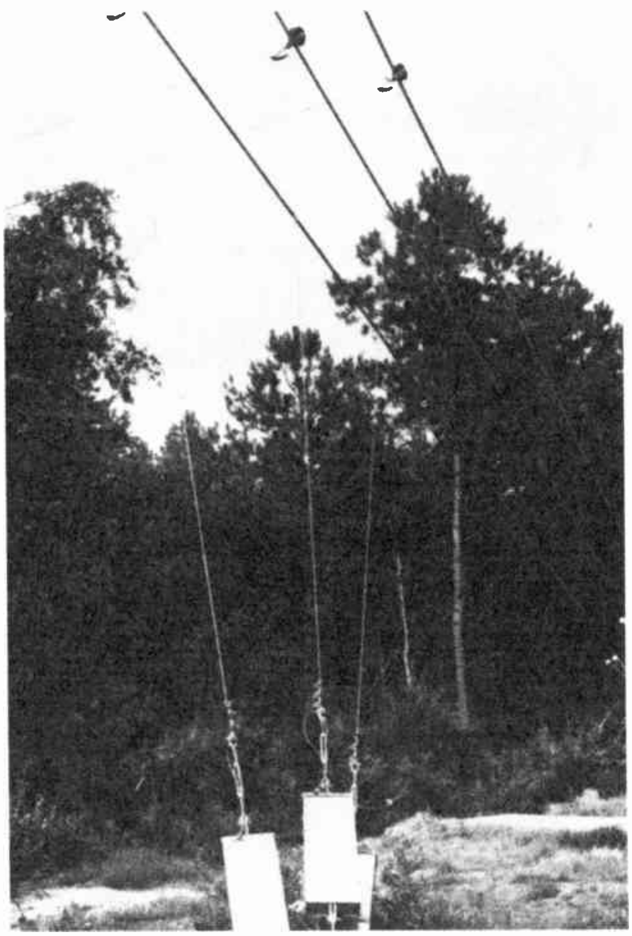

Figure 6. Anchor connection with snubber system to prevent galloping.

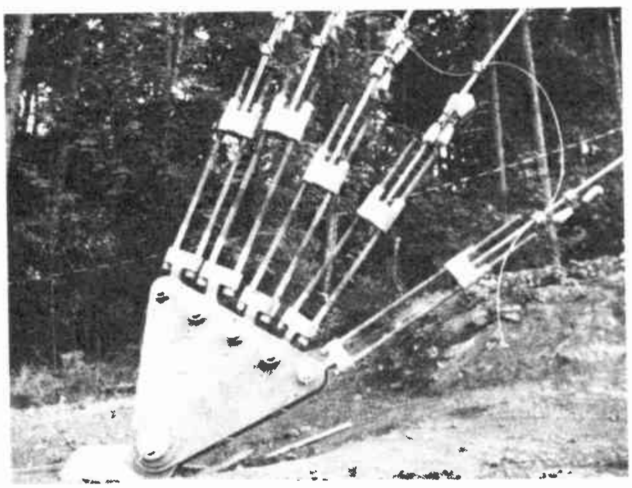

Figure 5. Typical anchor connection with dampers to prevent aeolian vibrations.

For tower structures, galloping is usually associated with the guy cables on tall towers, but in at least one instance it was related to a large rectangular waveguide. There have been several different methods involving detuning and energy dissipation used for preventing galloping in guy cables that appear to be successful. In the case of the rectangular waveguide, galloping was controlled by moving the waveguide inside the tower along the centroidal axis from its original position on the outside of one face. This reduced the torsional rotation of the structure which was the source of the perpetuating force. Based on this experience, it would appear prudent to always install this type of waveguide inside the tower unless adequate torsional rigidity is provided throughout the height of the tower.

Allowable Stresses and Safety Factors

Towers, like all other structures, are designed so that the maximum anticipated stresses are less than those which would cause failure. This ratio of failure stress to maximum allowable stress is known as the safety factor. It is intended to provide for several variations from the ideal conditions assumed for design including loads greater than anticipated, imperfections in materials, and tolerances in fabrication and construction.

The ANSI/EIA/TIA-222-E-91 Standard refers to the American Institute of Steel Construction (AISC) "Specification for the Design, Fabrication and Erection of Structural Steel for Buildings" for the design of the structure's members and to the American Concrete Institute (ACI) "Building Code Requirement for Reinforced Concrete Structures" for the design of the reinforced concrete foundations and guy anchors.

For towers under 700 feet in height the allowable stresses given in the AISC specification may be increased by one third. For towers 1,200 feet or taller, no increase is permitted. For towers between 700 feet and 1,200 feet, the amount of increase permitted is determined by linear interpolation.

In a similar manner, the required reinforced concrete strength for towers under 700 feet in height must equal 1.3 times the calculated reactions and for towers 1,200 feet and taller, 1.7 times the calculated reactions. Linear interpolation between these two values is used for towers between 700 feet and 1,200 feet to determine the required strength.

The minimum safety factor for guy cables is two for towers under 700 feet in height and 2.5 for towers 1,200 feet and taller with linear interpolation applied between these two heights.

EFFECTS OF ANTENNAS AND TRANSMISSION LINES

Except for AM radiators, the tower is the "necessary evil" to support the broadcast antennas and transmission lines at a suitable height above ground. Thus the effects of this equipment are of paramount importance.

Loads

Every antenna imposes a wind load and a dead load on the tower. If the antenna is mounted atop the tower, it also imposes an overturning moment. If it is mounted on a side of the tower, the antenna imposes a torsional moment. For TV and FM broadcast and microwave antennas, these loads are relatively large, and their location has a significant effect on the placement of guy cables.

Transmission lines feeding the various antennas also impose wind and dead loads on the tower. These loads are distributed uniformly between the antenna and their entry point near the base of the tower. The total load produced by a coaxial line or waveguide is frequently greater than that produced by the antenna itself. The shape of the transmission line influences the magnitude of the wind load, with circular or elliptical lines having loads that are 60% of those for rectangular lines with the same projected area.

It is important not to overlook the support system required for transmission lines. Some large waveguides have support systems that require nearly continuous vertical structural members that add substantial wind and dead loads. Small, flexible lines require supports at a maximum interval of three to four feet, which is often less than the vertical spacing of horizontal members in the tower. Thus, it may be necessary to provide an additional support structure for these lines, again adding to the total load.

An important consideration when locating transmission lines is that the 222-E Standard permits linear appurtenances that are attached to the tower face, and do not extend in width beyond the normal projected area of the face, to be treated as structural components rather than individual appurtenances for purposes of calculating wind load. The effect of this is to substantially reduce the magnitude of the calculated wind load on these appurtenances. An example is shown in Fig. 7. When this procedure is used, it is necessary that the transmission lines be installed around the tower faces as assumed for the design. Because this may not be easily controlled for lines possibly installed in the future, it may be prudent to prohibit the use of this procedure.

Width Restrictions

Some antennas impose restrictions on the width of the supporting tower. One common example is a side mounted FM antenna requiring a maximum width of 18 inches to 24 inches. For antennas with more than eight bays, this results in a very slender structure. When placed at the top of a tall guyed tower, the design of the guy system for this structure becomes

COMPARATIVE WIND LOADS ON

RS–222–D	1.53	4.59	1.78	
RS–222–E	1.53	4.59	1.78	
RS–222–C	1.00 (Ref.)	3.00	3.00	FLAT $W_A > W_L$
RS–222–D	1.70	5.10	5.10	
RS–222–E	1.70	5.10	2.07	

Figure 7. Effects of linear appurtenance locations on calculated wind loads.

extremely critical. Use of a cantilevered pole structure above the top of the main tower should be considered for these cases.

Another example of width restriction is a panel-type TV or FM antenna mounted on the faces of the tower. Here, too, it is often better to support these antennas on a cantilevered structure above the main tower rather than placing guys within the aperture of the antenna.

As previously mentioned, it is desirable to place large waveguides inside the tower near the vertical centroidal axis to prevent large torsional loads. This requires a tower having a minimum face width in the range of seven feet to eight feet to accommodate the waveguide and its supports.

Initial and Future Considerations

Because the antennas and transmission lines have such a significant effect on the tower design, it is important to consider all possible uses for a tower before it is designed. It is better to have unused capacity than to undergo expensive modifications or replacement in several years to obtain additional height or accommodate another antenna. This has become apparent in recent years with the proliferation of microwave, two-way communications, and cellular radio systems.

When providing for multiple antennas, it is important to determine not only the number and type of antennas and lines, but also their location on the tower. The distribution of load is equally important as magnitude.

Triangular top platforms ("candelabras") to support broadcast antennas on each corner have been successfully used for many years. They have the advantage of placing all antennas at the same height. A variation of this platform to support only two antennas ("tee-bars") has also been used. Both of these systems require multiple guy cables at the top platform to provide adequate torsional stability. It is possible to design the tower for a multiple antenna support platform without installing all antennas at the same time.

Another arrangement of multiple antennas is stacking, i.e., installing one antenna atop the tower and arranging others along the tower, one below the other. This arrangement can also be combined with a multiple antenna support platform.

If capacity for microwave antennas is required, it should be provided near guy levels and preferably above to minimize interference with the guy cables. The guy system and web bracing at these levels must be designed to provide adequate torsional rigidity.

Capacity for small antennas may be provided at various locations throughout the height of the tower. One arrangement for a large number of antennas is to provide a platform around the outside of the tower that is large enough to support the radio equipment for these antennas. The antennas can be mounted on the outside railing of the platform, thereby requiring only a short run of coax. Electrical power must be provided to the platform. This arrangement imposes a large concentrated load at the platform location with a relatively small uniform load between the tower base and the platform. If the same number of antennas were mounted along the tower and each fed by an individual coax line from the base, there would be only small concentrated loads at the antenna locations, but a relatively large uniform load due to the lines. This is an entirely different distribution of load, and would have a pronounced effect on the design.

Another important consideration for future antennas or height extensions is the electrical system. If an extension in height is planned, the wiring for the aircraft warning light system should be designed so that any additional lights can be connected to the system without adding or replacing wires in the existing conduit. The same holds true for any circuits required for future antennas. If the necessary wiring cannot be provided during the initial installations, capacity should be provided for additional conduits to hold the future circuits.

Replacement, Relocation, or Additions to Existing Towers

Since every tower has been designed for a specified arrangement of equipment, changes should not be made without considering their effects on the structural adequacy of the tower.

Two common misconceptions related to changes in equipment are "lower is better," and "smaller is better." Neither is necessarily correct, especially for guyed towers. Decisions based on these premises can have serious consequences.

It is much better to have a structural analysis of the tower made by a structural engineer experienced in tower design. Because of the significant changes that have been made in the methods of specifying loads in the various revisions of the design standard, the analysis should be made using the same criteria for wind and ice loads used for the original design and also for the current revision of the standard. An example of the differences in calculated loads is given in Fig. 8. This analysis will determine if any overstresses would occur in the tower or its foundations, and what modifications and reinforcing would be required to retain the structural integrity. To make this analysis, it is necessary for the engineer to have complete data on the tower and its foundations including configuration, member sizes, and material strengths. The use of presumptive values can result in an analysis with little value.

FOUNDATIONS AND ANCHORS

It is most difficult to predict the cost of the foundation system of a tower installation. This is due to the nonhomogeneous nature of soils, and the uncertainty of the conditions that may exist below grade. Therefore, it is necessary to have an investigation made of the subsurface soil conditions.

It is important to note that the soil design parameters given in the ANSI/EIA/TIA-222-E Standard are in-

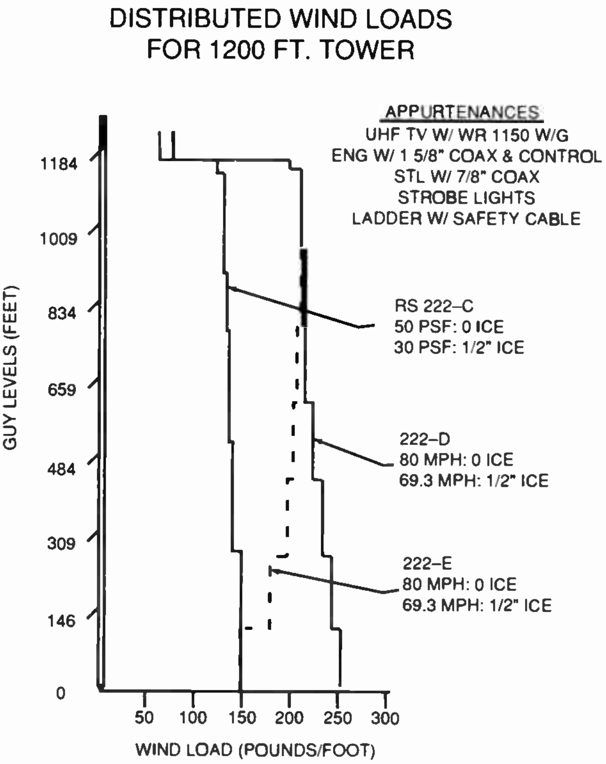

Figure 8. Comparison of calculated wind loads for different revisions of the design standard.

tended to serve only as a basis for preliminary design and estimating of foundation costs prior to obtaining specific soil data. They should not be used for the final design without verification by geotechnical investigation.

Soil Investigation

The soil investigation should be made by an engineering firm which specializes in soil investigations and evaluations, and is familiar with the general area of the tower site. It should consist of making a test boring at each foundation and guy anchor location, analysis of soil samples taken from the borings, determination of the structural properties of the soils, determination of ground water levels, recommendations of parameters for designing the foundations, identification of any special construction procedures required, and recommended backfill specifications. If piles or rock anchors are necessary, recommendations related to these should be provided. It should also address requirements for frost protection and buoyancy effects.

Because the loads imposed on foundations for towers are unique from those for conventional buildings (tower foundations have large uplift and horizontal components), it is important to provide the soil engineer with the loading conditions before they make their investigation. This will enable the engineer to plan their work in a manner suitable for obtaining and reporting the characteristics relevant to designing for the projected foundation loads.

Self-Supporting Tower Foundations

Except for relatively small towers with narrow base spreads, isolated foundations at each leg are usually more economical than a single mat for all legs. These foundations may be spread footings, drilled caissons or driven piles. If sound rock is present at shallow depths it is often economical to anchor the footing to the rock. These anchors should be proof-loaded to ensure their holding capacity in uplift.

Since these foundations are subjected to large uplift forces, it is important to consider buoyancy effects if ground water is present. Also, if driven or cast-in-place piles are used, they must be adequately anchored to the reinforced concrete cap.

Guyed Tower Base Foundations

These foundations may be spread footings, drilled caissons, or driven piles. Since they are subject only to downloads with relatively small horizontal forces, they require no special anchorage details for uplift, unless they are placed above expansive soils. Buoyancy is usually not a problem.

Guy Anchors

Deadmen (buried reinforced concrete blocks), drilled caissons, or driven piles may be used for these foundations. If sound rock is present at shallow depths it is often economical to anchor the foundation to the rock.

These foundations are subject to large horizontal forces as well as vertical uplift. Therefore, deadmen must have a large enough frontal area bearing against the soil to resist sliding; drilled caissons must have sufficient diameter and depth to prevent excessive lateral deflection as well as pull out from uplift; and driven piles must be sloped to prevent large lateral loads being imposed on them. Rock anchors may be installed along the slope of the resultant of the horizontal and vertical loads, or they may be installed vertically and post-tensioned to clamp the concrete cap to the rock to prevent sliding. Because of the uplift forces, it is important to consider buoyancy due to ground water and to provide adequate anchorage for driven or cast-in-place piles.

Construction

Since nearly the entire foundation system will be below finished grade and not subject to later inspection, it is important to carefully monitor its construction. The following items should be verified:

- Location and alignment of anchors in plan and elevation
- Condition of excavation surfaces on which concrete will be placed
- Position, size and grade of reinforcement steel
- Placement of concrete to prevent voids and air pockets

- Strength of concrete using test cylinders for 7- and 28-day break tests
- Protection of concrete against freezing during the curing period
- Placement and compaction of backfill
- Driving records and/or load tests of piles
- Proof loading and post-tensioning of rock anchors

For towers with extensive foundation systems, it is advisable to retain an independent inspections service for this work. Often the firm making the subsurface soil investigation can also provide this service.

ERECTION

The erection of towers is a highly specialized field and should be done only by firms having the proper equipment and experienced rigging personnel. It is also important that the firm have adequate insurance coverage including worker's compensation, general and automobile liability, and builder's all-risk for direct damage to the tower and antennas being erected.

Owner's Preparation

Prior to the arrival on site of the erection crew, the site should be made ready for work to begin. These preparations include:

Access
Suitable access from public roads for delivery of the tower materials and erection equipment is required. While a paved roadway is not necessary, the access must be able to handle heavy trucks and construction equipment.

Permits
All necessary building and construction permits should be obtained and posted as required. Any inspections required during construction should be noted.

Clearing
A work area must be cleared to permit unloading, sorting, and assembling the tower. Paths from the tower base to the guy anchors must be cleared for a width adequate to permit hauling the guy cables to the anchors and pulling them to the tower. Paths must also be cleared for the hoist line from the tower base to the hoist location, and for the tag line used to stabilize the loads as they are uplifted. The sizes and locations of these cleared areas should be agreed upon beforehand with the erector. A typical layout is shown in Fig. 9.

Electrical Power
Power for operating the temporary aircraft warning lights must be available before erection begins.

Assembly

The usual procedure for erecting a guyed tower is to assemble the individual sections on the ground and then lift them one at a time as an assembled unit. For a self-supporting tower, the wider sections near the bottom of the tower are often assembled in the air as the tower is constructed.

Assembly of the tower sections should be done on a level bed to ensure that they will be straight and not racked or twisted. Bolts must be properly tightened and have a locking device. For high strength galvanized bolts, tightening by the "turn-of-the-nut" method is preferable to using a calibrated torque wrench.

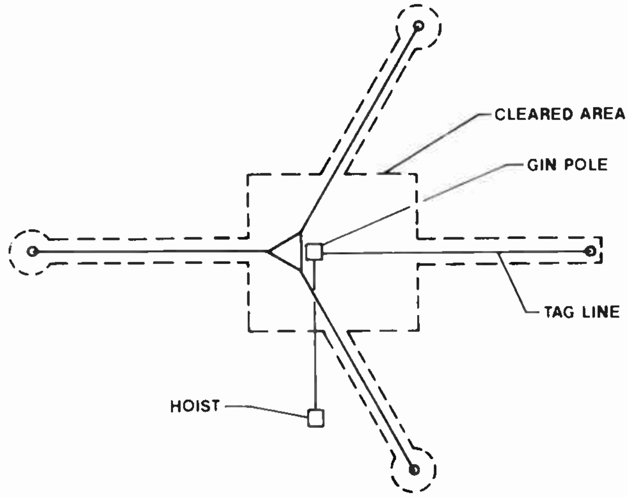

Figure 9. Typical layout for guyed tower.

Stacking

For a guyed tower, the first group of three to six sections are often joined together on the ground and then lifted into place using a crane. This portion of the tower is then guyed with temporary cables, and the remaining sections are erected one at a time using a vertical boom or "gin pole." This boom is moved or "jumped," up the tower as each section is installed. This arrangement is shown in Fig. 10. Temporary guys to stabilize the tower should be used when instructed by the designer.

For a self-supporting tower, a crane is often used to lift as many of the tower sections as possible, after

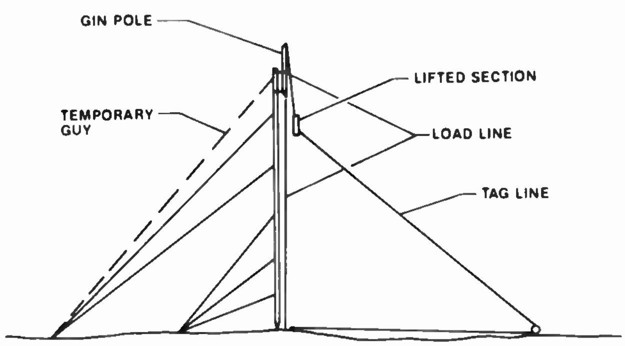

Figure 10. Typical erection setup for guyed tower.

which a gin pole is installed and used for the upper sections beyond the crane's reach.

Temporary aircraft warning lights must be installed at the top of the construction at the end of each day.

The tower should be grounded as soon as the first section is in place.

Guy Installation

When the tower reaches a guy attachment level, the cables at that level are installed. The guys in all three directions should be pulled out simultaneously to prevent any large unbalanced loads on the tower.

The tower should be checked for plumbness as each set of guys is installed and tensioned. Maintaining a plumb tower during erection eliminates the need for time-consuming adjustments later. Final tensioning of the guy cables and a plumbness check are done after the entire tower is erected.

REINFORCEMENT AND MODIFICATION OF EXISTING TOWERS

When equipment is replaced, relocated, or added to a tower it is often necessary to reinforce or replace existing structural components. The details and specifications for this work must be developed by the structural engineer who analyzes the tower.

Leg members may be strengthened by installing additional bracing or by field-welding additional material to them. Specific procedures in accordance with The American Welding Society *Structural Welding Code* must be provided and followed if field welding is required.

Bracing members and guy cables may be replaced with stronger components. Careful attention must be given to the connections for the new components to ensure their compatibility with the existing tower, as well as providing the required strength for the new components. When replacing components it is essential that temporary bracing or guy cables be installed before removing any existing component, and that it remain in place until the new component has been installed.

It is necessary that damage to the protective finish on existing members due to field welding or reaming be repaired. If required, the affected areas must be painted for aviation obstruction marking.

Foundation and guy anchors are the most difficult components to strengthen, and they may prove to be the limiting factor in determining a tower's capacity. The nature and feasibility of strengthening these components depend on the specific soil conditions.

INSPECTION AND MAINTENANCE PROCEDURES

To ensure trouble-free performance of a tower and its appurtenances, it is desirable to have a regular inspection and maintenance program. Portions of the program can be done by station personnel while others require experienced tower personnel.

Safety precautions should be observed at all times when working on or around the tower. If the tower itself is energized or if a high intensity RF field exists from antennas mounted on it, no work should be done on the tower without clearing it with the station engineer. When climbing the tower, safety belts and climbing devices should always be used. Automatic safety features on elevators should never be by-passed to save time. It is a good idea to never work alone. Failure to observe proper safety measures can result in serious injury or death.

Tower Structure

Damaged or Deformed Member

A visual inspection should be made of the entire tower structure to determine if any of the members have been deformed or damaged. Any bowed or kinked member should be noted as to type, location in tower, and nature and magnitude of deformation or damage. This information should be reported to the tower designer for evaluation and recommended action.

Condition of Paint

A visual inspection should be made of the entire tower structure to determine the condition of the paint. If the painting of the tower is for aircraft observation marking only, and not for corrosion protection, it is necessary only to note any general deterioration rather than small blemishes and scratches. If repainting is necessary, it is important to properly prepare all surfaces and select paints that are compatible with the existing finish.

Corrosion

Small scratches in the galvanized surface are not detrimental as the exposed surfaces will be protected by cathodic action of the adjacent zinc. If corrosion is observed, the source should be determined and noted. The affected areas should be wire-brushed clean to bare metal then painted with a zinc rich prime coat and, if necessary, a finish enamel coat of the appropriate color.

Connections

All bolts should be checked for tightness. Any loose bolts should be tightened in accordance with the original installation instructions.

Alignment

The tower structure should be checked for alignment using an engineer's transit. This check should be done only on a calm day, i.e., with wind velocity less than 10 mph, and in conjunction with measuring the guy tensions (described later).

Both plumbness and twist of a tower can be calculated from the measured horizontal deviations of each tower leg member from true vertical. Thus three transit set-ups (one on each leg azimuth) are required for a triangular tower, and four for a square tower. When the transit has been properly leveled, set the vertical cross-hair on the edge of the vertical leg at the tower base and lock the instrument in this position. By moving the telescope upward, it is then possible to observe the straightness of the leg over its entire height. The magnitude of misalignment can be accurately estimated by comparison with the tower leg diameter. A record should be made of the observations of each leg at each guy level.

Tolerances for plumbness and straightness should be as provided by the designer. EIA-222-E gives a plumbness tolerance that limits the horizontal distance between the vertical centerlines at any two elevations to 0.25% of the vertical distance between the two elevations. This should never be exceeded. A good rule of thumb in the absence of other data is to keep the tower plumb and straight within the diameter of the leg members. EIA-222-E gives a twist tolerance of 0.5° in any ten feet and a total twist limit of 5°.

If straightening of the tower is required, it should be done by adjusting the guy wires as described later.

When checking the plumbness of top mounted poles and pylon antennas, the effects of direct sunlight on them must be considered. It is best to make these checks early in the morning or on a cloudy day.

Guys and Guy Insulators

Inspection of the guys can be done visually only for those portions adjacent to the anchors and tower. The range of this visual inspection can be extended by using binoculars, but its reliability is limited. If experienced riggers are available, it is possible to ride down the guy on a bosun's chair, but this method should be used only under the supervision of qualified personnel.

Damaged components. A visual inspection should be made of the guy cables, insulators, and hardware. Cables and dead end grips should be checked for nicks or cuts in the individual strands. All porcelain insulators should be checked for chips, cracks, and oil leaks where appropriate. Fiberglass rods should be checked for surface tracking (black carbon track marks on surface of the rod), breakdown of the epoxy surface, and exposure of the individual glass strands. The manufacturers should be consulted with regard to corrective action.

Corrosion. If the guy cables show signs of corrosion, consideration should be given to coating or replacing them. The cost of cleaning and coating the cables should be considered along with the life expectancy of the coating when comparing it to the cost of replacement. All guy hardware should be checked using the same procedures for inspection and corrective actions as previously described for the tower structure.

Connections. All pins should be checked for tightness and the condition of the cotter keys. Dead end grips should be checked to ensure that their ends are completely snapped close, preventing any ice from forming inside. The surface appearance of the guy strand immediately next to the connections should be noted for evidence of slippage. Threads should be given a light petroleum coating.

Tensions. Guy tensions should be checked in conjunction with the tower alignment. These tensions should be measured at the anchor end and compared to the specified values. It is important to remember that they are dependent upon the ambient temperature.

For the usual guy arrangement with cables in three directions, it is necessary to measure the tensions in only one direction while keeping the tower plumb in all directions. For guy arrangements with cables in four or more directions, it is necessary to measure the tensions in only one of the two guys in the same vertical plane while keeping the tower plumb in that plane.

There are several methods of measuring guy tension with varying degrees of accuracy. For small guys up to ¾ inch, a shunt dynamometer calibrated for the size and type of strand is often used.

For larger guys, a series dynamometer may be placed in a temporary line between the anchor and a clamp on the cable. This line is then tightened until the permanent connection is relieved, and the tension is indicated on the dynamometer. Hydraulic jacks with a calibrated pressure gauge or load cells can be used in place of the temporary line and dynamometer. These are particularly effective for large guys attached with bridge sockets.

There are two indirect methods of measuring tensions in guys that do not have any large insulators or other loads in them. The intercept method consists of sighting along a straight bar attached at the bottom of the guy and measuring the vertical distance between the point where the line-of-sight intercepts the tower and the point where the guy is attached. This distance can be accurately estimated by counting the number of bracing panels. The tension in the guy is directly related to this intercept distance, the weight of the guy, and its length and slope.

The tension in a guy cable is also directly related to its length, weight, and natural frequency of free vibration. The natural frequency can be determined by putting the guy in motion with your hand and measuring the fundamental period with a stop watch. It should be noted that because a guy slopes, the tension on it varies along its length, and this method will only provide the average tension and not the tension at the anchor point. For long cables, this difference can be significant.

All tension measurements should be recorded along with temperature and wind speed and direction. If any substantial changes are noted from the values previously measured, careful checks for slippage of all connections should be made.

Tolerances for guy tensions should be as provided by the designer. In the absence of any other tolerance, tensions should be within plus or minus five percent of the specified values.

Any necessary adjustments in tensions can be made by adjusting the turnbuckle or bridge socket at the anchor. Make such adjustments slowly and carefully.

Never leave less than three threads sticking through the turnbuckle body or nut on the socket U-bolt. Remember that the tower must be kept plumb.

Base Insulator

The porcelain surface should be wiped clean with a soft cloth to remove accumulated dirt. A check should be made for cracks or chips on the porcelain surface. Scratches are often mistaken for cracks. Oil-filled insulators will display a wet surface or leak if cracked. If an oil stain or leak appears at the bottom of the porcelain on an oil-filled insulator and a crack cannot be found, incorrect loading possibly due to settlement of the pier should be suspected. A cracked base insulator should be replaced as soon as practical. Any sign of corrosion in the upper and lower bearing plates, rain shield, or lightning gap should be noted and corrected in a manner similar to that described for the tower structure. The lightning gap should be adjusted in accordance with instructions from the station engineer.

Tower Base and Guy Anchors

The tower base and guy anchors above grade should be visually inspected for spalling and cracking of the concrete. The soil surrounding the tower base foundation should be inspected for evidence of settlement. The anchor arms and surrounding soil should be examined for evidence of movement of the anchor. Any such settlement or movement should be noted.

Steel anchor shafts exposed directly to the soil should be inspected below grade for evidence of galvanic or electrolytic corrosion, especially in areas of high ground conductivity. Extreme caution should be exercised when excavating and backfilling during this inspection to ensure that the anchor's effectiveness is maintained.

Appurtenances

Ladder and safety device. The ladder and its connections should be checked for corrosion and tightness along with the tower. The sleeve and belt of the safety device should be visually examined and tested near the ground level before each use.

Elevator System. Inspection and maintenance of the elevator system should be in accordance with the manufacturer's instructions. It is a good practice to operate the elevator at least once a month.

Lighting System. Inspection and maintenance of the lighting system should be in accordance with the manufacturer's instructions. Checks for corrosion in the conduit, junction boxes, and light fixtures should be made along with the tower inspection. Any obstructions in the breather or drain in the conduit should be removed. Broken or cracked glass and any leaking gaskets should be replaced.

If the tower is equipped with an isolation transformer, its surface should be inspected for cracking and splitting. The surface should be painted with glyptal or a good quality enamel paint. Badly cracked surfaces should be recovered with cotton tape prior to painting.

Frequency of Inspection and Maintenance

A suggested schedule for inspections and maintenance performance is shown in Fig. 11.

Reports

A written report of each maintenance and inspection procedure performed should be made and filed with the station engineer.

SUGGESTED INSPECTION AND MAINTENANCE SCHEDULE

ITEM	Daily	Monthly	Before Each Use	Annually	After a major wind or ice storm	Manufacturer's Recommendation

2.2 Lightning Protection for Broadcast Facilities

Frank C. Breeze,
Tilden, Lobnitz & Cooper, Inc., Orlando, Florida

INTRODUCTION

While there is still debate among atmospheric physicists regarding the exact mechanism of charge separation in thunderstorms, much is known about lightning itself. Lightning currents and radiated fields have been carefully studied for many years, leading to a better understanding of how to successfully protect against damage and injury. Manufacturers have used this understanding to develop a wide variety of lightning protection and surge suppression products. Codes and practices are also continually being revised to reflect increasing levels of understanding.

This chapter takes a very practical look at measures which will help the broadcaster prevent damage to equipment and disruption of service in the presence of lightning. The focus of this chapter has changed significantly from the last edition. Discussion on lightning physics, structural protection and designing surge suppression devices from a component level has been minimized, shifting the focus to practical measures which will help equipment and systems remain alive and well in a moderate to high lightning environment.

THE NATURE OF LIGHTNING

Thunderstorm cells are formed when warm moist air rises into cooler regions of the atmosphere, driven either by convective or frontal activity. Vertically circulating air currents are established which, through freezing and thawing of moisture particles, are believed to cause a separation of charge between upper and lower regions of the cell. (See Fig. 1.) A typical thunderstorm is comprised of many such cells which form and die away, each with an average life span of about twenty minutes.

The abundance of electrons accumulating in the lower regions of a cell creates a difference in potential with the less negative regions in the upper cell area. These electrons also repel free electrons in the surface of the earth, again resulting in a potential difference between cloud and earth. This charging process continues until the dielectric property of the air between charged bodies is exceeded.

A lightning discharge may occur within a thunderstorm cell, between cells, or from a cell to the earth below. Intense ionization of the air occurs between the charged bodies, followed by a faintly visible stepped leader which forks and branches from the negative body toward the positive. In the case of a cloud-to-ground discharge, the approach of this leader triggers an upward streamer, usually emanating from a tall grounded object. A complete circuit is formed when the streamer connects with the stepped leader, resulting in an avalanche of current known as the first return

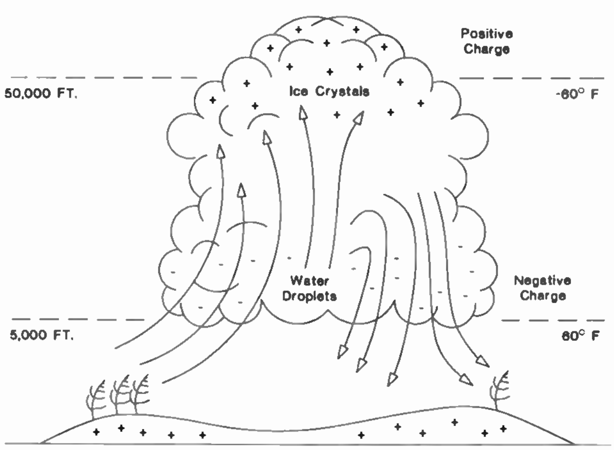

Figure 1. This thundercloud has reached its mature stage and a downdraft has developed on the cloud's lee side, producing a sudden drop in temperature, wind gusts, rain and perhaps hail, and lightning flashes.

stroke. Additional or subsequent return strokes may occur in rapid succession as depleted charge is replenished from surrounding areas of the cloud and earth.

Fig. 2 describes the annual frequency of thunderstorm days in various regions of the United States. A thunderstorm day is simply a day on which thunder is heard. Within the broad contours shown on the map there are often microclimates created by local terrain which may exceed or fall short of the average for the region.

Coarse methods of risk calculation[2] utilize isoceraunic data with the latitude and attractive area of a structure to establish the approximate frequency of strikes. Numerous lightning position and tracking systems are also in operation throughout the U.S. which record both the time and position of flashes to ground.

The strength of a lightning discharge is a function of the amount of stored charge, the quality of the channel through which the discharge occurs and the ability of the charged media to efficiently deliver stored charge to the discharge channel. Fig. 3 indicates the relative intensity of lightning discharges as a function of their frequency of occurrence. Approximately 50% of all lightning strikes deliver first return stroke current of 20,000 amperes or below. Only 2% reach levels of 140,000 amperes and larger strokes are even more rare.

Subsequent return stroke currents are always lower than the initial stroke as there is less charge remaining between the two bodies after the initial discharge. The importance of understanding the intensity of lightning current quickly becomes apparent when you consider that, by Ohms law, even an average 20,000 ampere lightning current flowing into a ten-ohm grounding system will cause the system to rise to a potential of about 200,000 volts above normal.

The radiated field from a lightning channel can pose a significant hazard to equipment and systems, particularly those which are interconnected by long lengths of cable. Fig. 4 is a composite of lightning electromagnetic field measurements made by a number

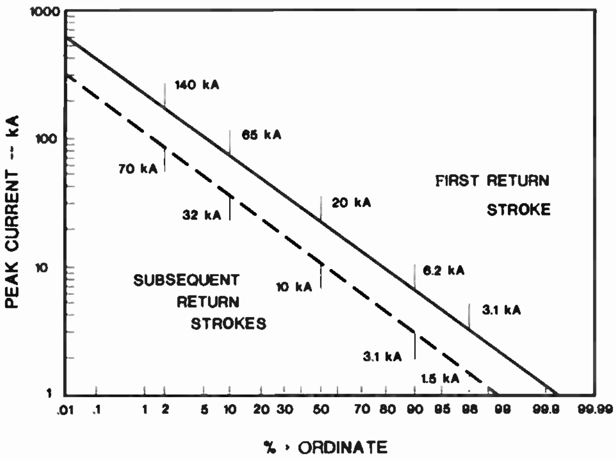

Figure 3. Lightning stroke intensity. Courtesy SRI International (Stanford Research Institute), Menlo Park, California 94025.

of researchers which have been normalized to a distance of ten kilometers. The figure shows a frequency domain distribution which peaks at about ten kilohertz at an intensity of slightly more than one volt per meter. It is important to realize that nearer strikes can create field strengths many orders of magnitude higher than those shown. The predominant low frequency component is also very effective in coupling energy into systems of wiring, even when buried in the ground.

The time domain current waveform associated with a typical lightning strike is characterized by a very fast leading edge or risetime, followed by a more gradual decay. Technically, risetime is the period of time required for the wave to increase from 10 to 90% of its crest value. Decay time is normally expressed as the time measured between the wave crest and 50% of the crest value. A description of a waveform such as 1.5 × 50 microseconds would indicate a single

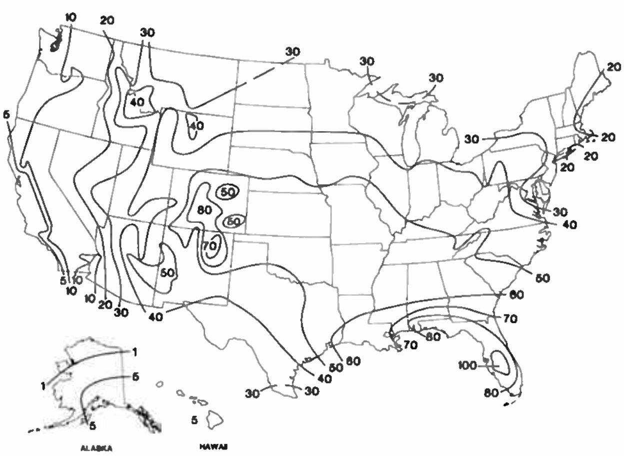

Figure 2. Average annual frequency of thunderstorm days in the United States.

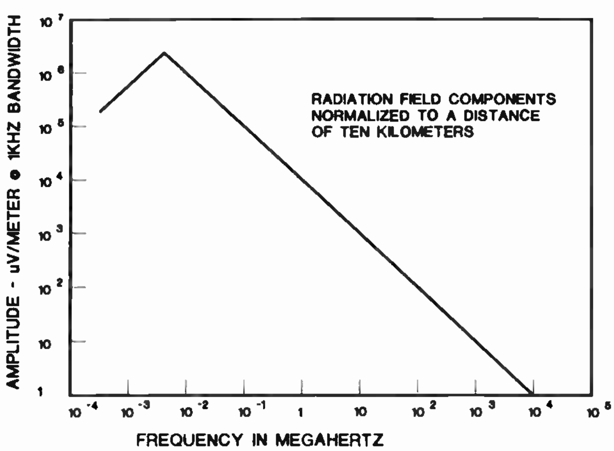

Figure 4. Lightning signal amplitude vs frequency.

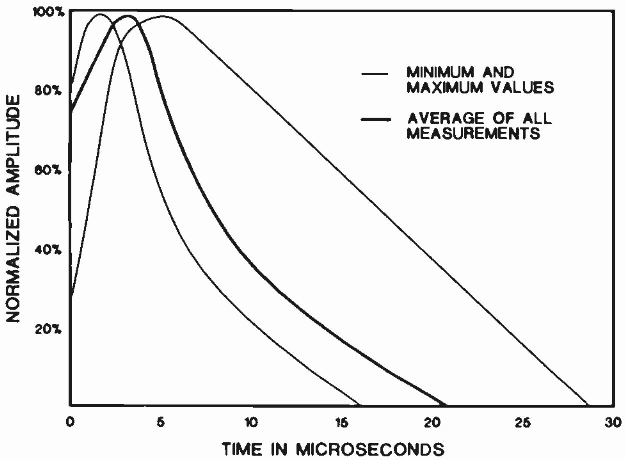

Figure 5. Lightning waveforms.

impulse waveform with a risetime of 1.5 microseconds and a decay time of 50 microseconds.

There are many variations on actual lightning waveforms seen in real world circuits. Waveforms such as those shown in Fig. 5 may be found with risetimes measured in a fraction of a microsecond near the point of lightning entry to a circuit. As a wave propagates through a wiring system, the risetime and the decay time will lengthen. The polarity of the impulse may be either positive or negative. Inductive and capacitive properties of the wiring system may cause the circuit to act as a resonant tuned circuit, producing a ringing wave which alternates in polarity. References which categorize the waveforms and current levels for several types of circuits are listed at the end of this chapter.[5,6]

PROTECTION OBJECTIVES

Lightning protection objectives may be grouped into three basic categories:

Structural Protection

Providing a means to intercept a lightning discharge, conduct the lightning current safely through or around the structure and dissipate the current into the earth. Lightning current passing uncontrolled through a structure may result in ignition of combustible materials, generation of explosive forces in masonry and other moisture bearing materials and burning or tearing of roofing systems. Secondary flashing between the primary current path and nearby grounded objects may also pose a threat to persons or elements of the structure.

Personnel Protection

Protecting personnel from the threat of a direct lightning strike and secondary flashing (sideflash), and controlling differences in potential between different parts of their bodies during a lightning event. Step potentials are voltage gradients seen along the surface of the earth as a lightning current radiates hemispherically from its point of entry into the soil. Touch potentials are voltage differences developed in a structure, natural object, or system during the passage of lightning current. Both step and touch potentials can be hazardous.

Equipment Protection

Controlling voltage potential differences between the various metallic circuitry leaving an item or system and between these circuits and the system's ground reference maybe "is key to protecting equipment." Controlling the potential differences to a value below the equipment damage threshold will insure the equipment survives. Providing tighter control to a value below the equipment upset threshold will help to insure the system rides through the lightning event without any noticeable effect.

STRUCTURAL PROTECTION STRATEGY

A traditional structural lightning protection system utilizes a system of air terminals to control the point of contact between a lightning discharge and the structure. Cables, or in the case of a tower or other steel framed structure, the structure itself is utilized to safely conduct the lightning current to a system of grounding electrodes. These electrodes, which may range from driven rods to radial wires, are utilized to pass the lightning current safely into the earth.

The basic premise behind traditional lightning protection design is based on the zone of protection created by any tall grounded metallic body. On conventional structures, a system of air terminals is used to create a network of overlapping protective zones. These zones insure that a lightning discharge contacts an air terminal rather than the structure. Towers, masts, and other conductive objects of sufficient mass and conductivity may be used as air terminals if properly bonded to the lightning protection system.

Fig. 6 shows traditional lightning protection for a studio facility with an adjacent microwave relay tower. Protective zones are based on an imaginary "rolling ball" 150 feet in radius being passed over the structure. The ball is also rolled around the structure tangent to earth. Air terminals are placed in such a way that the ball never contacts the structure or other objects requiring protection. Properly protected masts, light poles, and adjacent buildings may be taken into account when establishing zones of protection.

The protective zones created by the 150 foot radius ball have proven statistically adequate for most facilities and are the basis behind most codes and standards.[7,8,9] An interesting way to think about structural lightning protection design is to imagine rolling an inked ball of 150 foot radius around and over a structure. The ball should roll only on the earth, air terminals and other suitable metallic components which have been connected to the lightning protection system. Any other area which receives ink should be considered unprotected.

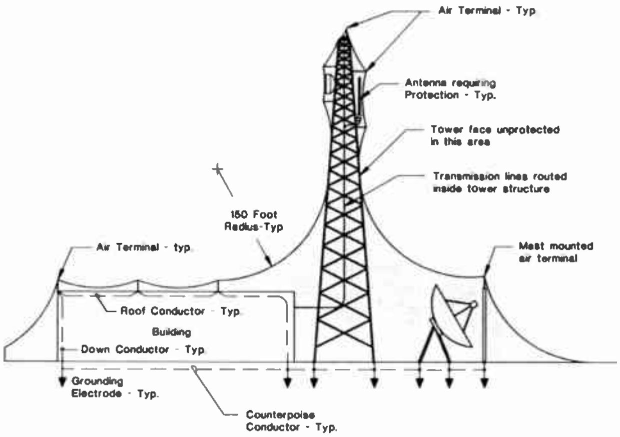

Figure 6. Traditional lightning protection for a studio facility with an adjacent microwave relay tower.

Most broadcast towers, and much of the equipment they support, have sufficient mass and conductivity to resist damage from direct lightning contact. Localized burning and pitting may occur in the immediate area of contact with the lightning channel, however, the brief duration of a lightning stroke causes little heating in areas away from the point of lightning contact. Fig. 6 shows how air terminals, properly bonded to the tower, may be used to protect more sensitive objects.

Whenever practical, transmission lines should be extended up the inside face of the tower to minimize the possibility of direct lightning contact. It is common practice to bond transmission lines to the tower at their highest and lowest points, forcing them to track the voltage gradient created in the tower by lightning. With the cable and tower at the same relative potential, there can be no secondary flashing between the tower and cable.

As a last note on the performance of towers, a passive grounded tower with continuous metallic guys will always stand out as the best performer when struck by lightning. The guys serve as additional lightning protection down conductors, significantly reducing the voltage gradient seen from top to bottom on the tower. Voltage gradients in the earth near the base of the tower (and around the station building) are also reduced as a large percentage of the lightning current is delivered to ground at the remote guy anchor points.

Self-supporting towers and AM broadcast towers with nonconductive guy segments will deliver the full lightning current to ground at their base, resulting in a larger voltage gradient in the earth near the base. AM towers normally use a discharge gap across a static discharge choke or tuned stub at the base insulator to provide a controlled point of flashover between the tower and its grounding system.

A comprehensive description of structural protection fundamentals is beyond the scope of this chapter. Readers desiring more information on structural protection are encouraged to obtain copies of the standards for structural protection listed at the end of this chapter.

PERSONNEL PROTECTION STRATEGY

The threat to personnel during a lightning strike ranges from the obvious danger of direct contact with a lightning stroke to the more obscure effects of step and touch voltages. Protection from a direct strike is accomplished with traditional structural protection methods, insuring that an adequate protective zone is provided in areas frequented by personnel.

Step and touch potentials are created as a lightning current passes through resistive soil and other available paths as it dissipates into the earth. A person in contact with only one point of the gradient will simply rise and fall in potential with the gradient without injury. A person in contact with multiple points on the earth or objects at different potentials along the gradient will become part of the current path and may sustain injury or death.

Fig. 7 indicates a number of methods for protecting personnel from the direct and secondary effects of lightning. A typical tower/transmitter site is used as an example. A technician responding to a service problem during a thunderstorm would likely exit his vehicle outside the gate, unlock and open the gate, and move his vehicle into the inside yard. The technician would then leave the vehicle, and enter the building.

The threat of a direct lightning strike to the technician has been minimized by establishing a protective zone over the areas to be traversed. This zone is created by the tower, air terminals on the roof of the transmitter building, and air terminals mounted atop light poles.

Step potentials are minimized through the use of a ground mat buried just below the surface of the area where the technician is expected to be outside the vehicle. Ground mats are commercially available, fabricated in a two-foot square pattern using #6AWG

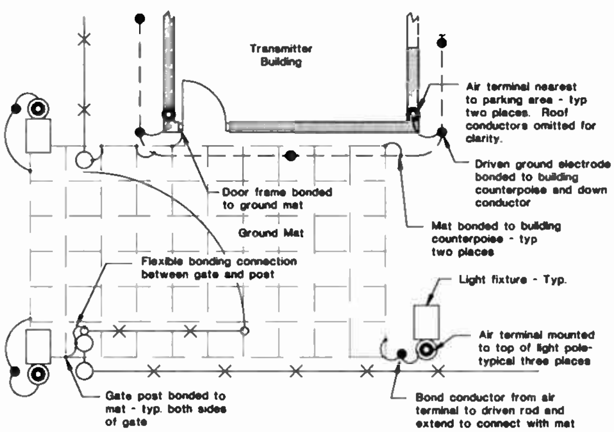

Figure 7. Personnel protection methods.

bare copper wire. Each intersection is welded creating, for all practical purposes, an equipotential plane which short-circuits the step potential gradient in the area above the mat. The mat as a whole will rise and fall in potential, however, there will be little difference in potential between the technician's feet. Mats should be covered with six inches of crushed stone or pavement.

The threat of dangerous touch potentials is minimized by bonding the ground mat to the fence at each side of the gate opening, bonding to the door frame of the transmitter building door, and providing a flexible bonding connection between the swing gate and its terminal post. Such bonding insures that the object being touched by the technician is at or near the same potential as his or her feet.

Bonding both sides of the gate opening to the mat helps to insure that the technician and both sides of the gate are at approximately the same potential while the gate is being handled. The flexible bond between the gate and its support post may be accomplished using a commercially available kit or by exothermically welding a short length of flexible 2/0 AWG welding cable between the two elements.

EQUIPMENT DAMAGE MECHANISMS

Most lightning damage to equipment occurs as the result of potential differences which exceed the tolerance level of the equipment. These potential differences may be presented to the equipment or system through external metallic circuits as a conducted or induced transient voltage surge. They may also occur as the result of differences in ground potential at various items of equipment which are connected together to form a system. Fig. 8 describes these mechanisms in greater detail.

Common mode surges, which are also referred to as "longitudinal mode" in many documents, arrive at the equipment with approximately equal potential on both sides of a balanced pair or on a number of circuits simultaneously. These surges may be induced into a wiring system by nearby lightning, directly coupled into the circuit or even created by the action of an upstream suppression device as it clamps two or more conductors together. Common mode surges may enter equipment on power phases, signal, and other circuits. Damage is normally sustained due to potential differences between the affected circuit(s) and equipment chassis or other uninvolved circuits.

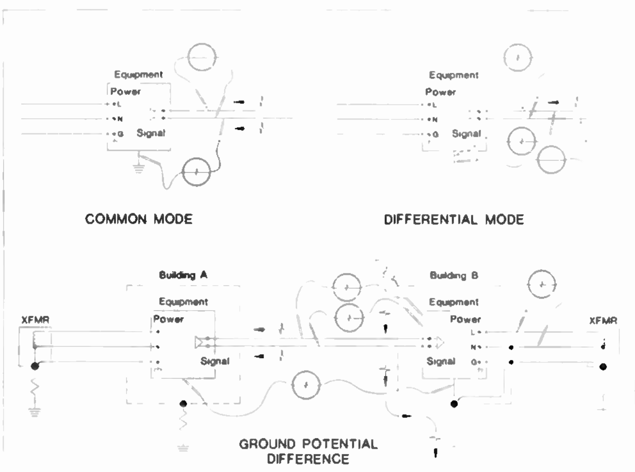

Figure 8. Equipment damage mechanisms.

Differential or normal mode surges are often more damaging than their common mode counterpart as most equipment is designed to operate in a differential fashion. In power circuits, a differential mode surge may appear on one or more phases relative to the neutral and ground conductors. In signal circuits, especially those operating on a balanced differential basis, the tolerance to differential mode surges is lower than for common mode. Common mode surges on electrical systems are routinely converted to differential mode at electrical services where one side of the service is referenced to ground. The same conversion process can occur on a balanced circuit when an upstream transient voltage surge suppressor (TVSS) device clamps one side of a pair before the other.

Ground differential damage is a bit more obscure than either of the other mechanisms, however, it is responsible for a great deal of damage to systems with equipment in multiple locations. Equipment in different buildings, or even equipment within different areas of the same building can be damaged through ground differentials.

In the simple example in Fig. 8, assume that building B receives a lightning strike of 20,000 amperes. Also assume the grounding system resistance is two ohms. As the lightning current flows into the earth through the two ohm grounding resistance, a 40,000 volt potential rise will be produced in the building B grounding system. Since the equipment in building B references the local building through its power cord and bonding conductor, its chassis will rise to about the same potential.

Circuitry within the building B equipment will attempt to track the building ground potential rise, except for the components which attach to wiring from building A. These components see a large difference in potential between the balance of their circuitry and the wiring to building A. Building A has not been involved in the ground potential rise and these circuits are still near ground potential.

Component breakdown occurs within the equipment in building B and a small fraction of the total lightning current attempts to find a path to ground through the wiring leaving for building A. Upon reaching the equipment at the remote building A, this current presents itself as a common mode surge causing damage to the equipment.

EQUIPMENT PROTECTION STRATEGY

Protecting equipment from the effects of lightning involves a combination of grounding, bonding, and surge suppression. Grounding provides a path to introduce lightning currents into the earth. Bonding serves to equalize lightning potential differences between various elements of equipment. Surge suppression limits differences in potential on active circuits which cannot be directly bonded.

The External Ground System

The effectiveness of a grounding system is a function of the type and extent of electrode system used, and resistivity of the surrounding soil. Soil resistivity is dependent on the quantity of free ions (chemical salts) in the soil, temperature, and moisture content. The character of the soil below a particular site may also vary significantly with depth and location due to layering of different types of soil, the presence of hardpan layers, and subsurface rock.

Temperature is a major concern in shallow grounding systems as it has a major effect on soil resistivity. During winter months the grounding system resistance may rise to unacceptable levels due to freezing of liquid water in the soil. The same shallow grounding system may also suffer from high resistance in the summer as moisture is evaporated from soil. It is wise to determine the natural frost line and moisture profile for an area before attempting design of a grounding system.

Fig. 9 describes a four-point method for in-place measurement of soil resistivity. Four uniformly spaced probes are placed in a linear arrangement and connected to a ground resistance test meter. An alternating current (at a frequency other than 60 hertz) is passed between the two most distant probes resulting in a potential difference between the center potential probes. The meter display in ohms of resistance may then be applied to the formula to determine the average soil resistivity in ohm-centimeters for the hemispherical area between the C1 and P2 probes.

Soil resistivity measurements should be repeated at a number of locations to establish a resistivity profile

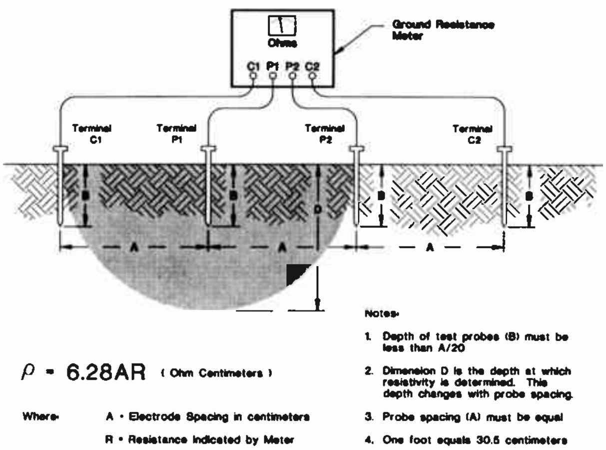

Figure 9. Four-point method for soil resistivity measurement.

for the site. The depth of measurement may be controlled by varying the spacing between the probes. In no case should the probe length exceed 20% of the spacing between probes.

Once the soil resistivity for a site is known, calculations can approximate the effectiveness of a variety of grounding system configurations. Fig. 10 includes equations for several driven rod and radial configurations which may be used for the purpose of estimating system resistance. Generally, driven rod systems are appropriate where soil resistivity continues to improve with depth or where temperature extremes indicate seasonal frozen or dry soil conditions.

Radials are also quite effective if placed below the frost line. They are often the only practical solution in areas with shallow subsurface rock. There have been instances at bald rock mountain top sites where radials were either grouted into saw cuts in the rock or simply pinned against the face of the rock.

The performance of a grounding electrode in high resistivity soil can often be improved through the addition of chemical salts. These salts leach into the soil, increasing the number of free ions with a proportionate decrease of soil resistivity in the area of the rod. Magnesium sulphate (epsom salts), copper sulphate (blue virol), calcium chloride, sodium chloride (table salt), and potassium nitrate have all been used for this purpose.

Fig. 11 describes the trench and well methods for applying chemical treatment. A typical precharged chemical ground rod installation is also shown. In a precharged rod, moisture from the air enters the rod through breather holes at the top of the rod and leaches through the chemicals inside, gradually exiting the rod through weep holes. As one might expect, chemically enriched grounds require recharging after a number of years to maintain their effectiveness. It is also wise to check with governing environmental agencies before introducing any foreign chemical into the soil.

The bentonite ground shown in Fig. 11 is a popular way of decreasing grounding system resistance of a rod electrode in uniform soil by up to 30%. Instead of driving the rod, it is placed in the center of a six to 12 inch augured hole. A slurry consisting of bentonite clay and water (well drillers mud) is then poured around the rod. As the water settles out, the resulting clay remains moist through absorption of moisture from the surrounding soil. Popular additives to the slurry include up to 75% powdered gypsum (calcium sulphate) and up to 5% sodium sulphate (galvanic anode backfill).

Ground Electrode Testing

Testing of grounding electrodes before they are connected to form a complex network is a fairly simple process. Fig. 12 describes the use of a ground resistance meter with the P1 potential electrode and C1 current electrode attached to the electrode under test. Most meters utilize a removable strap between these terminals so that only one test lead is required for the C1/P1 connection except during soil resistivity testing.

Hemisphere radius a	$R = \frac{\rho}{2\pi a}$
One ground rod length L, radius a	$R = \frac{\rho}{2\pi L}\left(\ln\frac{4L}{a} - 1\right)$
Two ground rods s > L; spacing s	$R = \frac{\rho}{4\pi L}\left(\ln\frac{4L}{a} - 1\right) + \frac{\rho}{4\pi s}\left(1 - \frac{L^2}{3s^2} + \frac{2L^4}{5s^4} \cdots\right)$
Two ground rods s < L; spacing s	$R = \frac{\rho}{4\pi L}\left(\ln\frac{4L}{a} + \ln\frac{4L}{s} - 2 + \frac{s}{2L} - \frac{s^2}{16L^2} + \frac{s^4}{512L^4} \cdots\right)$
Buried horizontal wire length 2L, depth s/2	$R = \frac{\rho}{4\pi L}\left(\ln\frac{4L}{a} + \ln\frac{4L}{s} - 2 + \frac{s}{2L} - \frac{s^2}{16L^2} + \frac{s^4}{512L^4} \cdots\right)$
Right-angle turn of wire length of arm L, depth s/2	$R = \frac{\rho}{4\pi L}\left(\ln\frac{2L}{a} + \ln\frac{2L}{s} - 0.2373 + 0.2146\frac{s}{L} + 0.1035\frac{s^2}{L^2} - 0.0424\frac{s^4}{L^4} \cdots\right)$
Three-point star length of arm L, depth s/2	$R = \frac{\rho}{6\pi L}\left(\ln\frac{2L}{a} + \ln\frac{2L}{s} + 1.071 - 0.209\frac{s}{L} + 0.238\frac{s^2}{L^2} - 0.054\frac{s^4}{L^4} \cdots\right)$
Four-point star length of arm L, depth s/2	$R = \frac{\rho}{8\pi L}\left(\ln\frac{2L}{a} + \ln\frac{2L}{s} + 2.912 - 1.071\frac{s}{L} + 0.645\frac{s^2}{L^2} - 0.145\frac{s^4}{L^4} \cdots\right)$
Six-point star length of arm L, depth s/2	$R = \frac{\rho}{12\pi L}\left(\ln\frac{2L}{a} + \ln\frac{2L}{s} + 6.851 - 3.128\frac{s}{L} + 1.758\frac{s^2}{L^2} - 0.490\frac{s^4}{L^4} \cdots\right)$
Eight-point star length of arm L, depth s/2	$R = \frac{\rho}{16\pi L}\left(\ln\frac{2L}{a} + \ln\frac{2L}{s} + 10.98 - 5.51\frac{s}{L} + 3.26\frac{s^2}{L^2} - 1.17\frac{s^4}{L^4} \cdots\right)$
Ring of Wire – diameter of ring D, diameter of wire d, depth s/2	$R = \frac{\rho}{2\pi^2 D}\left(\ln\frac{8D}{d} + \ln\frac{4D}{s}\right)$
Buried horizontal strip length 2/L, section α by b, depth s/2, b < a/8	$R = \frac{\rho}{4\pi L}\left(\ln\frac{4L}{a} + \frac{a^2 - \pi ab}{2(a+b)^2} + \ln\frac{4L}{s} - 1 + \frac{s}{2L} - \frac{s^2}{16L^2} + \frac{s^4}{512L^4} \cdots\right)$
Buried horizontal round plate, radius a, depth s/2	$R = \frac{\rho}{8a} + \frac{\rho}{4\pi s}\left(1 - \frac{7}{12}\frac{a^2}{s^2} + \frac{33}{40}\frac{a^4}{s^4} \cdots\right)$
Buried vertical round plate, radius a, depth s/2	$R = \frac{\rho}{8a} + \frac{\rho}{4\pi s}\left(1 + \frac{7}{24}\frac{a^2}{s^2} + \frac{99}{320}\frac{a^4}{s^4} \cdots\right)$

Notes:

1. Approximate formulas, including the effect of images
2. Dimensions must be in centimeters to return result in Ohms
3. ρ =resistivity of earth in Ohm–Centimeters
4. For 10 ft (3m) rods of 1/2" (12.7mm), 5/8" (15.88mm) and 3/4" (19.05mm) diameters, the grounding resistance may be quickly determined by dividing the soil resistivity ρ in ohm–centimeters by 292, 302 and 311 respectively.

Figure 10. Formulas for calculation of resistance to ground.

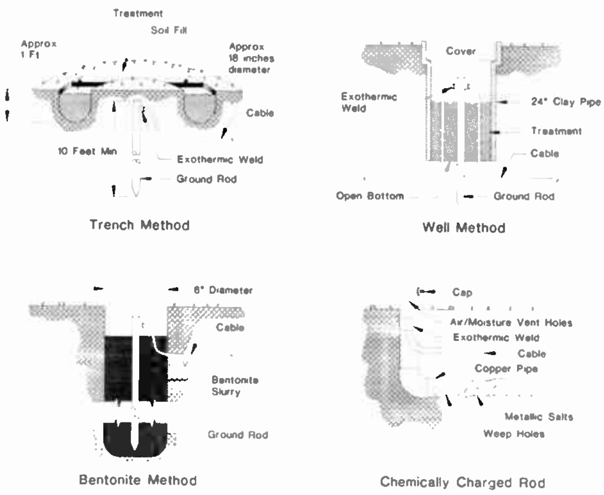

Figure 11. Trench and well methods for chemical treatment.

Probe C2 is inserted into the ground away from the electrode under test according to the instructions provided with the meter. The P2 probe is normally inserted along an imaginary line between the electrode and C2 probe at 62% of the distance to probe C2.

Testing is accomplished by passing an alternating current through the soil between the test electrode and C2 probe while reading the potential at the P2 probe. The ground resistance meter will evaluate these parameters, displaying the resistance of the electrode under test directly in ohms. If the C2 probe is placed too close to the electrode under test an invalid reading will result due to a shallow uniform voltage gradient between the C1 electrode and probe.

Testing of a completed grounding system is performed in essentially the same manner as an individual electrode. The logistics of performing the test can, however, become quite complicated due to the distance required between the probes.

The first step in the test process is to identify the spacing required between the nearest point of the grounding system and the C2 probe. See Fig. 13. A recommended starting point is five times the longest diagonal dimension of the grounding system. In a long linear site, the diagonal distance is usually apparent. For other sites, it is often easier to use the diameter of the smallest circle which completely encloses all of the components of the grounding system. The C2 probe should be placed in a direction away from all underground metallic utility lines and power lines as they may short-circuit the current path and invalidate the readings.

Once the C2 electrode is placed, resistance readings should be taken along the path between the ground system connection and C2 and plotted in terms of resistance versus distance. If there is adequate distance between the system under test and the C2 electrode, a flat will be present in the resistance curve. The correct resistance may then be read from the curve at 62% of the distance to probe C2. If no flat exists, the C2 probe is too close to the system under test.

On a new site it is often possible to perform ground system tests before the power company ground/neutral conductor is attached to the system. It is worthwhile to conduct a before and after test with probes in the same position to determine the influence of the power company attachment during future tests. It is also worthwhile to install permanent electrodes and marker monuments at the original P2 and C2 probe positions to insure the repeatability of future tests.

Grounding Resistance

The bottom line question in designing a grounding system is usually; "What value of grounding resistance do I need"? At electrical services the answer is dictated by the National Electric Code. If the first ground rod doesn't provide 25 ohms or less, drive a second rod. For towers, transmitter manufacturers will often have

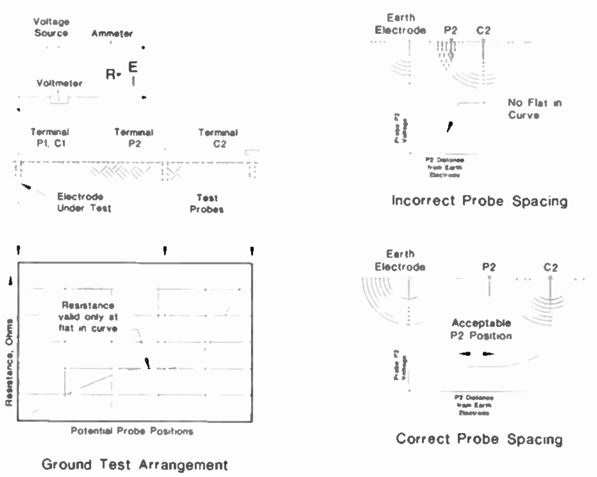

Figure 12. Ground electrode testing.

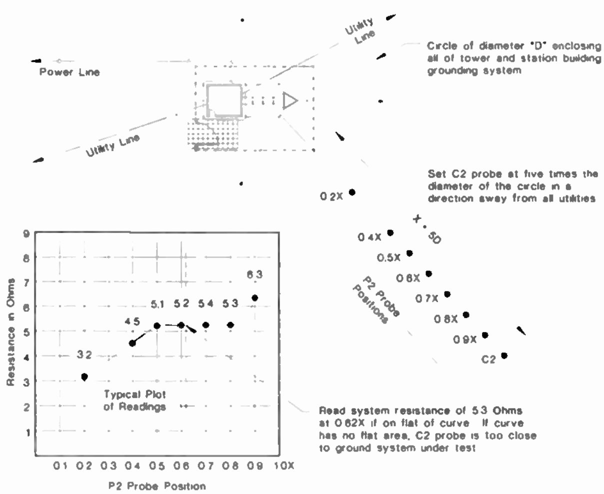

Figure 13. Ground system testing.

their own practices which dictate a specific value of grounding resistance. Lacking other guidance, the answer is to provide as good a ground as you can reasonably afford, focusing first on those locations subject to the greatest lightning currents, and to a lesser degree on areas of smaller exposure.

Tower-Building System

In a typical tower-transmitter building arrangement, the tower is normally subject to more frequent and larger lightning currents than the station building. It is therefore reasonable to place emphasis on the tower grounding system with less emphasis on that for the station building. Improved grounding at the tower will result in less current flowing between the tower and station building grounding systems, reducing potential differences between the two systems.

Fig. 14 describes a typical grounding configuration for a guyed tower and associated transmitter building. Tower grounding may be accomplished either by a system of driven electrodes between the tower base and guy points or by radial counterpoise conductors. In the driven electrode configuration, one radial counterpoise conductor is extended from the base of the tower to each guy point. This conductor serves as an attachment point for driven electrodes near the tower base, at guy locations and at intermediate points.

The rings shown feeding the system of radial conductors should stop within a few feet of the tower base. The complex mesh created by multiple bonds between the rings and radials will help to feed lightning current efficiently from the tower legs into each of the radial conductors. Apart from providing more copper in contact with the earth, there is no advantage in adding additional rings in the area between the tower base and guy points. Current flowing from the tower base out on the radials will produce approximately equal potentials between adjacent radials. With nearly equal potentials at both ends, additional bonding conductors

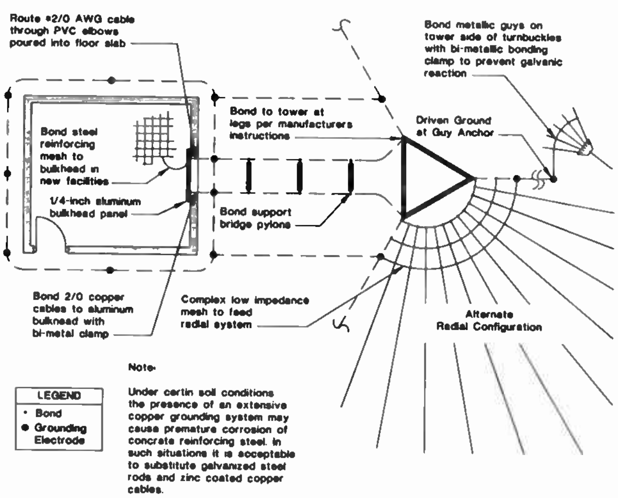

Figure 14. Typical tower ground system.

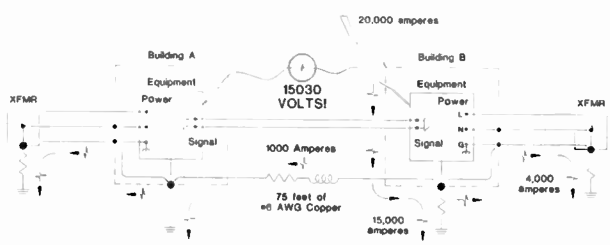
between the radials will carry little or no current. There is only a slight advantage in bonding between radials for currents introduced into the grounding system at guy points.

A ground ring is shown which encircles the station building helping to equalize potential differences within the building. The station building ring also serves as a connection point for driven electrodes, fencing and other objects which must be bonded (see Fig. 7). Four parallel bonding conductors are shown between the station building ground ring and the tower grounding system. These conductors reduce the level of current carried between the tower and station building by the transmission lines.

A $\frac{1}{4}$-inch aluminum (or copper) bulkhead plate is shown on the side wall of the station building which is bonded to the station grounding ring. This plate serves as a single point ground for all equipment within the station building. In new construction, the steel reinforcing mesh in the station building floor should be bonded together to the bulkhead panel to minimize potential differences between the equipment and floor during a lightning strike.

In the previous discussion, a great deal of attention was devoted to the subject of bonding as a means of equalizing potentials during a lightning strike. Fig. 15 repeats the earlier example of damage due to ground potential differences. This time, however, a bonding conductor is provided between the two grounding systems in an attempt to keep both at the same potential.

Kirchoff's law tells us that current will divide itself among all of the available parallel paths through a circuit in proportion to the impedance of each path. Lightning currents behave in the same way, flowing through all available paths to ground. In direct current circuits, the voltage produced across any circuit component is the product of current and resistance. When dealing with rapidly changing lightning current, inductance of the circuit plays a far larger role than simple resistance. Recall that an inductor tends to oppose any change in current until it has stabilized its magnetic field.



I = 1000 amperes
R = .03 ohms (from wire tables)
L = 22.5 microhenries (0.3uh/ft × 75 feet)
di = 1000 amperes (same as I)
dt = 1.5 microseconds risetime

$$E = IR + L\frac{di}{dt}$$

$$E = 1\text{x}10^{3} \times 3\text{x}10^{-2} + 22.5\text{x}10^{-6} \times \frac{1\text{x}10^{2}}{1.5\text{x}10^{-6}}$$

$$E = 30 + 15000$$

$$E = 15030 \text{ volts}$$

Figure 15. Example of ground potential difference.

The bonding conductor shown in Fig. 15, by virtue of its connection to ground at remote building A, serves as one of several paths for lightning current to follow on its way to ground. In this case, only 5% or 1,000 amperes of the lightning current flows through the 75 foot conductor with the remainder of the 20,000 amperes flowing into the grounding system of building B and its electrical service. Assuming a 1.5 microsecond risetime for the lightning current, the peak end-to-end voltage on the conductor is 15,030 volts. 15,000 volts of the total is the result of inductance in the conductor. The remaining 30 volts is the result of the conductor's resistance.

The normal reaction to lowering the potential difference in the previous example is to suggest a larger cable. After all, larger cables have less resistance and lower voltage drop. Changing to a larger cable, however, has little effect on the circuit inductance, affecting primarily the 30 volt portion of the total.

Fig. 16 provides a comparison of inductance values for a one-foot length of various sizes of round conductors and strip materials. Strip materials are considerably more effective for the same cross sectional area as a round conductor, making them more attractive as a bonding medium for lightning protection purposes. Another interesting property of strip material is that once you reach a width of about four inches, the major reason for thickness is mechanical strength and mounting convenience.

As a final note on the inductance of bonding materials, *never expect an insulated conductor in steel conduit to carry lightning current effectively*. Ferrite beads make a reasonably effective low pass filter when placed around an insulated conductor. Steel conduit around an insulated conductor creates the same effect, increasing the inductance of the cable within the conduit at least an order of magnitude. Where this condition exists (and there are many locations) a marginal compromise is to bond both ends of the cable to the conduit, permitting the conduit to serve as part of the circuit.

Single Point Grounding

If, after the exercise in bonding, you conclude there is no way of preventing potential differences in a conductor carrying lightning current, you are correct. There is, however, a method of preventing lightning current flow through a bonding circuit and with no current flow there can be no potential difference between the bonded items. This method is called single point grounding.

In Fig. 17 the equipment chassis and all metallic circuits leaving the equipment for the outside world have been bonded together and to a ground conductor at a single point. There is no possibility of a difference in potential between the circuits entering the equipment or between these circuits and the chassis as they are all bonded together. There is also no possibility of current flow from the single point ground into the equipment through any of the circuits as the equipment is isolated from the structure.

A surge entering on the power or signal lines cannot present itself to the equipment in differential mode as the lines are all connected together. A common mode surge arriving at the single point ground will pass harmlessly to ground through the grounding conductor and ground electrode resistance. There will be potential rise at the single point ground due to inductance and resistance in the grounding circuit, however, no current can flow through the equipment as it remains isolated from other points of ground reference. The equipment will simply rise and fall in potential, tracking the potential of the single point ground.

A lightning strike to the building or other structures connected to its grounding system will also cause the single point ground to rise and fall in potential. The equipment, however, sees no potential difference as its chassis and all external metallic circuits are tied "together at the single point ground. The only difficulty with the example in Fig. 17 is that nothing works.

Fig. 18 provides a more realistic approach to single point grounding. The only difference between Fig. 18 and the preceding example is that Transient Voltage Surge Suppression (TVSS) devices are used on the

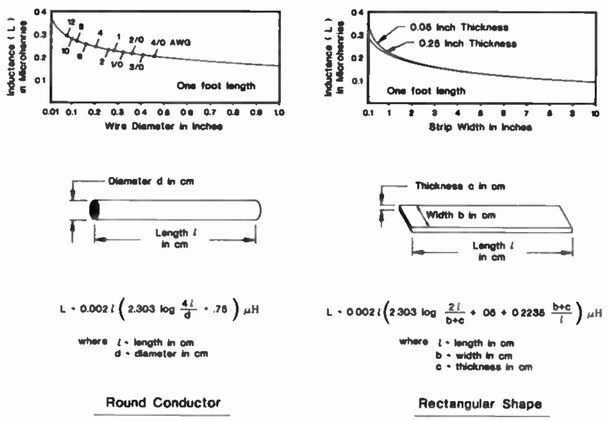


Figure 16. Inductance values for round conductors and strip materials.

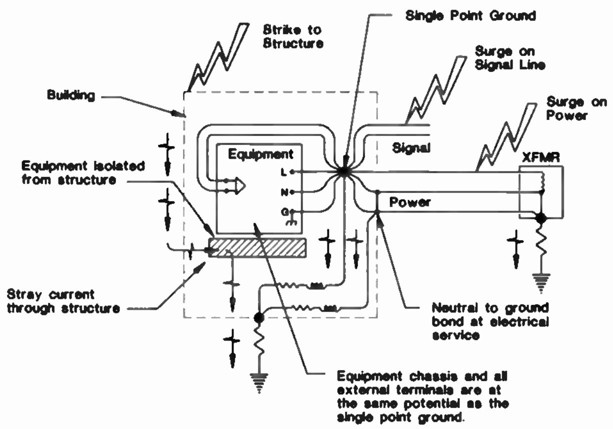

Figure 17. Single point grounding.

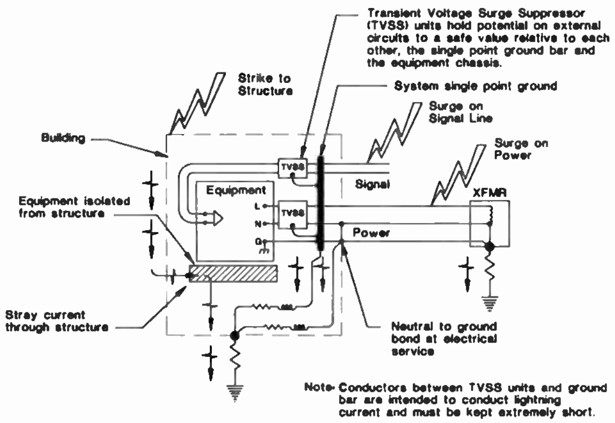

Figure 18. Single point grounding with transient voltage surge suppression units.

active circuits which, for obvious reasons, cannot be directly bonded to the single point ground.

For the purpose of this discussion, it is helpful to think of surge suppressors as a conditional bond, clamping or limiting the excursion of voltage on active circuits to a safe level relative to each other and to the single point ground. The single point ground may rise and fall in potential as the suppressors discharge current into it or during a strike to the building, but the difference in potential presented to the protected equipment is always held within safe limits.

It is worthwhile noting that TVSS devices will clamp in response to a rise in potential on their ground terminal as well as for legitimate transients on their active conductors. A strike to the building or nearby structure will cause a significant elevation in ground potential. The single point ground will rise in potential by virtue of its connection(s) to the building grounding system. The TVSS units, seeing their ground terminals rise in potential above their remotely connected active circuits, will clamp, forcing the active circuits to track the potential of the single point ground and the chassis of the protected equipment. Again, the voltage excursion seen by the equipment is held to a safe level and no damage is sustained.

Applications of Single Point Grounding

The application of single point grounding is normally limited to equipment within a room or a group of rooms. While it is possible to design larger configurations, the need to bring circuits in at different locations soon dictates the need for multiple locations, each treated as an island of equipment with its own suppression devices and single point of ground reference. Larger single point grounding systems are also more susceptible to induced voltages from nearby lightning by virtue of their increased cable lengths.

As an example of two extremes in scale, a computer room which serves terminals throughout a station complex may be engineered with a single point grounding system and proper surge suppression on its external circuits. The terminals and their printers, however, are scattered throughout the building, referencing ground at each location through their power cords. It is possible to designate the ground pin on the receptacle for each terminal/printer combination as the single point ground for the equipment at that location. A combination power and data suppressor may be provided for each location which insures that these conductors are held within safe limits of the receptacle ground pin and chassis of the equipment. The equipment is isolated from stray grounds by placement on a desk top.

Fig. 19 is an example of how single point grounding applies to a typical broadcast transmitter building. A ¼-inch bulkhead panel in the wall of the building serves as a single point ground reference for all equipment within the small facility. All coaxial cables, waveguides, and raceways from the tower are bonded to the bulkhead as they pass into the building.

The physical size of the electrical equipment dictates that it cannot be located directly at the bulkhead panel. To minimize the effect of bonding system inductance, a six-inch wide bonding bus is extended to each side of the bulkhead. Width of the strip provides the necessary low inductance. Its ¼-inch thickness, while not necessary for electrical reasons, provides the installer with a bus which may be drilled and tapped to accept short bonding pigtails to the equipment.

Support hangers for cables and raceways serving the protected equipment are isolated from the roof structure to prevent inadvertent current flow through the raceways. Isolation is provided between the equipment feet and floor slab by a polycarbonate plastic pad. Such isolation may not be necessary if adequate isolation is provided by the equipment feet. Nylon bolts may be used with conventional expansion anchors to secure equipment to the floor without violating the integrity of the single point grounding system.

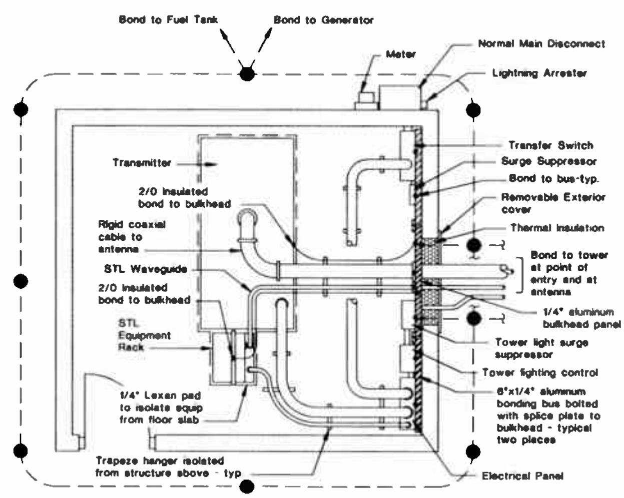

Figure 19. Single point grounding to a typical broadcast transmitter building.

Surge Suppression

Surge suppressors are shown at the transfer switch to protect the incoming power circuits and on the circuitry from tower lights. Both suppressors should be bonded to the grounding bus, keeping the length of their bonding lead as short as possible. Suppression should also be provided on all metallic communications lines and circuits serving lighting, winches and other electrical items outside the building. Again, locate these suppressors at the point of entry for the circuits and bond their ground leads to the bus with the shortest possible lead length.

The lightning arrester shown at the main disconnect outside the building is an inexpensive device, however, it serves an important purpose. Under normal operation, the main disconnect is closed and the transfer switch is connected to utility power. In this configuration, the lightning arrester and surge suppressor at the output of the transfer switch are in parallel. It is unlikely that the surge suppressor will allow the arrester to operate due to the difference in clamping level. During operation on emergency power, however, the scenario is quite different.

A lightning strike to the utility line will propagate along the line as a traveling wave in both directions from the point of lightning contact. Upon reaching the open circuit input of the transfer switch, the wave will reflect back on itself, effectively doubling its initial crest value. The same condition can occur at the main utility company disconnect if it should be open during servicing.

Flashover within electrical equipment is serious in itself, however, the problem is compounded when operating voltage is present. The flashover arc provides a low impedance path for 60 Hz fault current and significant damage to the equipment may occur. The arrester will help prevent this condition from occurring by limiting the traveling wave voltage.

Fig. 20 indicates a method of connecting a three-phase surge suppressor to an electrical panel. Many manufacturers are recommending connection of their products using a thermal circuit breaker rather than drilling and tapping the buses of the panel or attaching the suppressor to the main lugs. It is of great importance to minimize the length of the suppressor leads and that of the grounding conductor as their inductive voltage drop is additive with the initial clamping voltage of the suppressor.

The surge suppressor example in Fig. 20 indicates the use of a shunt wired device. There are, however, large surge suppression devices on the market which permit up to several thousand amperes of load current to flow through them. On these devices, only the length of the grounding lead between the suppressor and ground bus is critical.

Signal Line Suppressors

Fig. 21 shows a common surge suppressor configuration for telephone and signal line applications. Most suppressors of this type are constructed as multi-stage hybrid devices utilizing a high-energy first stage, a fast acting second stage, and an impedance in series between the two stages to coordinate their clamping behavior. Because of the multi-stage design, these devices must be installed in series with the protected circuits.

The treatment of shields is often an issue when dealing with signal line surge suppressors. Fig. 21 shows shields being bonded to the suppressor ground bus to force them to track the single point ground. If ground loop or other technical restrictions prevent direct bonding of the shields, they should be protected as any other active circuit.

The bonding lead distance for signal line suppressors is often more critical than for power devices. Tolerance levels of signal circuits are normally lower than for power supply inputs, and the relatively small voltages developed in the suppressor ground leads can become significant.

Signal line surge suppressors are sold in a variety of shapes and sizes for different applications. The

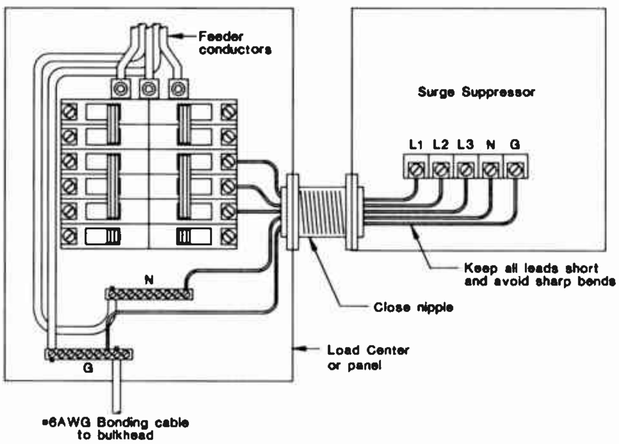

Figure 20. Three-phase surge suppressor.

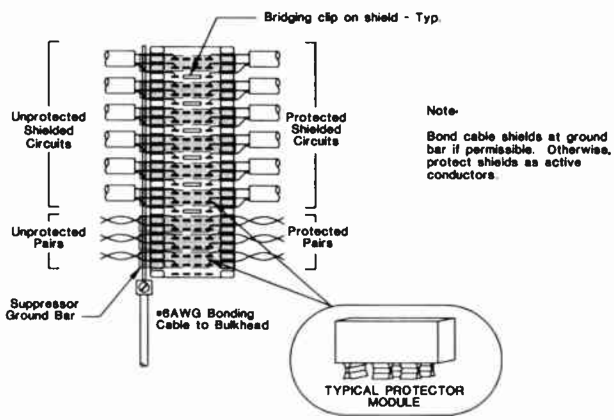

Figure 21. Signal line suppressor.

suppressors should generally clamp transient voltage on a circuit to within 150% of normal peak operating voltages and even lower in some applications. Since most signal line suppressors are inserted in series with the circuit being protected, it is wise to evaluate the effect of their series impedance on the operation of a circuit.

The effect of suppressor capacitance can be important in many high speed data, RF, and video applications. One simple way of evaluating the effect of this capacitance is to equate it to equivalent cable feet. For example, if the desired suppressor exhibits capacitance of 100 picofarads and the cable used in the circuit is rated at ten picofarads per foot. Will the circuit tolerate an additional ten feet of cable? If so, the suppressor capacitance should produce no noticeable effect on the circuit.

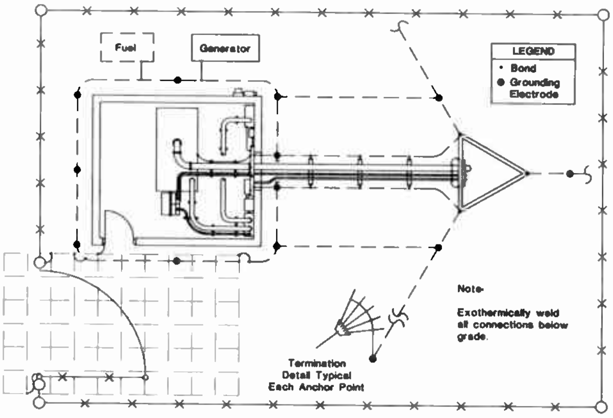

Figure 23. Typical bonding and grounding recommendations.

Isolated Ground Receptacle

Fig. 22 shows an isolated ground receptacle circuit commonly used in computer room grounding applications. The receptacles used in this type of circuit differ from the norm in that their ground sockets are electrically isolated from their mounting tabs. They are therefore isolated from their outlet box and structural ground at each receptacle location. A dual system of grounding conductors insures that equipment plugged into an isolated ground (IG) receptacle references ground first at the single point ground.

The use of isolated ground receptacles helps to insure that plug-in terminals, printers, diagnostic and other ancillary equipment is properly referenced to the single point ground and not the local structure. It only takes one item of equipment connected between the protected equipment and a remotely grounded receptacle to compromise the integrity of the grounding system.

Fig. 23 is a composite of the bonding and grounding recommendations for the typical transmitter site. While complicated in appearance, each component has its purpose as part of a simple to understand subsystem.

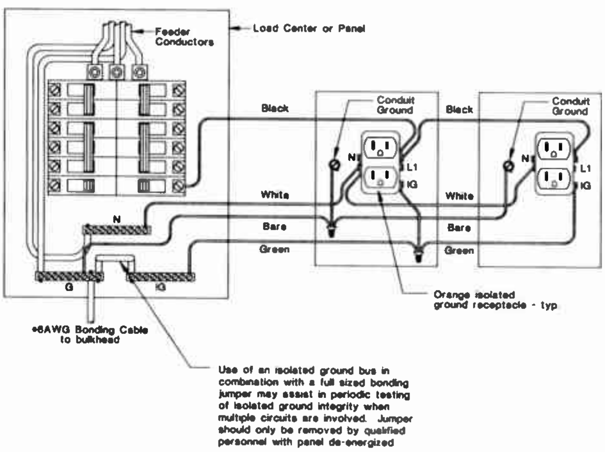

Figure 22. Isolated ground receptacle.

CONCLUSION

This chapter has been written in tutorial form as every site is different and no single set of recommendations will apply to every situation. The principles set forth, while tailored to a broadcast environment, apply equally to other systems. There are still a few mysteries to be solved in completely understanding lightning, but once it enters a wiring system it becomes an electrical current which is both predicable and understandable.

Many of the elements covered in this chapter have been touched on lightly to keep the chapter to a reasonable size. A list of recommended publications is included at the end of this chapter which deal with the subject material in greater depth.

2.3 Transmission Lines

Harry D. McKee
Bruce J. Carlson
Robert D. Leonard
John A. Midkiff
Andrew Corporation, Orland Park, Illinois

INTRODUCTION

Transmission lines transmit or guide energy from one point to another. Usually, this needs to be done with maximum efficiency, keeping losses due to heat or radiation as small as possible.

This chapter discusses the three major types of transmission lines in common broadcast use.

1. Semi-flexible transmission lines with two concentric conductors (coaxial) transmitting in transverse electromagnetic (TEM) mode. In a TEM mode, both the electric (E) and magnetic (H) fields are entirely transverse to the direction of propagation (Fig. 1A).
2. Rigid transmission lines with concentric conductors (coaxial) which also are transmitting in TEM mode.
3. Transmission lines incorporating a single hollow conductor (waveguide) in which the E or the H (or both) fields always have a component in the direction of propagation. In Fig. 1B, for example, the E field in the rectangular waveguide shown is transverse to the direction of propagation, hence the "TE" designation for *transverse electric*. Note that the magnetic field has a component in the direction of propagation. All waveguides used at UHF television frequencies transmit in a transverse electric configuration.

General Selection Criteria

The three major criteria for selecting transmission line are:

1. Frequency band of operation
2. Power handling capability
3. Transmission efficiency (attenuation)

Table 1 shows the general characteristics of the most commonly used broadcast transmission line types together with an approximate rating of associated installation complexity, accessories and overall cost. Readers are cautioned that these are very general ratings and individual circumstances may cause wide variations.

Frequency

Frequency of operation in a transmission line is usually a function of the diameter. In semi-flexible

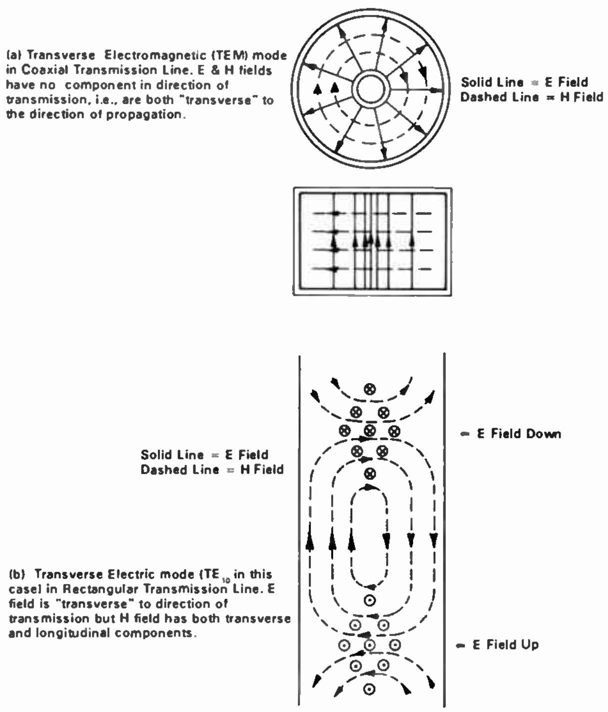

Figure 1. E & H Field configurations in coaxial line (A) and waveguide (B).

Recommended Maintenance	Annual Insp.	Annual Insp.	Annual Insp.
Initial Material Cost	Most Ecomomical	More Expensive	More Expensive
Initial Installation Cost	Lower	Higher	Higher

coaxial lines (Figs. 2A and 2B), outer conductor sizes range from ¼" to 9" diameter. In rigid line (Fig. 2C) typical diameters range from ⅞" to 9³⁄₁₆". In the AM, FM, and TV operating bands, the most commonly used sizes of semi-flexible or rigid coax range from 1⅝" to 8³⁄₁₆" diameter.

For rectangular waveguides used at UHF-TV frequencies (Fig. 2D), sizes range from 5.25" × 11.5" (WR1150) to 9.0" × 18.0" (WR1800). Circular and truncated waveguides (Fig. 2E and 2F) generally range from 13" to 18" nominal diameter.

Power Handling

Power handling in a transmission line is usually limited by the amount of heat generated as current flows on the skin of the conductors, caused by the resistivity of the conductor material. Heat generated in the inner conductor must be transferred by convection, radiation, and conduction to the outer conductor, then passed to the surrounding environment by convection and radiation.

In broadcast applications, the limiting factor is usually the amount of heat which the dielectric support material between the conductors can absorb before it begins to soften. If that happens, the inner conductor can change position, which causes a change in the characteristic impedance of the transmission line. This creates a voltage standing wave ratio (VSWR) mismatch within the transmission line, causing degraded performance due to higher reflected power.

On a size for size basis, corrugated semi-flexible cables, having a greater length of copper per unit of line length than rigid line, generate slightly higher I^2R (heat) losses per unit of length than rigid line.

Waveguide, having no inner conductor and no dielectric support material, has very high power handling capability. Consequently, it is more commonly used in very high power UHF applications.

Attenuation

Size for size, semi-flexible cable will have higher attenuation than rigid line since the corrugated construction technique contains more copper per unit length. In addition, more dielectric is needed to maintain concentricity of the inner conductor of semi-flexible transmission line. Besides absence of corrugations, the copper tubes used for rigid lines tend to support themselves, so less dielectric support material is required.

Waveguide, which eliminates the center conductor and associated supporting dielectric, has the lowest attenuation of the three types. Due to the low attenuation characteristics, it may become the medium of choice in areas where high operating costs (due to higher utility rates) must be minimized. However, the price for low attenuation is a significantly larger size, which adds substantial wind loading to the tower.

SEMI-FLEXIBLE CABLE

General

Semi-flexible transmission line has seen increasing use in the broadcast industry over the years because it is ideal for a wide variety of low and medium power applications. This line achieves its flexibility through the use of corrugated copper conductors. The term semi-flexible is used because in larger sizes, 1⅝" and

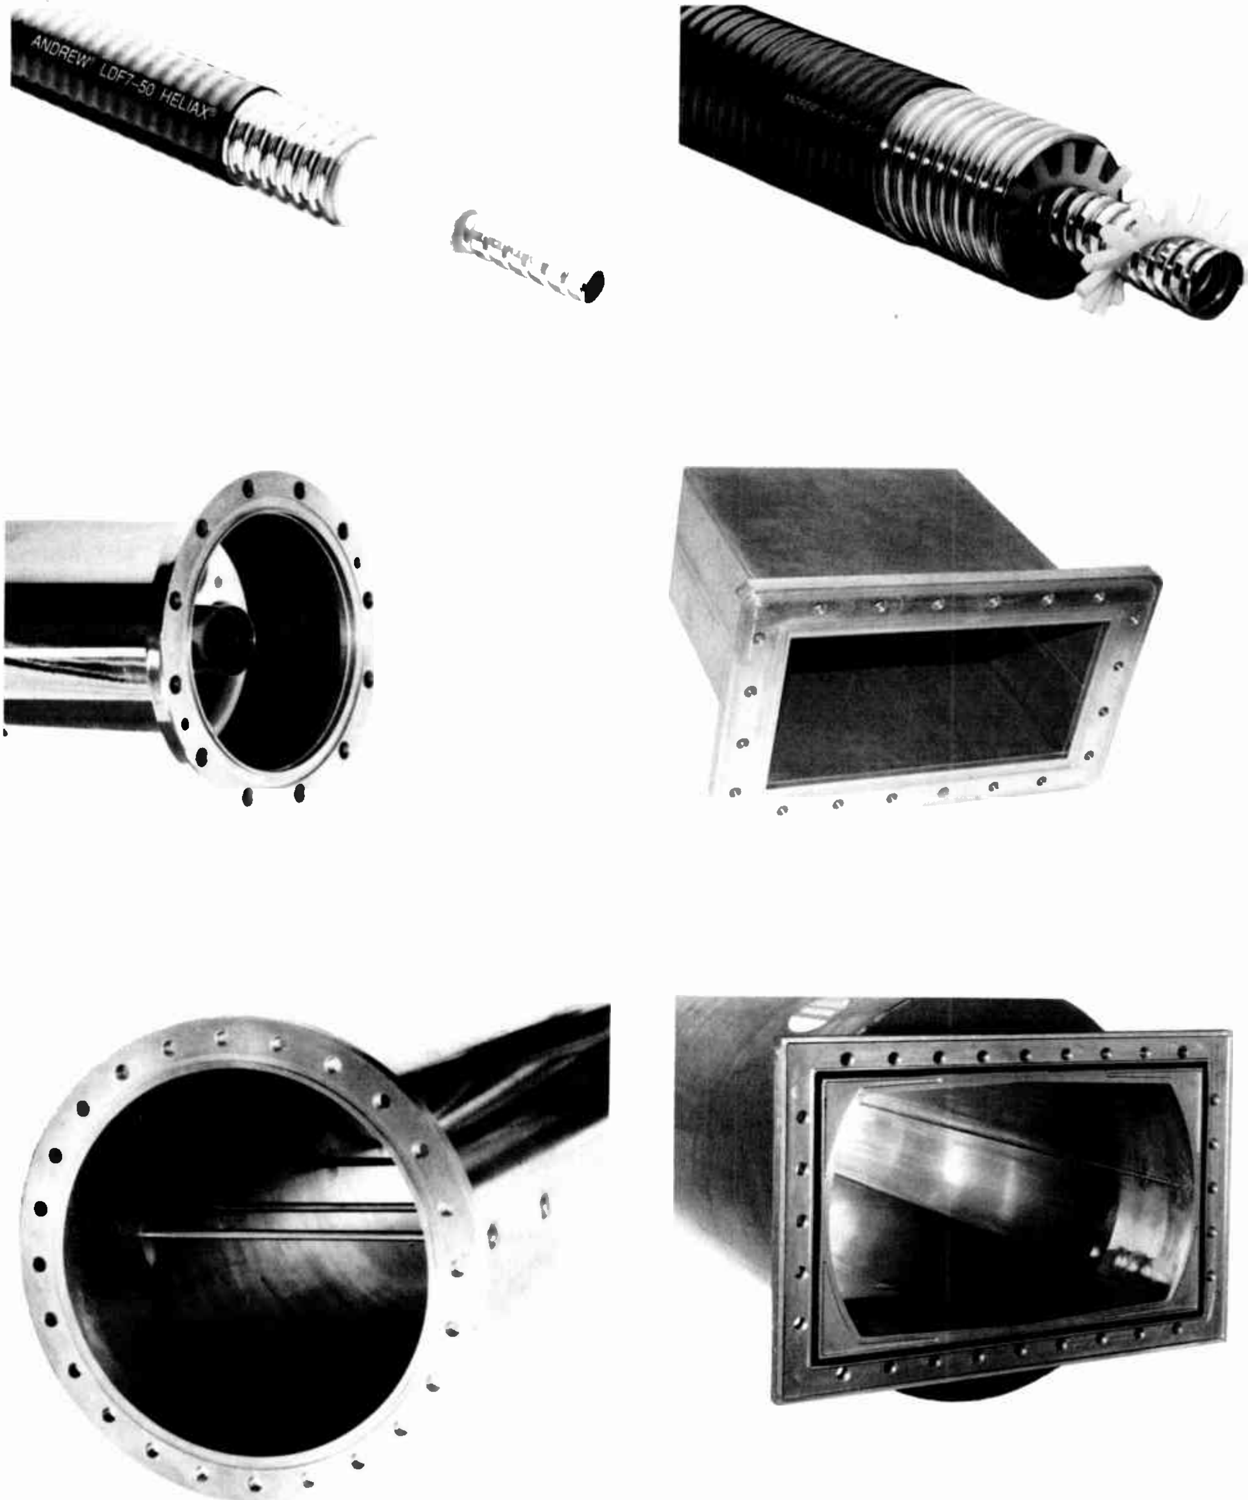

Figure 2. Various broadcast transmission lines.

TABLE 2

Typical minimum bend radius for semi-flexible cable (minimum of 10 bends).

Line Size	Typical Minimum Bend Radius
1⅝"	20"
2¼"	22"
3"	30"
3½"	30"
4", 4⅛"	40"
5"	50"
6⅛"	79"
8"	98"
9"	118"

up, the minimum bending radius becomes quite large (Table 2).

The advantages of semi-flexible cable are:

1. One-piece installation without the multiple connections of rigid line, since it is supplied in continuous lengths.
2. Easier to install than rigid line, since exact length is not critical.
3. High reliability through accommodation of thermal expansion and contraction, due to its corrugated construction.
4. Long life in corrosive environments or if buried, when provided with a protective polyethylene jacket.

Types of Semi-Flexible Cable

Semi-flexible cable is supplied in two types, foam dielectric and air dielectric.

Foam-Dielectric Cable

Foam-dielectric coaxial cables (Fig. 3) are designed for most antenna feeder systems which do not require a pressure path to the antenna. Typical applications include AM and FM radio and low-power television (LPTV). Sizes range from ¼" to 1⅝", with the smaller sizes being available in two versions: standard and superflexible. Superflexible cables, intended for installation in confined spaces, have deeper corrugations than standard foam cables, which permit them to be bent on a smaller radius and with the capability of more repeat bends. They are often used with earth station antenna systems and as jumper cables. Some smaller diameter cables are available with either 50 ohm or 75 ohm (nominal) impedance; 1¼" diameter and larger cables are furnished with 50 ohm impedance only. Foam-dielectric cables are constructed with a closed-cell, low density foam dielectric which prevents water penetration while providing low attenuation and high relative velocity of propagation.

Air-Dielectric Cable

Air-dielectric cables (Fig. 4) utilize a spiral polyethylene (or other polyolefin) spacer to separate the conductors. Compared to foam-dielectric cables, air-dielectric coaxial cables have slightly lower attenuation and higher average power rating, due to the superiority of air as a dielectric. They are pressurized in operation, and so are used to provide dry gas to pressurized antenna systems. When equipped with a pressurization alarm, damage to a pressurized cable can be detected immediately. Air dielectric cable is manufactured in sizes required for most broadcast applications.

A recent variant of air-dielectric cable is sectionalized semi-flexible coaxial cable in large diameter (up to 9"), supplied in 38-foot sections for transportation in standard shipping containers. This eliminates the delivery and installation problems associated with large diameter continuous coaxial cable, which must be shipped on immense reels. Sectionalized coaxial cable is available for HF, MF, and LF frequencies only. Large flanges connect the sections and provide good electrical contact and pressure tightness.

Coaxial Cable Design Considerations

Coaxial transmission line theory is presented in detail in Chipman[5] and Ramo[10]. The following discussion focuses on the information that is of the most practical value to broadcast engineers.

The basic principle in the design of a coaxial transmission line is to maximize the power handling capabilities while minimizing the attenuation for a given size line. This involves adjusting the inner conductor diameter to achieve an optimum value for each of the performance characteristics. The resulting ratio will determine the characteristic impedance of the line.

Impedance

The impedance is related to the dimensions of the inner and outer conductors and the dielectric constant

Figure 3. Typical foam-dielectric cable.

Figure 4. Typical air-dielectric coaxial cable.

of the dielectric material between them. It can be expressed by the following equation:

$$Z_C = \frac{60}{\sqrt{\epsilon'}} \ln \frac{D}{d}$$

where: Z_C = Characteristic impedance, ohms
ϵ' = Dielectric constant = relative permittivity of dielectric (ϵ' = 1.0 for air dielectric)
D = Inner electrical diameter of outer conductor, in
d = Outer electrical diameter of inner conductor, in

Power Handling

Power handling is limited by either of two factors: the maximum peak power, determined by electric field strength, or the maximum average power, determined by the allowed temperature rise of the inner conductor.

For a coaxial construction the electric field is at a maximum near the outer surface of the inner conductor. Maximum electric field strength can be calculated as follows:

$$E_{MAX} = \frac{.278}{d} \sqrt{\frac{P}{\ln \frac{D}{d}}}$$

where: E_{MAX} = Maximum electric field strength, volts/in
P = Power level of signal, watts

E_{MAX} is at a minimum when the ratio D/d is equal to 1.65, resulting in an impedance of 30 ohms for an air dielectric line.

Determining the average power limitation for a coaxial line involves complex thermal models. An approximate optimization is that the optimum ratio of D/d should equal 2.72, resulting in an impedance of 60 ohms.

Attenuation

Attenuation is due to dielectric losses and conductor losses. The loss of the dielectric material is directly proportional to frequency and also to the "loss factor" of the material. For the most commonly used dielectrics in RF transmission lines (i.e., Teflon®, polyethylene, air etc.), the loss factor is fairly small (of the order of 0.0002) and dielectric losses are small compared to conductor losses. Conductor loss is related to dimensions, permeability, and conductivity of the material. It varies with the square root of the frequency and is defined by the following equation for copper conductors:

$$\alpha = \frac{.433}{Z_C}\left(\frac{1}{D} + \frac{1}{d}\right)\sqrt{f}$$

where: α = Attenuation, db/100 ft
f = Frequency, MHz

As can be derived from this equation, attenuation is minimized when D/d is equal to 3.59, which results in an impedance of 77 ohms.

It is seen from this discussion that there is a trade-off in design between optimizing for line peak power, average power, and attenuation. In general, most lines are manufactured with an impedance of either 50 ohms or 75 ohms. The 50 ohm case provides a good balance between the 30 ohm optimum level for peak power and the 60 ohm optimum level for average power. If average power rating is the primary factor, a 50 ohm line should be used; but if attenuation is the main consideration, then a 75 ohm line should be selected. A 50 ohm line will have roughly 8.0% higher attenuation than a 75 ohm line with identical outer conductor diameters.

Cut-Off Frequency

The cut-off frequency of a coaxial line is the frequency above which undesirable modes of propagation are generated. A coaxial cable, therefore, must not be used above this frequency. Cut-off frequency, f_C, is inversely related to conductor dimensions and dielectric constant, as shown in the following equation:

$$f_C(GHz) = \frac{7.52}{\sqrt{\epsilon'}\,(D+d)}$$

Consideration of maximum frequency is important in high power TV applications where the cut-off frequency falls in the UHF bands for larger size coaxial cables (6⅛" and above). A maximum operating frequency is always specified for semi-flexible cable, which is somewhat lower than the calculated cut-off frequency.

Cable Selection

General

Semi-flexible coaxial cable for broadcast applications is selected on the basis of cut-off frequency, power being transmitted, loss (attenuation), size, installation, and cost. The following discussion describes the typical components required in a system and the electrical performance evaluation in terms of power ratings, attenuation, efficiency, connector loss, VSWR, and derating considerations for the various sizes of cable available. Each installation should be considered on an individual basis.

Coaxial Components

A schematic drawing of a typical semi-flexible transmission line broadcast installation is shown in Fig. 5. Table 3 lists some typical components for the various coaxial cable sizes available. This is only a partial list and individual manufacturers' catalogs should be consulted when planning a semi-flexible coaxial cable system.

Power Ratings

There are two power ratings for a coaxial line. One, the peak power rating, is based on voltage breakdown considerations; the other, the average power rating, is based on the maximum heating the cable construction can safely withstand. At VHF, FM, and UHF frequencies, coaxial cables are average power limited, while the peak power rating is usually the limiting factor in amplitude modulation applications at medium freqency (MF). For amplitude modulation high frequency (HF)

TABLE 3

Typical components for semi-flexible coaxial cable installation.

Item No.	Description
2	Semi-Flexible Coaxial Cable
3	Antenna End Connector
4	Transmitter End Connector w/Gas Barrier
5	Hanger Kits

applications, the line may be either average or peak power limited depending on the conditions.

Peak power is the maximum RF power which can be reached in a short interval (a few RF cycles). (This is not the instantaneous power when the RF voltage is at a maximum, but is the power averaged over an RF cycle; "peak" here refers to peak amplitude of modulation.) In a continuous wave (CW) carrier (including FM), peak power equals average power. In 100% AM, the power rises to four times the carrier power at the peaks of the modulation envelope, so in this case peak power is four times the carrier power.

The peak power rating of a cable is dependent on voltage breakdown considerations which are essentially not frequency-sensitive; thus, this rating is considered constant with frequency. It is determined by the maximum voltage withstanding capability between the inner and outer conductors. This voltage capability varies with line size, line pressure, and type of pressurization gas.

A conservative method of determining peak power ratings is to use the equation:

$$P_{PK} = \frac{\left(\dfrac{E_p \times 0.707 \times 0.7}{2}\right)^2}{Z_C}$$

where: P_{PK} = Cable peak power rating, standard conditions, kW
E_P = DC production test voltage, volts
0.707 = RMS factor
0.7 = DC to RF factor (empirically verified)
2 = Safety factor on voltage
Z_C = Characteristic impedance, ohms

An adequate safety factor on peak power is necessary to safeguard against voltage breakdown, which can result in permanent damage to the cable. Manufacturers of coaxial cables may use different safety factors for published peak power ratings, so this should be taken into account when comparing catalog values. Cables are available which have been high-voltage tested to the equivalent of 400% of their rated peak power, resulting in a safety factor of 2 on voltage and 4 on peak power.

Peak power ratings can be determined using the average power chart in Table 4 for various sizes of semi-flexible coaxial cable. The peak power ratings correspond to the average power rating numbers at 1 MHz (AM). The ratings are for CW power, terminating VSWR of 1.0 and one atmosphere absolute of dry air pressure. Peak power must be derated for modulation technique and VSWR.

Average power is the power in the signal capable of creating heat. The average power rating of semi-flexible coaxial cable is based on the maximum inner conductor temperature which will permit safe, long-term performance for the particular dielectric material used. Since the average power rating is limited by heating, which is created by line losses, it decreases with increasing frequency. Table 4 is a listing of manufacturer's semi-

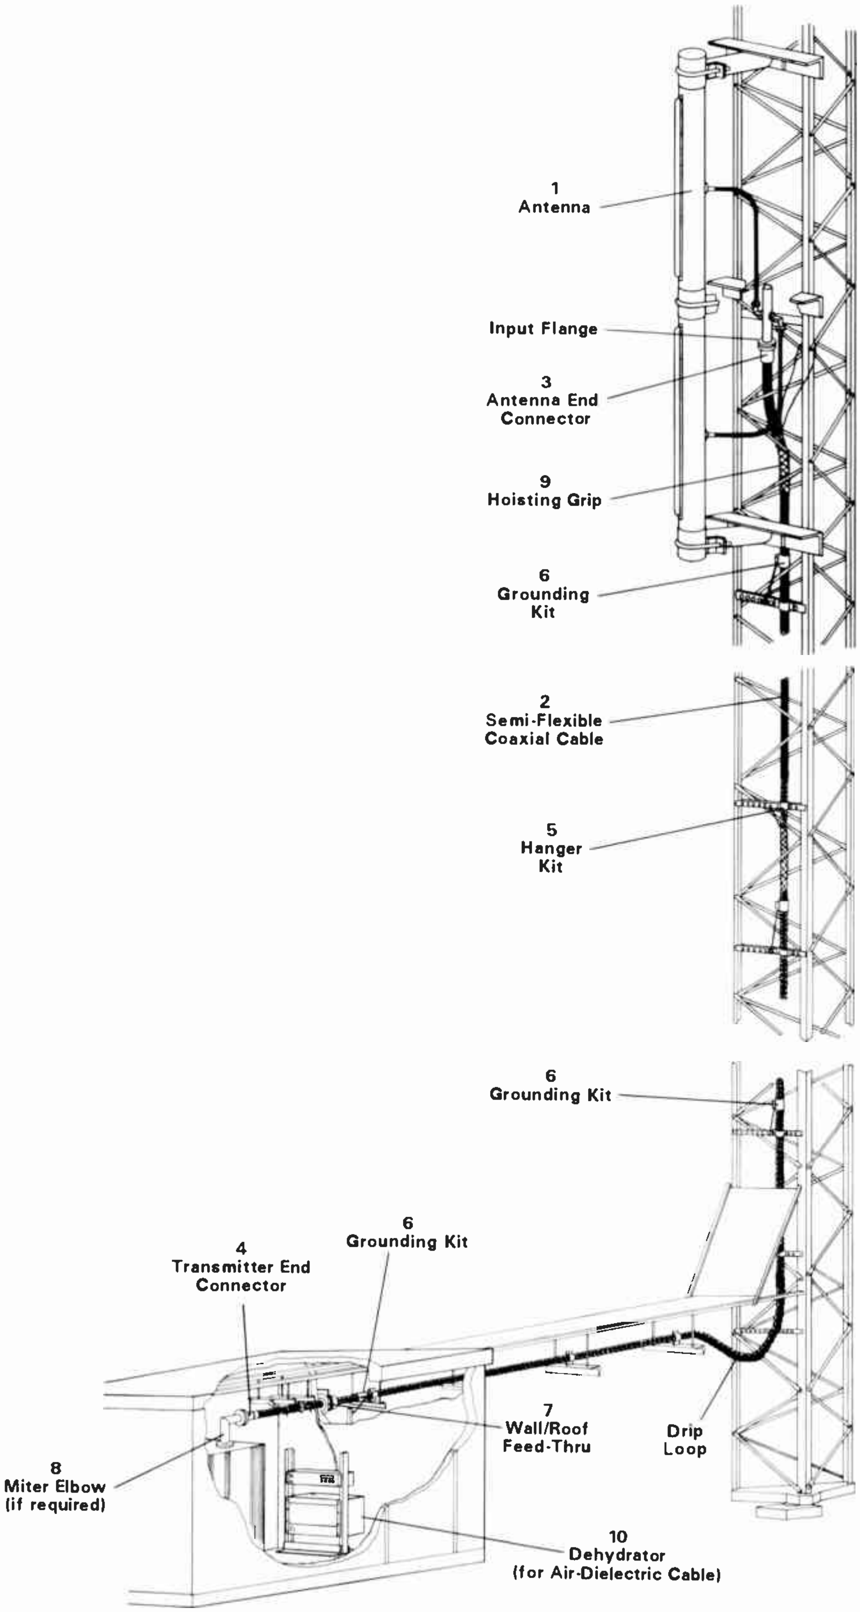

Figure 5. Typical semi-flexible cable broadcast installation.

Average transmitter power calculations.

Modulation	Average Power Calculation
HF, AM	$P_{AVG} = P_C(1 + \frac{M^2}{2})$
FM	$P_{AVG} = P_T$
TV	$P_{AVG} = .8P_{TV}$

P_{AVG} = Average transmitter power (visual & aural)
P_C = Carrier power
M = Amplitude Modulation index
P_T = FM transmitted power
P_{TV} = TV peak sync. power

Note: Commercial AM (530 to 1610 kHz) is usually peak power limited.

flexible coaxial cable average power ratings for a VSWR of 1.0 and ambient temperature of 104°F (40°C). Average power must be derated for ambient temperature and VSWR. A discussion of average power ratings of coaxial cable is given in Chipman[5] and Martin[7].

The average power that is applied to a transmission line is dependent on the nominal CW power of the transmitter and the type of modulation, and can be calculated for different modulation schemes using Table 5. The 0.80 factor used for the TV average power calculation is based on a totally black picture (60% peak TV power) plus aural signal (20% peak TV power). This can be considered a maximum average power level.

Attenuation

The attenuation of a transmission line is an expression of the ratio of input power to output power in decibels. It is determined by the material properties and construction of the line.
A listing of semi-flexible coaxial cable attenuation for various sizes and construction, set up by broadcast channels and frequencies, is presented in Table 6. The constructions listed are 50 ohm foam and air dielectric cables. Sizes correspond to the nominal diameter over the jacket. This data is based on a VSWR of 1.0 and an ambient temperature of 75°F (24°C).

Efficiency

Efficiency is a convenient way of expressing the power loss of a transmission line and is useful in selecting the appropriate line for the application. It is defined as the ratio of power delivered to the antenna to input power into the transmission line. It is easily calculated from the attenuation and length of the transmission line by applying the following equation:

$$\text{Efficiency} = \frac{\text{Power (out)}}{\text{Power (in)}} \times 100\%$$

$$\text{Efficiency} = \frac{100\%}{10^{\alpha/10}}$$

where: α = Total line attenuation in dB

Example: 300 feet of HJ9–50 5″ air dielectric coaxial cable for Channel 6.
Carrier frequency = 83.25 MHz
Attenuation = 0.071 db/100 ft (Obtained from Table 6)
L = 300 ft
α = 0.213 dB (.071 × 3)

$$\text{Efficiency} = \frac{100\%}{10^{.213/10}}$$

$$= \frac{100\%}{10^{.0213}}$$

$$= 95.21\%$$

The remaining power is dissipated in the transmission line as heat.

Connector Loss

The effect of connectors on transmission loss is negligible, except for small connectors (SMA, TNC) at frequencies of several GHz and higher. Therefore, for broadcast use, connector loss can be ignored.

Voltage Standing Wave Ratio (VSWR)

VSWR is an important factor in selecting a transmission line for a particular broadcast application. Typical VSWR values for standard semi-flexible cable and low VSWR semi-flexible cable are listed in Table 7.

The narrow bandwidths utilized in broadcast applications usually allow low VSWR cable to be selected. Therefore, it is important to let the manufacturer know what channel or bandwidth will be used.

Derating

The attenuation and power performance of transmission lines are affected by various external factors which must be taken into consideration. Cable attenuation and average power ratings are stated for particular operating conditions, which most likely will not be representative of a typical application. Performance will be affected by temperature, load VSWR, line pressure, line VSWR, and type of modulation.

Line attenuation will vary with ambient temperature as shown in the curve in Fig. 6. For example, if ambient temperature is increased by 101°F (56°C) above 75°F (24°C), to 176°F (80°C), attenuation will increase by a factor of 1.115 or 11.5%. Therefore, in the previous example for 300 ft of 5″ air dielectric cable, at 176°F total line attenuation would increase by a factor of 1.115, from 0.213 dB to 0.237 dB. This would decrease the efficiency to 94.69%.

The VSWR of the attached antenna will increase the total transmission loss of the system. Typically this is very small if there is a good match between the line and the antenna. Fig. 7 shows the minimum increase in loss with load VSWR, assuming a VSWR of 1.0 at the input of the transmission line.

The average power rating should be adjusted according to the actual ambient temperature, as shown in Fig. 8. In the example above, the average power

TABLE 6
Attenuation of semi-flexible coaxial cable assuming VSWR = 1.0 and ambient temperature = 75°F(24°C).

TABLE 7

Typical VSWR and return loss values for standard and low VSWR semi-flexible cable.

Frequency MHz	Band	Standard Semi-flexible Coaxial Cable Typical VSWR (Return Loss)	Low VSWR Semi-flexible Coaxial Cable Maximum VSWR (Return Loss)
0.53-1.61	AM	1.02 (40.1 dB)	N.A.
3-30	HF	1.02 (40.1 dB)	N.A.
54-216	VHF,FM	1.10 (26.4 dB)	1.05 (32.2 dB)
470-740	UHF	1.12 (24.9 dB)	1.08 (28.3 dB)
740-806	UHF	1.15 (23.1 dB)	1.10 (26.4 dB)

rating of the 5″ coaxial cable at 83.25 MHz would be 80.8 kW for 104°F (40°C) ambient temperature. If the long term average ambient temperature is 63°F (17°C), then the average power rating can be increased by a factor of 1.5, resulting in a 121.2 kW average power rating.

Average power should also be derated for VSWR. The derating factor (D.F.) is calculated from the formula given below where F^1 is a factor that varies with frequency and line size. Select the F^1 factor from Fig. 9, calculate the D.F. and divide into the average power.

$$DF = \frac{(VSWR^2 + 1)}{2\,(VSWR)} + \frac{F^1\,(VSWR^2 - 1)}{2\,(VSWR)}$$

The following example is a calculation for the Channel 6 case with 5″ coaxial cable:

VSWR = 1.10 (Typical system VSWR with semi-flexible cable)

F^1 = .39 (From Fig. 9)

$$D.F. = \frac{(1.10^2 + 1)}{2\,(1.10)} + \frac{.39\,(1.10^2 - 1)}{2\,(1.10)} = 1.042$$

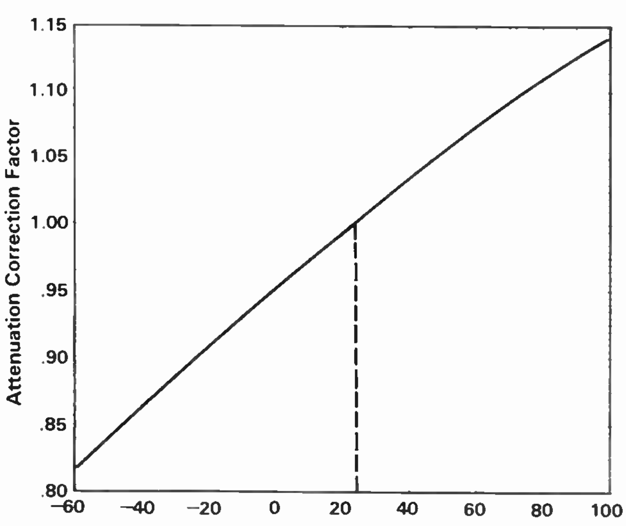

Figure 6. Variation of attenuation with ambient temperature.

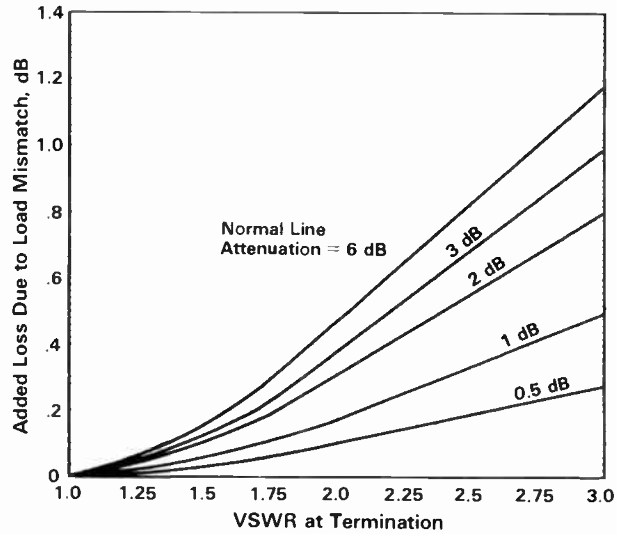

Figure 7. Effect of load VSWR on transmission loss.

Therefore, the average power rating of 80.8 kW (Table 4) will be decreased by a factor of 1.042, resulting in a 77.5 kW rating.

The peak power rating can be increased by pressurization, the use of high-density gases with high dielectric strength, or both. These effects are shown in Fig. 10.

Peak power ratings for semi-flexible cable must be derated for VSWR and modulation technique, as shown in Table 8:

Rated transmitter power must be less than the calculated derated peak power of the semi-flexible coaxial cable for safe operation.

Other Cable Characteristics

After selecting a cable on the basis of operating frequency, power handling, and attenuation, its other

Peak power derating for modulation and VSWR.

Modulation	Peak Power Derating Calculation
AM	$P_T < \dfrac{P_{PK}}{(1+M)^2 VSWR}$
FM	$P_T < \dfrac{P_{PK}}{VSWR}$
TV	$P_T < \dfrac{P_{PK}}{(1+AU+2\sqrt{AU})\,VSWR}$ $< \dfrac{P_{PK}}{(2.09)\,VSWR}$

P_T = Rated transmitter power
P_{PK} = Peak power rating of Table 4 or Table 17
M = Amplitude Modulation index
AU = Aural to visual ratio (20% Aural: AU = .2)
2.09 = Modulation derating factor for TV

characteristics should be considered. Some of these characteristics for typical semi-flexible coaxial cables are presented in Table 9. They include relative velocity, nominal inside transverse dimension in centimeters (required for FCC Form 302), diameter over jacket, minimum bend radius, and weight.

Connectors, Splices, and Adaptors

Usually the connector type is dictated by the antenna and transmitter input types and the performance required from the system. However, equally as important as connector selection is the care with which it is attached.

The instructions included with each connector must be followed with close attention to cable trimming dimensions. All surfaces must be as clean as possible to insure good electrical contact for the entire 360° around the cable edge. This is especially critical for higher power applications. All components must be tightened properly, and there must be no gaps on the electrical contact surface.

It is recommended practice to make all connector and splice attachments at ground level so that no chips from the cutting operation fall inside the cable. When a connector or splice must be attached to a cable already installed on the tower, tin snips or an equivalent tool should be used to do the preliminary cutting on the cable so as not to generate metallic chips. Rags should then be stuffed into the open cable ends to prevent chips from the final trimming and flaring operations from falling inside. Once the last chip-producing operations are completed, the rags can be carefully removed to avoid dropping any of the trapped particles.

Proper attachment of the finished connector to the mating antenna or radio equipment prevents loosening of the connection from vibration and other environmental stresses. Connectors with screw-on interfaces should be taped securely, using a two-part taping system. First, a layer of electrical tape is applied over both connectors (Fig. 11). Then a layer of butyl rubber tape is used to fill in any voids and make the outer surface relatively even (Figs. 12 and 13). Finally, additional electrical tape is added to compress the rubber tape and enclose the finished connection (Fig. 14). The resultant shape of this method has led to naming it the "Football Wrap."

Mated EIA style connectors must be carefully tightened. To avoid distorting the flange, tighten bolts that are opposite (not adjacent) to each other. Overtightening the hardware can also cause flange distortion. Care must be taken when seating O-rings to avoid pinching them between the flanges, which could result in poor electrical contact and air pressure leakage. See Table 10 for flange hardware requirements and recommended torque values.

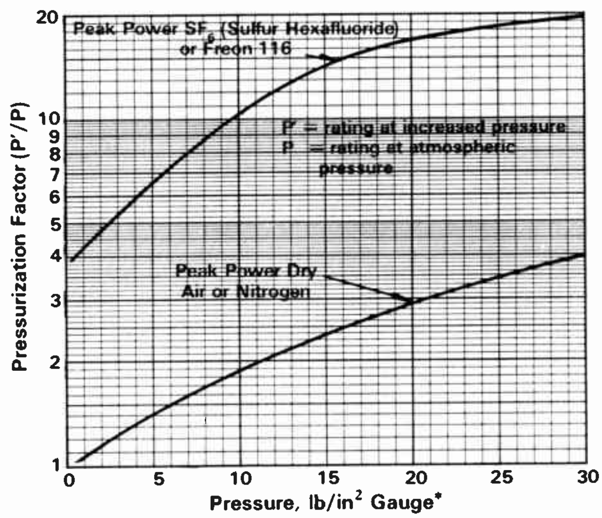

Figure 10. Pressurization factors.

TABLE 9
Characteristics of typical 50 ohm coaxial cables.

Size	Max. Freq GHz	Velocity Percent	Nominal Inside Transverse Dimension cm	Dia. Over Jacket Inches	Min. Bend Radius Inches	Weight lb/ft
Foam-Dielectric Cable

Figure 11. Wrap both connectors with layer of 3/4" plastic tape. Overlap tape to half its width and extend wrapping two inches beyond connection.

Figure 12. Cut butyl rubber tape into six 12" lengths. Form a tapered surface by starting with two tapes folded to half their widths. Finish with one full-width tape.

Figure 13. Lay three rubber tapes along the connection so they overlap. Pull tape as necessary for overlap. Press tapes together along overlaps.

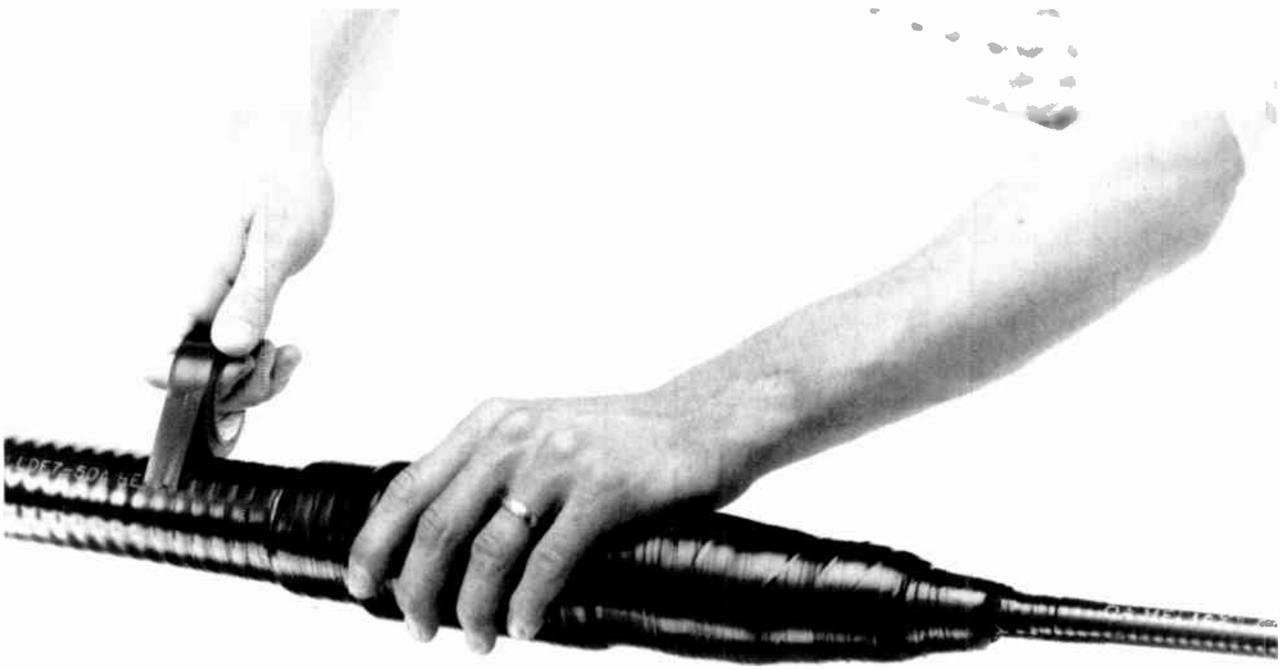

Figure 14. Wrap connection with layer of 2" tape, then layer of ¾" plastic tape. Overlap each winding to half the tape width. Extend wrapping two inches beyond previous tape. DO NOT PULL tape to tear it during last few turns; instead, cut it. (Pulled tape eventually unravels.)

Installation

General

Care is required in installing semi-flexible transmission line to assure a lasting installation and prevent damage. Procedures are outlined in Fig. 15. These tips distill the experience of many years of successful semi-flexible transmission line installation.

TABLE 10

EIA flange hardware requirements and recommended torque values.

EIA Flange Size	Bolt Size	No. of Bolts	Recommended Torque Value
7/8"	1/4"	3	80 lb-in (9.0 N-m)
1 5/8"	5/16"	4	140 lb-in (15.8 N-m)
3 1/8"	3/8"	6	20 lb-ft (27.1 N-m)
6 1/8"	3/8"	12	20 lb-ft (27.1 N-m)
8 3/16"	3/8"	18	20 lb-ft (27.1 N-m)
9" (SCL950)	3/8"	20	25 lb-ft (34.0 N-m)
9 3/16"	3/8"	20	20 lb-ft (27.1 N-m)

Hoisting grips are used to attach the cable to the hoisting line during lifting. Cable hangers (for ½" and larger cables) or nylon cable ties (for ⅜" and smaller cables) are used to affix the cable securely to the tower, and angle and round member adapters eliminate any need to drill holes.

Preparation for Installation

Inspect the cable for possible shipping damage and pressure loss. Most air dielectric cables are pressurized to 10 psig (70 kPa) for shipment. Allowable pressure drop is 1 psig (7 kPa) per 24 hours. Do not install cable which exceeds the standard leak rate without first checking to determine the cause.

Coaxial cables are usually shipped on reels or in cartons. These containers should be carefully handled to avoid damaging the cable. Reels should always be stored and moved on their flange edges and should never be laid flat or dropped during handling.

If a cable has been fitted with factory-attached connectors, leave their pressure plates or protective covers in place until ready to attach them to the mating

Installation "Do's"

1. Do keep reels on their flange edges during transportation and storage.
2. Do keep connectors and accessories stored where they will not be damaged by rain or dirt.
3. Do keep air dielectric cables pressurized and foam dielectric cables capped while in storage.
4. Do use hoisting grips to lift and secure each cable in place.
5. Do protect antenna end connectors from damage while lifting the cable up the tower.
6. Do securely install hangers on cable at the manufacturer's recommended spacing.
7. Do secure the cable coming out of the antenna to a tower member to prevent stress to the antenna input connection.
8. Do tighten EIA style connections to their recommended torque levels sequentially, to avoid flange distortion.
9. Do tighten the antenna end connection firmly to the antenna input.
10. Do tape connections to avoid loosening and water penetration.
11. Do pressurize air dielectric cable to 3–8 psig with dry air or nitrogen.
12. Do ground each cable run, as a minimum, at the top and bottom of the vertical run and at the equipment shelter entrance.

Installation "Don'ts"

1. Don't lay reels on their sides.
2. Don't install any cable that shows signs of physical damage.
3. Don't install foam dielectric cable that has been left uncapped. The exposed end should be cut back several feet and the cable given a TDR test (see Testing section) to be sure that no moisture penetration has occurred.
4. Don't install air dielectric cable that does not have positive air pressure. First, purge out any moisture that may be inside.
5. Don't release pressure from air cables unless making a connection, cutting cable from a bulk length, or purging the line.
6. Don't pay off cable from the reel too quickly, as it could cause tangling.
7. Don't attach cable to the tower where it could chafe against tower components.
8. Don't bend cable tighter than its minimum recommended bend radius.
9. Don't overtighten Type "N" connectors with pliers. These connections are designed for hand tightening only.
10. Don't leave connector interfaces unprotected from the environment.
11. Don't exceed the maximum air pressure level of the component with the lowest maximum pressure rating (such as an antenna or pressure window) when pressurizing a complete transmission line/antenna system.

Figure 15. Coaxial cable installation "do's" and "don'ts."

pieces of equipment. This will protect the connector interfaces from handling damage.

Installation on Towers

Hoisting grips should be attached to the cable and hoist line as shown in Fig. 16. When installing lengths of more than 200 ft (60 m), additional hoisting grips at 200 ft (60 m) maximum intervals are required.

Reels can be used to unroll the cable slowly during hoisting. A pipe inserted through the reel hub and supported by stands will allow controlled unreeling. Pay off the cable from the bottom as shown in Fig. 16. Cable shipped in cartons can be uncoiled on the ground and carefully pulled up.

After the cable has been lifted, the hoisting grips can be permanently attached to the tower. The bottom end of each grip should be securely taped to the cable to prevent loosening and eventual slippage.

Hanger Installation

Proper hanger installation techniques are vital to trouble free operation. The purpose of hangers is to prevent cable movement from wind, rain, ice, and other forces. Excessive movement could damage the cable from abrasion and work hardening of the outer conductor. Each site needs to be evaluated thoroughly to determine what type of hanger (and standoff, if any) should be used and how far apart they should be spaced. As a starting point, the manufacturer's recommended hanger spacing for the size cable being installed should be considered.

The following are examples of the site variables that should be addressed:

- Cable size
- Tower height
- Proximity of tower members and joints
- Wind velocity extremes
- Average wind velocity
- Ice loading
- Temperature extremes
- Accessibility for future maintenance

As a general rule, hanger spacing should be halved (i.e., use double the number of hangers) when the wind velocity is consistently over 40 mph (65 km/h), where

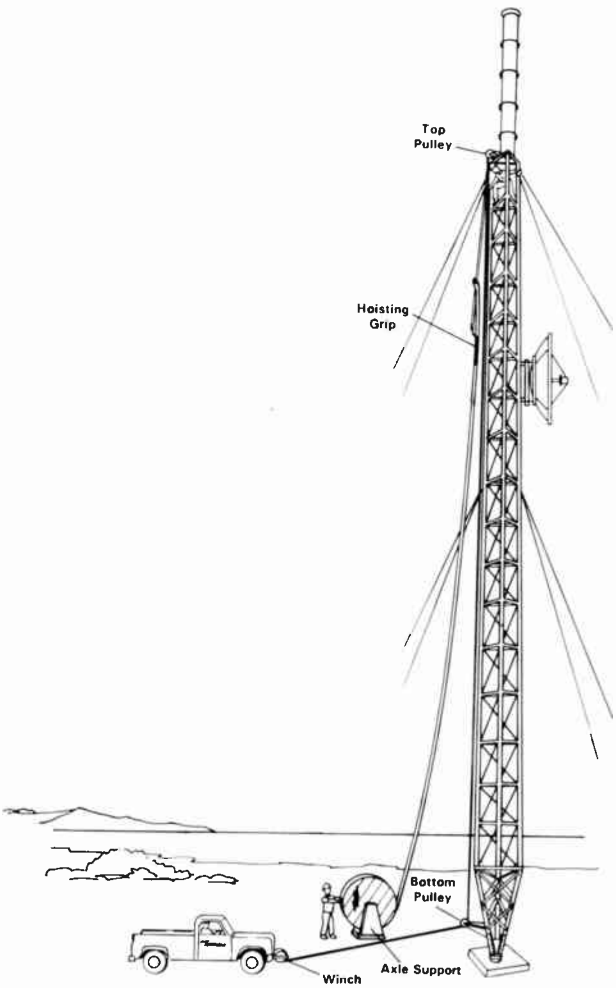

Figure 16. Installation of coaxial cable.

peak wind velocity may exceed 125 mph (200 km/h) and/or when heavy radial ice [½" (13 mm) to 2" (50 mm) thick] is expected to form.

Horizontal Runs

Horizontal coaxial cable runs need to be adequately supported. Typically they are either supported by an ice shield or buried.

Horizontal runs supported by an ice shield. Horizontal cable runs supported by ice shields or other structures normally require the same hanger spacing as the vertical run. A broad drip loop (Fig. 5) will help prevent moisture accumulation at the building entry feed-through. If water emerges from the building entry connection, indicating that the jacket has been damaged somewhere along its length, allowing water entry, a notch in the jacket at the bottom of the drip loop will allow for drainage.

Buried horizontal runs. Jacketed corrugated copper cables are very corrosion resistant and can be safely buried. Cable should be located below the frost line and placed in the middle of a 12" layer of sand to protect the jacket from stones or other sharp objects.

Conduit is also very desirable for burial installations, especially when the cable is to be placed under a service road. Care should be taken so as not to exceed the tensile strength of the cable when pulling it through. See Table 11 for typical tensile values. Conduit pulling lubricants should be applied generously to the cable. Bends should be kept to a minimum and should be long and sweeping to prevent overstressing.

Since any buried cable will likely become wet or occasionally submerged, all buried connectors or splices should be protected with a good weatherproofing kit. See "Connectors, Splices, and Adapters" section above for a step-by-step description of weatherproofing connections. Fig. 17 shows a photograph of a well-sealed splice connection.

Pressurization

Air dielectric transmission lines are pressurized with dry air or nitrogen for two reasons. First, the inside of the line must be kept dry to prevent possible corrosion of the copper inner and outer conductors. Second, electrical performance will be severely impaired if water enters the line, as VSWR and attenuation can be degraded.

Table 12 summarizes the advantages and disadvantages of four pressurization systems: nitrogen, manual regenerative dehydrator, automatic regenerative dehydrator and automatic continuous membrane dehydrator. Automatic dehydrators are recommended for unattended sites or those with a large number of runs.

After all connections have been made, purge and repressurize air dielectric cable to remove any residual moisture. Follow the guidelines set forth in the "Moisture Purging" section.

A gauge pressure of 8 psig is adequate for most installations. A pressure exceeding 10 psig (70 kPa) is unnecessary and could lead to damage to antennas, gas barriers, or other pressure sensitive devices. Usually the upper pressure limit is determined by the pressure rating of some other system component, such as the antenna.

After installation, check all connections for leaks. Use commercially available leak detectors or liquid detergent. An unbroken soap film applied over the entire joint will show even very small leaks.

The desiccant in a dehydrator may become saturated by ordinary atmospheric humidity if the dehydrator

TABLE 11

Typical tensile strength of coaxial cables commonly used for burial in conduit.

Cable Size	Dielectric Type	Tensile Strength
½"	low density foam	250 lbs (1112 N)
½"	air	700 lbs (3113 N)
⅞"	low density foam	325 lbs (1445 N)
⅞"	air	800 lbs (3560 N)
1¼"	low density foam	1500 lbs (6670 N)

Figure 17. A well-sealed splice connection protected with a "football wrap."

does not run for long periods (several weeks). It is good practice to allow some pressure (1 psig to 3 psig) to be released from the cable periodically. This enables the dehydrator to regenerate its desiccant.

Moisture Purging

Removing moisture from air dielectric semi-flexible cable may be necessary due to loss of pressure during storage, installation, or operation. It is also a good preventive maintenance practice to purge the cable periodically, since condensation can form from normal capillary action, especially on larger size cable.

On cables that are known to have been without pressure for some time, make sure there is no water near the bottom connector. This can be done by removing the connector body and lowering that end of the cable to see if any water drips out.

To purge the cable, attach an air line to the transmitter end connector gas port plug and remove the plug from the antenna end connector. Purge the line with dry nitrogen or air from a dehydrator. Set the regulator to 5 psi to 10 psi and purge at the rate of one hour for every 50 ft of cable.

If access to the antenna end connector is limited, an alternate method is to pressurize to 8 psig and let the air escape at the transmitter end of the cable after one hour. Repeat this procedure several times, allowing one hour each time for the air to mix.

After purging, replace the gas port plug and pressurize the cable to 8 psig. Then test the cable for insulation resistance as described in the "Testing" section following. Repeat the purging procedure if necessary.

TABLE 12

Comparison of broadcast pressurization systems.

Advantages	Disadvantages
Dry Nitrogen Tank System	
Good for small tight systems.	Low purge and system volumes.
Low dew point, −90°F (−68°C).	Complex regulator and alarm installations.
No power required.	Cylinder transportation and handling.
No moving parts and noise free.	
Manual Regenerative Dehydrator	
Good for small tight systems.	Requires periodic inspection.
Low power consumption.	Saturated silica gel must be baked and/or replaced.
10–15 year life expectancy.	Requires power.
Oil and lubrication free.	Low purge and system volume.
Dew point in excess of −36°F (−38°C).	Generates low level noise.
Automatic Regenerative Dehydrator	
Provides oil free air.	Requires power.
Dew point in excess of −40°F (−40°C).	Moving parts require maintenance every 5,000 hours.
System easy to install.	Generates periodic noise.
High purge and system volumes.	
No lubrication required.	
Automatic Continuous Membrane Dehydrator	
Provides oil free air.	Requires power.
Dew point in excess of −50°F (−46°C).	Moving parts require maintenance every 6,000 hours.
System easy to install.	Generates low level noise periodically.
No lubrication required.	
Meets UL®, CSA® requirements.	

Grounding

Grounding of semi-flexible transmission line is very important in order to protect against the extremely large currents created during lightning strikes, since the outer conductor forms a direct connection to the transmitter equipment.

The tower presents a lower impedance to ground for lightning than either the outer conductor of the coaxial cable or the antenna input connector; consequently, the outer conductor of the cable must be grounded close to the antenna, allowing the currents to travel down the tower to earth ground. On long vertical runs, grounding the cable at 200 ft (60 m) intervals is considered prudent. It should also be grounded at the bottom of the vertical run and again at the point where it enters the equipment building (to the external building grounding system), as shown in Fig. 5, as this is the last point at which lightning currents can be shunted to ground before they enter the transmitter room. Inside the building, grounding is covered by local requirements; for example, grounding inside the building as well as outside may be required by Article 820–33 of the National Electrical Code.®

Ground connections must be made with high quality copper wire or straps. Military standards and some local codes prohibit the use of braided copper straps or fine stranded wire. These materials will corrode in time, increasing the impedance of the connection and leading to possible equipment damage when lightning strikes occur.

After installation, all ground connections at the cable should be weatherproofed to prevent electrical contact degradation and to keep moisture from collecting between the cable jacket and outer conductor. Local building codes vary, so grounding plans should be checked for compliance to these codes.

Considerations for AM Tower Installations

If the supporting tower is also used as an AM broadcast radiator, it is necessary to prevent the AM energy from being grounded by the transmission line that feeds the TV or FM antenna. One way to accomplish this is to isolate the line up the tower for a distance of a quarter wavelength (at the AM broadcast frequency) from the base, using insulated cable hangers (Fig. 18). Because of the quarter wave isolation from the base of the tower, a very high impedance between the tower and the line is presented to the AM energy. Common practice is to make the isolated section approximately 0.22 wavelength long and to use a variable capacitor at the base of the tower to tune to quarter wave resonance. An RF isolation transformer is also an acceptable technique to avoid grounding.

Caution: Since a high RF potential exists between the line and the tower, the line should be mounted where it will not be accidentally touched by anyone on the tower climbing ladder.

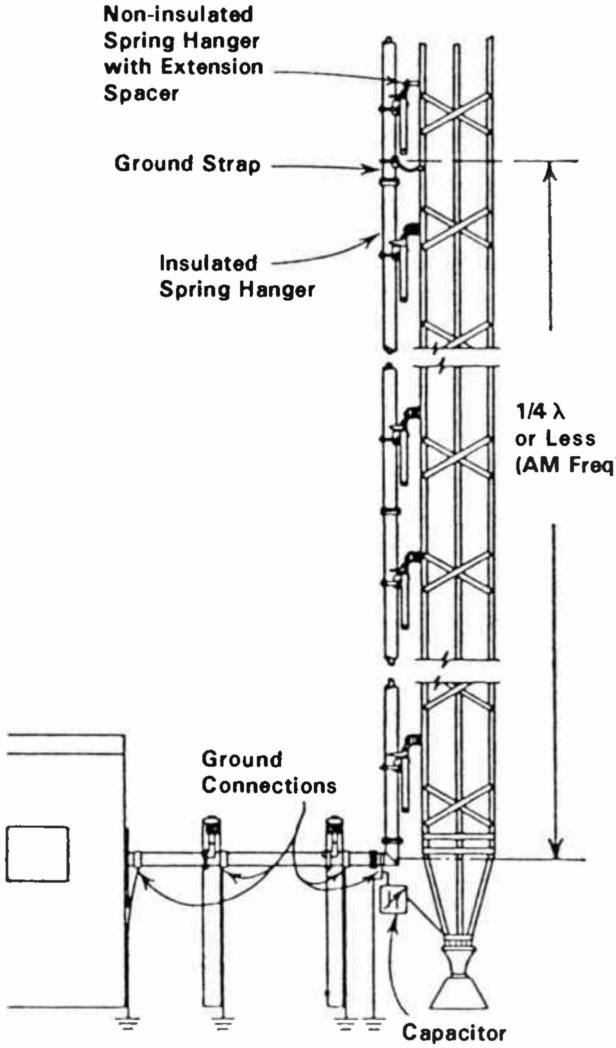

Figure 18. Installation on AM tower.

Sampling Lines

In order to obtain the desired pattern in an AM directional antenna, the relative phase and magnitude of the current in each radiator must be controlled. Monitoring of this current is done by installing sampling loops on one leg of each tower, with a length of coaxial cable terminated via a strap or end terminal. This coaxial cable is called a sampling line.

The purpose of a sampling line is to carry the current that results from the voltage induced across the sampling loop (which should be proportional to the tower current) to a phase monitor. Whether the sampling line current is a true representation of the phase of the radiator current depends on the phase stability of the sampling line.

Ordinary coaxial cable should not be used for sampling lines, since it is subject to significant phase variation with temperature change when first installed. Instead, special phase stabilized foam polyethylene dielectric or air dielectric coaxial cable should be specified. This cable has been repeatedly cycled by the manufacturer through a wide temperature range to eliminate phase instability caused by hysteresis. Foam dielectric cables are generally preferred for sampling lines, these cables being ordered from the manufacturer precut to a precise electrical length.

Testing

General

Electrical testing of semi-flexible coaxial cable should be performed after installation and prior to applying power. Testing should also be used for troubleshooting after VSWR trips have occurred, to locate the cause of the trip. It is advantageous to test while installation personnel are still on site.

Electrical testing is usually done to verify the performance of the transmission system. Common tests that are performed are the return loss (VSWR) sweep test and RF pulse test. These tests operate over the bandwidth of the system and give a good indication of line and antenna performance. Network analyzers with time domain capabilities and lightweight line analyzers can be used for overall system performance checks and are also excellent for locating discontinuities not detectable by RF pulse methods. Traditional time-domain reflectometry (TDR) devices can also be used to locate these discontinuities, but will not give an overall indication of performance over the channel bandwidth. This section reviews each technique and presents actual data taken on transmission line systems.

Sweep Test

The sweep test is a frequency domain test that measures the return loss of the line swept over the channel bandwidth. This test should be performed before power is applied to the line and must be done with the end of the line terminated in either the antenna or a load. The effects of the terminating device will be included in the measurement.

A return loss sweep test curve of a UHF-TV transmission system is shown in Fig. 19. The system consists of 800 ft of HJ9–50 air dielectric semi-flexible coaxial cable and a top mounted antenna. The maximum return loss level is about −26 dB (1.106 VSWR). The rippling effect in the trace arises from the continuous phasing of the reflection from the ends of the system.

RF Pulse Test

The RF pulse test shows the performance of the line in the time domain. This test displays impedance changes versus time and allows the user to correlate relative electrical (return loss) performance to general location in the line.

The test is done by applying a CW burst to the line and observing the reflected signal in time. The frequency of the CW is equal to the center frequency of the channel bandwidth, and the duration of the burst is equal to the inverse of the channel bandwidth times two. This technique allows the performance of the transmission system over the channel bandwidth to be displayed in time (length). The disadvantage of the pulse test is that information over only a small bandwidth is used to derive the time domain characteristics. This means the display will show only gross defects in the system.

In most time domain tests, such as RF pulse, the response curve expresses return loss in decibels versus time on the horizontal axis. A rough conversion of time to distance for air dielectric cables is 2.0 nanoseconds per foot. (This allows for the round trip time of the pulse.) The calculation can be refined by including the velocity of propagation of the particular cable.

Network Analyzers

Network analyzers with time domain capabilities can be used for both sweep testing and simulation of RF pulse and TDR testing. The advantages of this equipment are that one unit contains all the necessary transmission testing functions and the time domain functions allow excellent control over the resolution. The time domain can be used to simulate an RF pulse by looking over only a small frequency range (i.e., channel bandwidth), or over the entire range of frequencies up to line cut-off. Using the equipment up to cut-off gives excellent resolution and allows small impedance variations to be displayed in time (length). Therefore, the analyzer can be used to locate problems that are not seen with pulse testing but could lead to eventual failures. The disadvantages of a network analyzer are size and cost.

An impedance plot of a transmission system using a network analyzer is shown in Fig. 20. The time domain information was calculated from data taken in the frequency domain up to 900 MHz. Note that this sensitive test revealed a slight discontinuity (−43 dB) in the vertical run, arising from a splice in the coaxial cable.

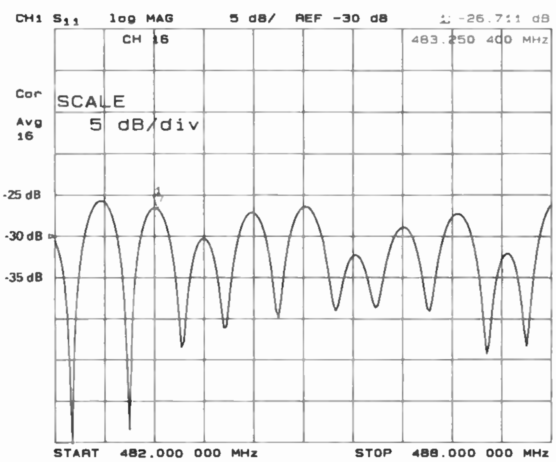

Figure 19. Swept return loss of system including antenna and 800 ft. of HJ9-50, 5″ air dielectric semi-flexible coaxial cable.

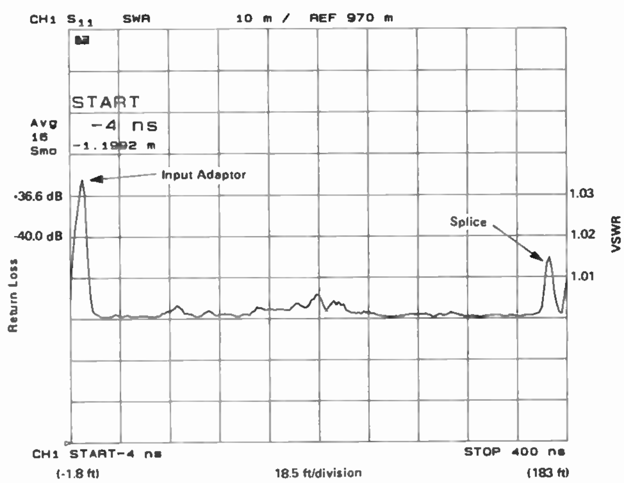

Figure 20. Time domain impedence plot of system including antenna and 800 ft. of HJ9-50, 5″ air dielectric semi-flexible coaxial cable (first 183 ft. shown).

(Note: All of these tests were performed using an HP 8753C Network Analyzer with time domain analysis. This unit is excellent for performing complete line verification and debugging.)

Time Domain Reflectometry (TDR) Test
A TDR test can be used to examine a transmission line for faults. The TDR test set transmits a fast rise time voltage step and measures the reflected signal. This signal will have significant frequency components up to 35% of the inverse of the pulse rise time. Therefore, it is important to adjust the pulse rise time to the cut-off frequency of the line.

Since TDR is a broadband test, it cannot be used to determine the performance of the line over the channel bandwidth.

Transmission Line Analyzers
Commercial transmission line analyzers are available that are made for field use so they are easily hand-carried to the site. The majority are used as fault finders and simulate a TDR test, but it is beneficial to have a unit that will also do a sweep test and simulate an RF pulse test. One such unit is the Systron Donner model 5220 Transline Analyzer. The 5220 will provide all of the characteristics discussed in the network analyzer section, but is easy to use, lightweight and provides a hard copy printout.

Insulation Resistance Test
An insulation resistance test can be performed on a semi-flexible coaxial cable to determine if it is sufficiently dry after purging with dry air before applying power. This test should be performed after any line has suffered from moisture ingress. The insulation resistance between the inner and outer conductor should be greater than 100,000 Megohms. There are many inexpensive units available that can measure insulation resistance.

Maintenance
Semi-flexible coaxial cable should be maintained according to the following guidelines:

1. Maintain at least 3 lb/in^2 of dry air or nitrogen pressure at all times.
2. If a leak occurs, keep positive pressure on the line until the leak is repaired. This will reduce moisture ingress.
3. Locate and repair pressure leaks immediately.
4. If moisture problems are suspected, shake the line near the bottom of the vertical run to see if significant performance changes occur. If so, open line and let water drain.
5. Purge system after pressure leak repair.
6. Do not continually override the transmitter reverse power trip. When a trip occurs, inspect line carefully to determine problem before reapplying power.
7. Visually inspect system on a yearly basis, checking hangers for tightness, grounding kits for good contact, and connectors for pressure leaks.

RIGID LINE

General
This section reviews the common sizes of rigid coaxial transmission lines used in broadcast applications, ranging from ⅞" to 9³⁄₁₆" in diameter. Fig. 21 shows the construction of a typical coaxial rigid line. Rigid lines have inherently low attenuation and VSWR which make them ideal for high power broadcast applications. Inner conductors are fabricated using high conductivity oxygen-free hard copper tubing. Outer conductors are also made of copper, but can be constructed with aluminum to reduce cost and weight. The lengths are made in 20 ft. (nominal) flanged sections. The copper inner conductor is supported in the outer conductor by peg or disc insulators with a low dielectric constant, low dissipation factor, high voltage breakdown, and good stability at high operating temperatures. Teflon, which has these characteristics, is usually used for the support insulator in rigid lines. The outer and inner conductor diameters are chosen to obtain a desired characteristic impedance of the line, normally 50 or 75 ohms.

The inner conductors of adjacent line sections are joined together by inner connector "bullets" which have fitted Teflon insulators that are captured in the outer flanges. Fig. 22 shows a connector for a 6⅛" 75 ohm line. Tension spring fingers on each end of the inner connector fit inside the inner conductors and connect two adjacent inner conductors together mechanically and electrically. This ensures efficient transfer of power. The insulator serves to anchor the inner conductor within the outer conductor in a vertical installation. Silver plating is commonly used on inner connectors to reduce the resistive losses of the joint.

The outer conductors are attached by bolting the flanges together; RF electrical contact is made between flanges by a raised contact surface. A pressure seal is maintained in the line by a flange O-ring. EIA standards RS-225 and RS-259 cover some 50 ohm and 75 ohm rigid coaxial transmission lines.

Propagation Factors

TEM Mode of Propagation
In a coaxial line the usual mode of energy wave propagation is TEM (Transverse Electromagnetic). In this mode the electric and magnetic fields are both perpendicular to the direction of energy propagation (Fig. 1A). This mode determines the impedance, attenuation, phase shift, and velocity of propagation characteristics.

Velocity of Propagation
The velocity of propagation (V_P) is equal to $\frac{1}{\sqrt{\epsilon'}}$ and is expressed as a fraction of the speed of light in a vacuum (approximately 300,000,000 m/sec). For example, TFE Teflon has a dielectric constant, ϵ', of 2.1, so its V_P equals 0.69. Therefore, the TEM wave

Figure 21. 6⅛", 75-ohm rigid coaxial line.

will travel at 207,000,000 m/sec through a solid piece of Teflon.

Determination of Cut-Off Frequency

The cut-off frequency of a coaxial line is the frequency above which undesirable modes of propagation are generated. Therefore a coaxial line must be used below this frequency Cut-off frequency, f_c, is inversely related to conductor dimensions and the relative dielectric constant of the insulation material as shown in the following equation:

$$f_c(GHz) = \frac{7.52}{\sqrt{\epsilon'}(D + d)}$$

The coaxial line should operate below this frequency.

Consideration of maximum frequency is important in high power TV applications where the cut-off frequencies start to fall in the UHF bands for the larger size coax lines (6⅛" and above). The specified maximum operating frequency for rigid coax includes a safety factor and is somewhat lower than the calculated cut-off frequency.

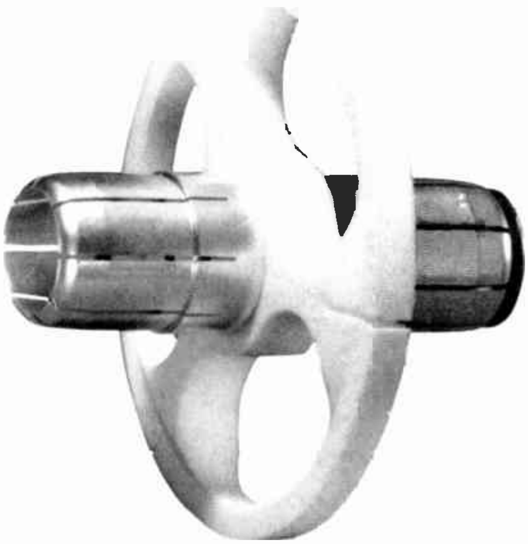

Figure 22. Inner connector for a 6⅛", 75-ohm rigid line.

VSWR, Return Loss, Reflection Coefficient

The voltage standing wave ratio (VSWR), return loss, and reflection coefficient are expressions relating the impedance of a transmission system to the reference impedance (usually 50 or 75 ohms). A change in impedance, from reference, will produce a reflected signal from the incident wave. The reverse and forward traveling signals will produce a standing wave in the line. Some useful conversion equations are given in Table 13.

Narrow band VSWR spikes will occur in a transmission line system when there are inherent periodic impedance changes. The frequency of the VSWR

TABLE 13
Conversion formulas.

$RL = -20\log(\lvert\Gamma\rvert)$	$VSWR = \frac{1+\lvert\Gamma\rvert}{1-\lvert\Gamma\rvert}$	$\lvert\Gamma\rvert = \frac{VSWR-1}{VSWR+1}$
$\lvert\Gamma\rvert = 10^{-\frac{RL}{20}}$		$\lvert\Gamma\rvert^2 = \frac{Pr}{Pn}$

RL: Return Loss, dB
Γ: Reflection Coefficient
VSWR: Voltage Standing Wave Ratio
Pn: Incident Power, Watts
Pr: Reflected Power, Watts

spikes is inversely related to the distance between discontinuities according to the following equation:

$$F_{SPIKE}(MHz) = \frac{492.15 \times V_P \times N}{L}$$

where: F_{SPIKE} = Frequency of VSWR spikes, MHz
N = Any integer
V_P = Velocity of propagation (assuming an approximate speed of 300,000,000 m/sec)
L = Equal distance between impedance discontinuities, ft

The level of the VSWR spike depends on the number of evenly spaced discontinuities and magnitude of impedance change.

High Power/Thermal Issues

Thermal Analysis

In a high power broadcast application, the inner conductor of a transmission line will run substantially hotter than the outer conductor. For example, if 60 kW average power is applied to a 6⅛" 75-ohm rigid line at a carrier frequency equivalent to channel 27 (549 MHz), the inner conductor will typically run 74°F hotter than the outer conductor.

With the thermal expansion of copper being 9.8×10^{-6} in/in/°F, the inner will expand by 0.174" over a 20 ft section of line with respect to the outer. In semi-flexible line this growth is absorbed in the corrugations of the inner and outer conductor. For conventional rigid line, the only place for this movement to occur is on the interface of the inner conductor and inner connector. Since the inner connector at each flange is captured by the Teflon insulator, the movement is contained in each section.

To allow for this movement the inner conductor of the line is made slightly shorter so that it will not bottom out on the shoulder of the inner connector when it expands. When the power level in the line is varied, the inner conductor will move on the inner connector. This movement, which is most severe when the transmitter is turned on for operation, will cause an electrical and mechanical degradation in the inner joint and eventually produce metallic shavings. These shavings, over time, can accumulate on the flange insulators and create a path allowing a voltage flashover to occur. The degradation will also cause an increase in I^2R losses at the joint resulting in additional power losses and possible overheating of the dielectric insulator supporting the inner connector.

Expansion/Contraction Compensation Devices

To overcome this problem in the inner joints of rigid lines, expansion/contraction compensating devices are used. Two basic designs are available for high power rigid coaxial lines: the watchband spring and the bellows (Fig. 23). The watchband spring allows the movement to occur on a spring which is built into one end of the inner connector. This effectively reduces wear between the inner connector and inner conductor. The bellows device is built into the inner conductor and absorbs the differential growth/shrinkage of the inner. This eliminates any mechanical movement of the inner conductor on the inner connector, similar to the corrugation principle used in the construction of semi-flexible transmission lines.

The other major area of concern at the junction of the inner connector and inner conductor is overheating due to poor contact pressure. Localized hot spots, created by years of resistive losses at points of higher resistance around the joint circumference, can ultimately cascade to failure. The watchband spring must provide the proper amount of uniform contact pressure throughout the life of the joint while being subjected to the abrasion of the expansion/contraction process. In the bellows approach, all the surface area of the spring fingers is in contact with the inner conductor and provides the maximum contact pressure desired to assure efficient power transfer. Since no movement occurs at this joint in the bellows line, the amount of bullet insertion force can be maximized and will remain constant.

The different compensation methods must be evaluated by the user to ensure that the possibility of flashover due to metallic shavings, or heating due to varying contact pressure, is reduced as much as possible over the life of the line.

Applications

Generally, rigid lines are used for the main feeder run from the transmitter diplexer output to the antenna input in high power FM, VHF, and UHF television broadcast applications and for interior runs between transmitter and diplexer.

Line Selection Issues

Rigid line is selected on the basis of frequency of operation, power to be transmitted, acceptable loss of power (attenuation), installation, and cost. During the selection process the attenuation and power ratings of the line must be derated to take into consideration the particular characteristics of the installation site. This section discusses what factors must be considered when selecting a rigid line for a particular site. The section concludes with a case study for a given TV application that walks through all of the calculations that are necessary in the selection process.

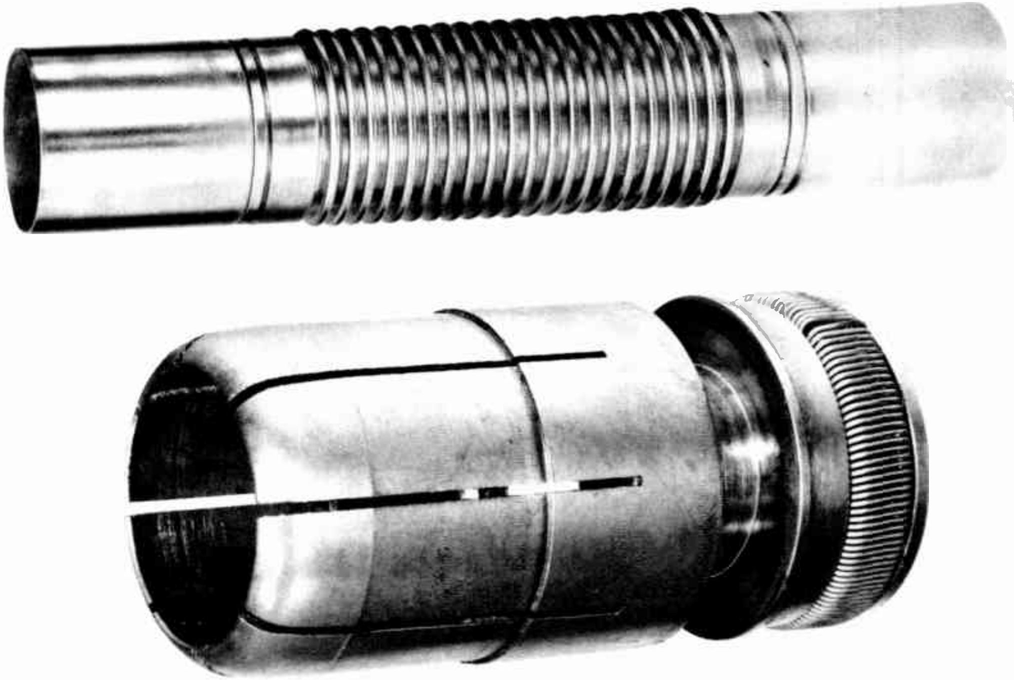

Figure 23. Compensation devices.

Characteristics

Table 14 is a partial listing of rigid line characteristics for the standard sizes and impedances.

Note that for the same size line, 75-ohm versions have a higher cut-off frequency than 50-ohm versions. Also, note that the velocity of propagation is expressed as a percentage of the speed of light in a vacuum.

Section Lengths

When selecting a rigid line for an application, the section length must be taken into consideration. The length must be chosen such that the frequency of operation does not fall into a VSWR reject band. The section length must not correspond to the half-wavelength or any multiple thereof. Table 15 is a listing of recommended lengths versus TV channel number or FM frequency.

While these are not the only choices possible, they do provide the most operating margin from the VSWR reject bands. Other choices can be used as long as the desired operating frequency is at least 2.0 MHz away from the calculated VSWR spike location.

Peak Power

The peak power rating of a coaxial transmission line is limited by the voltage breakdown (flashover) between the inner and outer conductors and is the maximum RMS power which can be reached in any

modulation interval. At one manufacturer, peak power ratings are determined according to the following equation:

$$P_{PK} = \frac{\left(\frac{.7E_P}{2\sqrt{2}}\right)^2}{Z_C}$$

where: P_{PK} = Peak power rating (standard conditions), watts
E_P = DC production test voltage, volts
0.7 = DC to RF factor
2 = Safety factor on voltage
$\sqrt{2}$ = RMS factor
Z_C = Characteristic impedance, ohms

In this case the production test voltage, E_P, is 35% of the theoretical breakdown voltage for a given line size. Peak power ratings vary between manufacturers depending on the voltage safety factor and test voltage values used.

One manufacturer's peak power ratings for common rigid line sizes are given in Table 16 and correspond to the power rating at 1.0 MHz (AM). These values must be derated for VSWR, modulation, and pressurization.

Peak Power Derating

Peak power ratings can be increased by pressurization and/or use of high density gases with high dielectric strength (i.e., sulfur hexafluoride and Freon 116). The effects are shown in Fig. 10. The disadvantage, however, is the inherent risk of voltage breakdown in the event of failure of the pressure system.

Peak power derating calculations for modulation techniques and VSWR are the same as for semi-flexible cable, and are given in Table 8.

Average Power

Average power ratings are based on a maximum inner conductor operating temperature generated from losses in the conductors. Table 16 lists the average power ratings of rigid lines. These are based on an inner conductor temperature of 216°F (102°C), an ambient temperature of 104°F (40°C), a terminating VSWR of 1.0 and dry air atmospheric pressure. When engineering for a specific application, average power must be derated for higher ambient temperature, expected termination VSWR and type of modulation.

Average Power Derating

The average power rating must be adjusted according to the actual ambient temperature since the ambient will influence the maximum temperature of the inner conductors. Fig. 24 shows the variation of average power with ambient temperature.

The average power rating must also be derated to account for VSWR. The derating factor is calculated from the following formula:

$$D.F. = \frac{(VSWR^2 + 1)}{2(VSWR)} + \frac{F^1(VSWR^2 - 1}{2(VSWR)}$$

where F^1 is a factor that varies with frequency and line size and is selected from the appropriate curve of Fig. 25.

The average power of the transmitter must be less than the calculated derated average power rating of the transmission line. As for semi-flexible cable, average power can be calculated for different modulation schemes using Table 5.

Attenuation

The attenuation of a transmission line is an expression of the ratio of input power to output power in decibels (dB). Table 17 is a listing of attenuation values versus carrier frequency based on an ambient temperature of 75°F (24°C) and unity VSWR. The line attenuation must be derated for ambient temperature and load VSWR.

Attenuation Derating

Fig. 6 shows the relationship between ambient temperature and the attenuation correction factor. The VSWR of the attached antenna (load) also contributes to the total transmission loss of the system. Typically this is very small due to the good match that usually exists between the line and antenna. Fig. 7 shows the increase in loss with load VSWR, assuming a VSWR of 1.0 at the input of the transmission line.

Efficiency

Efficiency is an expression of the power loss for a transmission line and is useful in selecting the appropriate line for an application. It is defined as the ratio of power delivered to the antenna to the input power into the transmission line. It is easily calculated by knowing the corrected attenuation and length of the rigid line and applying the following equation:

$$\text{Efficiency} = \frac{100\%}{10^{\frac{\alpha}{10}}}$$

where: α = Total line attenuation, dB

* Peak Power Rating Value

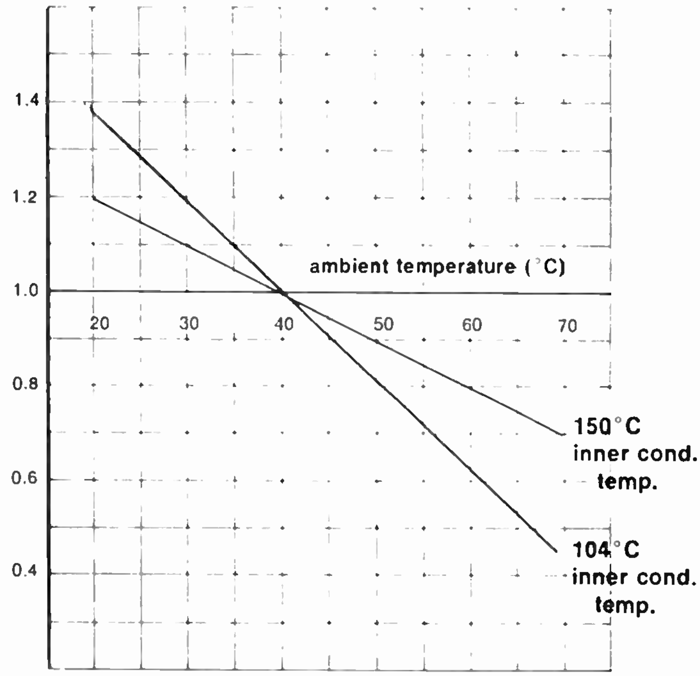

Figure 24. Variation of average power with ambient temperature.

VSWR

Rigid lines offer generally lower VSWR specifications than semi-flexible lines, over a single channel bandwidth. A good rigid line will have a maximum VSWR of 1.02 per component and 1.07 for a complete run (not including antenna). Fine matchers used at the input and output of the line can further improve the VSWR at particular locations in the operating band.

Selection Example

Following is an example of rigid line selection for a UHF-TV broadcast application. For the station characteristics given, a group of acceptable rigid lines are selected.

Station Characteristics.

Channel	56
Frequency Band	722 to 728 MHz
Video Carrier Frequency	723.25 MHz
Transmitter Power (Peak Sync.)	60 kW
Aural Power, 20%	12 kW
Modulation	TV
Line Length	600 ft
Load/Antenna VSWR (Inflated)	1.25
Average Ambient Temperature	68°F (20°C)

Cut-Off Frequency (Table 14). Cut-off frequency (f_C) of line must be greater than 728 MHz (top of channel band). Line sizes ⅞" to 6⅛" meet this requirement.

Peak Power Derating for VSWR and Modulation (Tables 8 & 16).

$$P_{PK} > P_{TRANSMITTER}(1 + AU + 2\sqrt{AU})\ VSWR$$
$$AU = .2\ (\textit{aural is 20\% peak sync.})$$
$$P_{PK} > 60\ kW\,(1 + .2 + 2\sqrt{.2})\ 1.25$$
$$P_{PK} > 60\ kW\,(2.09)\ 1.25$$
$$P_{PK} > 157\ kW$$

Peak power rating (P_{PK}) of line must be greater than 157 kW.

Line sizes 3⅛" to 9³⁄₁₆" meet this requirement.

This leaves a preliminary acceptable range of 3⅛" to 6⅛" rigid line sizes.

Transmitter Average Power Calculation (Table 5).

$$P_{AVG} = 0.8\ (P_{TV}) = 0.8\ (60\ kW) = 48\ kW$$

Rigid Line Average Power Rating Adjustments for Actual Ambient Temperature and Antenna VSWR.

Line Size Line Impedance	3⅛" 50Ω	4¹⁄₁₆" 50Ω	6⅛" 50Ω	6⅛" 75Ω
Rigid Line Average Power Rating (Table 17)	21.23 kW	30.52 kW	61.14 kW	52.89 kW
Adjustment for 68°F (20°C) Ambient (Fig. 25) x 1.37	29.09 kW	41.81 kW	83.76 kW	72.46 kW
Derating for Antenna VSWR F' Factor (Fig. 26)	.01	.01	.01	.01
Derating Factor Calculation:				
Adjusted Average Power ÷ 1.027	28.32 kW	40.71 kW	81.56 kW	70.55 kW

Derating Factor Calculation:

$$D.F. = \frac{(VSWR^2 + 1)}{2\,(VSWR)} + \frac{F'(VSWR^2 - 1)}{2\,(VSWR)}$$
$$= \frac{(1.25^2 + 1)}{2\,(1.25)} + \frac{.01\,(1.25^2 - 1)}{2\,(1.25)}$$
$$= 1.027$$

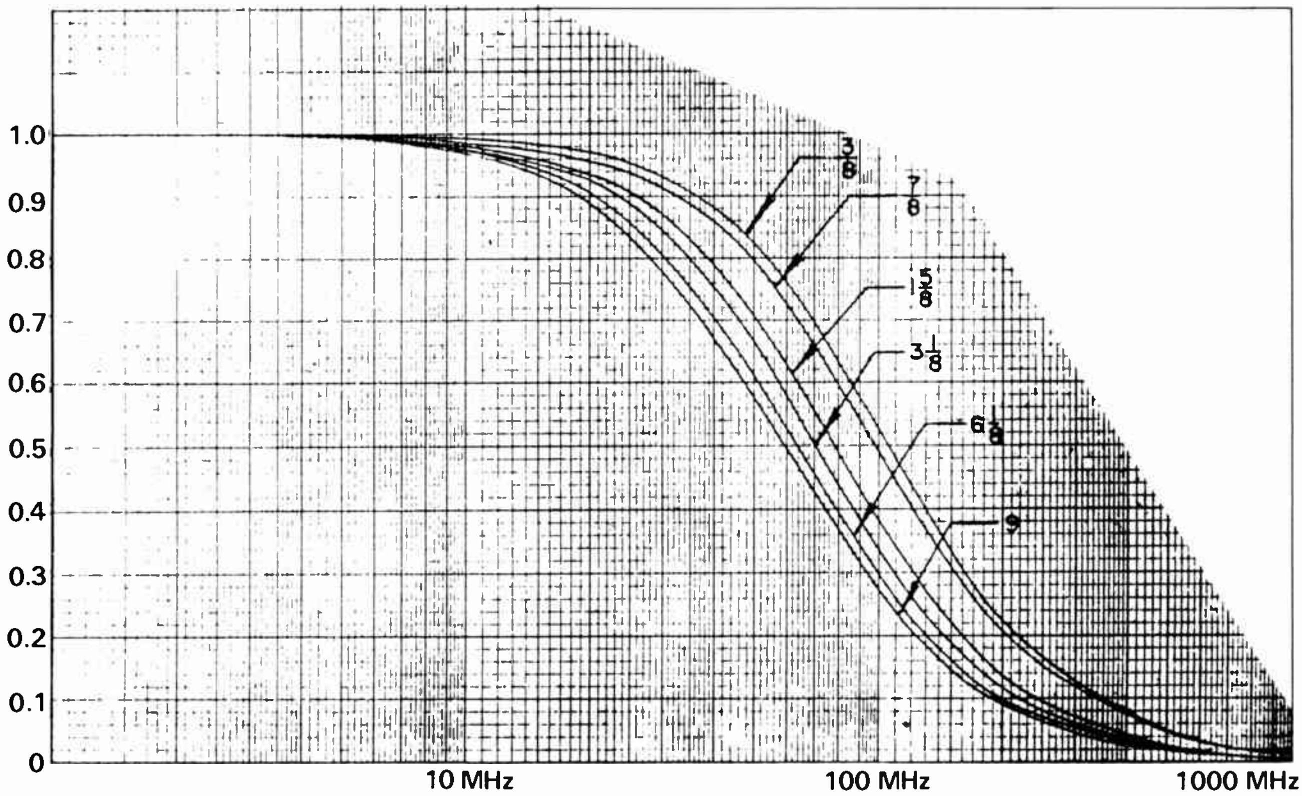

Figure 25. Derating factor for average power due to load VSWR.

Only the 6⅛" 50-ohm and 75-ohm rigid lines meet *all* of the following requirements:

1. Adjusted average power ratings greater than the effective transmitter average power level of 48 kW.
2. Peak power ratings greater than 157 kW.
3. Cut-off frequencies greater than 728 MHz.

Rigid Line Attenuation Adjustments for Actual Ambient Temperature and Load VSWR Effects and Efficiency Calculations.

Line Size Line Impedance	6⅛" 50Ω	6⅛" 75Ω
Total Line Attenuation (Table 18), x 6	.160 dB x 6 = .960 dB	.146 dB x 6 = .876 dB
Adjustment for 68°F (20°C) Ambient (Fig. 6), x .99	.960 dB x .99 = .950 dB	.876 dB x .99 = .867 dB
Derating for Load VSWR (Fig. 7), + .02	.950 dB + .02 = .970 dB	.867 dB + .02 = .887 dB
Efficiency Calc. $Eff = \frac{100\%}{10^{\frac{\alpha}{10}}}$	$\frac{100\%}{10^{\frac{.970}{10}}}$ = 79.98%	$\frac{100\%}{10^{\frac{.887}{10}}}$ = 81.52%

Therefore, we can conclude that either 50-ohm or 75-ohm 6⅛" rigid coaxial line will work for this application. The performance of a system for both types of line is as follows:

	System Req.	50Ω Line	75Ω Line
Cut-Off Frequency, MHz	>728	788	900
Peak Power, Derated, kW	>157	1500	1000
Average Power, Derated, kW	>48	81.56	70.55
Total Attenuation, Derated, dB		.970	.887
Line Efficiency, %		79.98	81.52

Both lines satisfy the peak power, average power, and frequency cut-off requirements, but the 75-ohm line will deliver about 2% more power to the antenna with an average weight reduction over the 50-ohm line of approximately 7.5%.

Rigid Line Systems

General

A rigid coaxial transmission line system is composed of an interior run and exterior horizontal/vertical runs. The exterior runs should be pressurized to prevent

ingress of moisture. The fundamental consideration in a rigid line system is differential thermal expansion between the steel tower and copper rigid line. Over a temperature range of −25°F (−32°C) to +125°F (+52°C), expansion of copper is about 1½"/100 ft and steel is about 1"/100 ft. This results in a differential expansion of ½" per 100 ft. Provisions must be made for the line expansion to prevent severe buckling strain on both the transmission line system and tower.

Various hangers are available from rigid line manufacturers that will fasten the line to the tower and horizontal bridge and allow for differential thermal expansion.

Mechanical Interfaces

Interface standards have been established by the Electronic Industries Association (EIA): RS-225, for 50-ohm rigid coaxial lines, and RS-259, for 75-ohm rigid coaxial lines. These standards specify line and flange dimensions and tolerances for most of the available line sizes.

Components are available from line manufacturers that permit the correct interface connection of different line sizes and impedances.

Coaxial Components

Table 18 is a list of typical components used in a rigid line system as depicted in Fig. 26.

TABLE 18

Typical rigid line components and uses.

It.	Component	Application
1	19–20 ft. Line Section	Construct horizontal/vertical run.
2	90° Elbow	Change direction of run.
3	Gas Barrier	Access port to connect pressure system. Isolate pressurized sections of line (e.g. exterior/interior line interface).
4	Adaptor	Connect two components together of different size but same impedance.
	Impedance Transformer	Connect components together of different impedances (e.g. 50-ohm patch panel to 75-ohm line).
	Fine Matcher	Fine tune diplexer output to line and line to antenna.
	Field Flange Kits	Used with field cut line section to obtain a special length line to complete a run.
8	Rigid Hanger	Support line rigidly at top of tower.
9	Vertical Spring Hanger	Support weight of line along tower and accommodate expansion.
10	Lateral Brace	Restrict lateral movement of line at the bottom of tower due to forces created by expansion of vertical and horizontal runs.
11	3-Point Suspension Hanger	Allow vertical movement of rigid line in horizontal run as vertical run varies in length due to thermal effects.
12	Wall Feed-Thru	Provide weather tight access thru building wall.
13	Dehydrator	Maintain positive pressure in line.

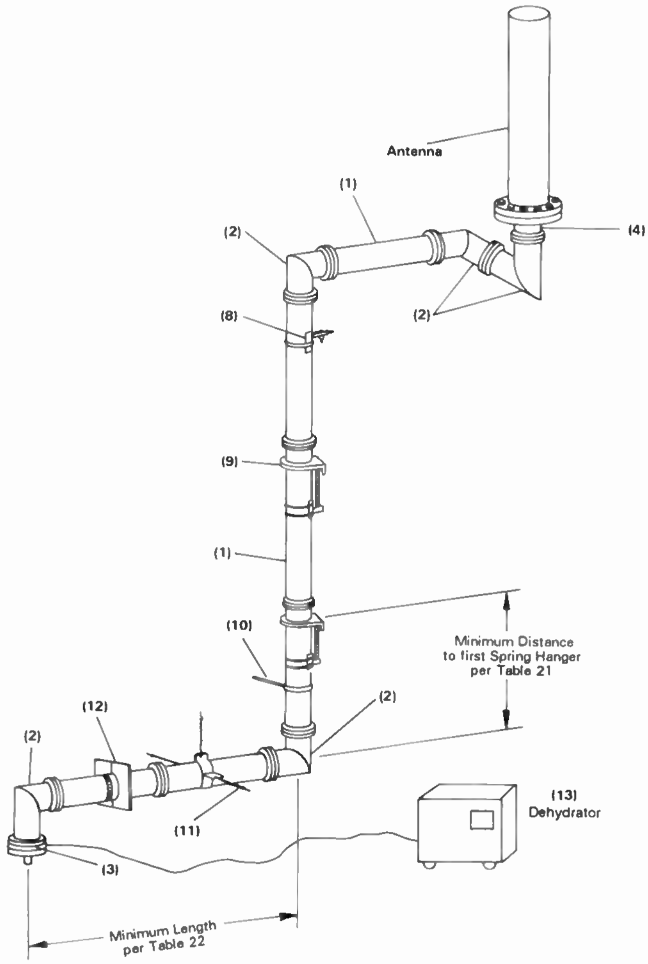

Figure 26. Typical broadcast rigid line system.

Coaxial line components should be supplied with 1 inner connector, 1 hardware kit, 1 "O" ring gasket, and 2 protective end caps. Hangers should be supplied with mounting hardware unless otherwise stated.

Installation

Rigid transmission line installations may begin at either the top or bottom of the tower. However done, they require proper positioning of the bottom elbow to allow for both expansion and contraction of the rigid line. In addition, a special length section is often required, and an "elbow complex" may be needed to allow alignment with the antenna.

Vertical Run

For installations originating at the top of the tower, the following general steps should be followed:

1. Use appropriate adaptor and/or transformer to adapt the antenna feed (size and impedance) to the line.
2. Field cut lengths and multiple elbows can be used to obtain the required orientation of the line to the tower and antenna.

3. Use reinforced elbows for larger line sizes (4¹⁄₁₆" and greater).
4. Mount the first vertical section to the tower using rigid hangers. The number will correspond to the size of the line and length of vertical run.
5. Use vertical spring hangers every ten feet to mount the vertical run to the tower. Tower steel must provide support for a straight vertical run and maintain clearance for movement. Adjust spring hangers to their proper setting.
6. Use a field cut section at the bottom of the tower to bring the vertical run down to the desired height for attachment to the horizontal run.
7. Set the distance from the horizontal run to the lowest vertical spring hanger according to Table 19.
8. Use a lateral brace near the bottom to restrict lateral motion while permitting vertical and horizontal movement.
9. Use 90° reinforced elbows to change direction from vertical to horizontal, or to obtain a nonhorizontal angle of elevation for the run to the transmitter building.

For installations originating at the bottom of the tower the above steps should be followed, except temporary rigid hangers should be used on the first vertical line section installed. The temporary rigid hangers must be removed after the permanent rigid hangers have been placed on the top vertical section to prevent damage due to differential expansion. The position of the bottom elbows must be carefully determined based on current ambient conditions to provide clearance for the expected expansion of the vertical run without interference from tower members. Field cut sections and elbows will be needed at the top of the vertical run to obtain the desired height and orientation for connection to the antenna.

Horizontal Run

Three point suspension hangers are used every ten feet to support the rigid line to the horizontal support structure. It is recommended that the minimum length of horizontal run shown in Table 20 be used to avoid overstress from thermal expansion. The horizontal run should enter the transmitter building through a wall feed-thru with a gas barrier used inside the building to allow pressurization of the exterior run.

TABLE 19

Minimum distance to first vertical spring hanger versus length of horizontal run (refer to Fig. 26).

Horizontal Run (feet)	Minimum Distance to Lowest Hanger (feet) 3⅛"	4¹⁄₁₆"	6⅛"	8³⁄₁₆"	9³⁄₁₆"
20	5	6	9	12	13
40	6	7	11	15	17
60	7	8	13	17	20
80	8	9	14	19	22
100	9	10	16	21	23

TABLE 20

Recommended length of horizontal run.

Vertical Run (feet)	Recommended Lengtyh of Horizontal Run (feet) 3⅛"	4¹⁄₁₆"	6⅛"	8³⁄₁₆"	9³⁄₁₆"
100	15	15	15	20	20
500	25	30	35	40	40
1000	35	40	50	60	60
1500	40	50	60	70	70
2000	45	60	70	80	80

Do's & Don'ts

Installation "do's" and "don'ts" are provided in Fig. 27.

Pressurization

General

External rigid coaxial transmission lines must be maintained under dry gas, nitrogen, or dry air, to prevent electrical performance degradation and possible transmission system failure. If a positive dry air pressure is not maintained inside the lines, "breathing" can occur—allowing moist air and dust to enter the line through the joints. This moisture will condense and accumulate on the internal surfaces of the transmission line system causing oxidation and corrosion, resulting in:

- Increase in line attenuation from oxidation and moisture
- Increase in VSWR from moisture accumulation
- Corrosion in mechanical joints causing localized I^2R losses and hot spots
- Voltage flashover caused by dust and other contaminates, left on the insulators

Transmission lines pressurized with dry gas maintain the high initial performance of the transmission system, but also reduce the risk of damage and costly interruption of service. Dry gas may be obtained from either nitrogen bottle or a dehydrated air system. Pressurization values must not exceed the lowest component pressure rating in the transmission system (usually the antenna).

Selection

Table 12 summarizes the advantages and disadvantages of four pressurization systems: nitrogen, manual regenerative dehydrator, automatic regenerative dehydrator, and automatic continuous membrane dehydrator.

When selecting a pressurization system, the transmission system volume, normal leakage rate, ambient temperature swing, solar load changes and system advantages/disadvantages must be considered to ensure proper operation.

Installation "Do's"

1. Do lift components with connector end up unless marked otherwise.
2. Do check the spring hangers for free travel and proper alignment.
3. Do consult manufacturers' spring loading charts.
4. Do tighten flange bolts alternately, one side, then the other, before torquing.
5. Do check to make sure O-rings are fully seated in groove.
6. Do pressurize the line immediately following installation and maintain a positive pressure at all times.
7. Do use reinforced elbows for exterior installations of larger size coax (4 1/16" and larger).
8. Do perform electrical testing before applying power.
9. Do purge and pressurize line before applying power.
10. Do remove all burrs from field cut conductors.

Installation "Don'ts"

1. Don't hoist coupled sections of line.
2. Don't force components together.
3. Don't assemble line components that contain water or condensation.
4. Don't install line that exhibits any evidence of damage.
5. Don't dismiss rigger until line is completely installed, holds pressure, and electrical testing has been performed.
6. Don't apply power to line until it has been purged and pressurized.
7. Don't use damaged O-rings.
8. Don't assemble a horizontal run without support.
9. Don't exceed pressure rating of any component (antenna, gas barrier, etc.).
10. Don't exceed torque specifications on flange hardware.

Figure 27. Rigid line installation "do's" and "don'ts".

Purging

System purging must be done after any of the following conditions have occurred:

1. When a line has been installed and before power is applied.
2. When a pressure seal has been broken on the outside run of the transmission line for maintenance work.
3. When positive pressure has not been maintained in the line.

The line must be purged with a minimum of three volumes of air to ensure dryness to the desired dew point. This is accomplished by opening a joint or using an available purge valve near the antenna to allow the gas to flow through the entire length of line, drawing moisture out with it.

Testing

General

Electrical testing of rigid line systems should be performed for any of the following conditions:

1. After initial installation (prior to applying power).
2. After VSWR/reverse power trips to determine mode and location of failure.
3. Periodically, to verify performance of system.
4. After persistent signal fluctuations of "in-line" waveform monitor and signal analyzer.

It is advantageous to test when installation personnel are still on site. Electrical testing is usually done to verify the performance of the transmission system. Thorough testing done at this stage will both verify initial system performance and also detect and locate most "bugs" in a system that could lead to eventual failures. These minor defects usually occur during installation.

The most useful tests are the VSWR/return loss sweep test and the RF pulse test. These tests operate over the bandwidth of the system and give a good indication of line and antenna performance. Network analyzers with time domain capabilities and lightweight line analyzers can be used for overall system performance checks, and are also excellent at locating discontinuities (not detectable by RF pulse) which may lead to future line failure. Traditional time-domain reflectometry devices (TDR) can be used to locate these discontinuities, but will not give an indication of performance over the channel bandwidth. This section reviews each technique and presents actual data taken on transmission line systems.

Sweep Test

The sweep test is a frequency domain test that measures the return loss of the line in the channel bandwidth. This test should be performed before power is applied to the line, and must be done with the end of the line terminated in either an antenna or load. The effects of the terminating device will be included in the measurement.

A return loss sweep test curve of a UHF transmission system is shown in Fig. 28. The system consists of 380 ft of 6 1/8" 75-ohm rigid line, various components (elbows, gas barriers, adapters, etc.), and a top mounted antenna. The maximum return loss level is about 20 dB (1.22 VSWR) at the top of the band. The rippling effect in the trace arises from the continuous phasing of the reflection from the ends of the system.

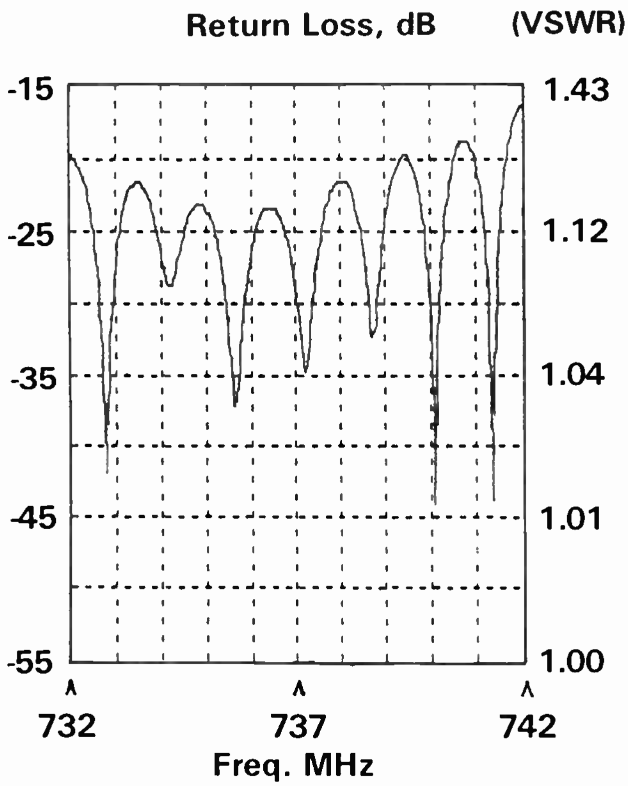

Figure 28. Swept return loss of a 380 ft, 6⅛″ 75-ohm rigid line system including antenna. (VSWR of this system is higher than normally expected.)

The return loss level is high and we should be able to determine the location of the problem using one of the time domain techniques.

RF Pulse Test

The RF pulse test displays the performance of the line in the time domain. This test shows impedance changes versus time and allows the user to correlate relative electrical performance to general location in the line.

The procedure is to apply a CW burst to the line and observe the reflected signal in time. The frequency of the CW signal is equal to the center frequency of the channel bandwidth and the duration of the burst is of the order of inverse of the channel bandwidth. This technique allows the performance of the transmission system over the channel bandwidth to be displayed in time. The disadvantage of this approach is that information over a only a small bandwidth is used to derive the time domain characteristics. This means that the display will show only gross defects in the system. An RF pulse test curve for 1,000 ft of 6⅛″ 75-ohm rigid line and antenna for channel 14 is shown in Fig. 29. An accurate conversion of 2.1 nanoseconds per foot of line can be applied showing that 1 division on the horizontal axis is equal to 238 ft of line. This conversion takes into consideration the round trip time of the pulse. The return loss over the length of the line is very good with the worst spike of −43 dB at approximately 666 ft.

Network Analyzers

Network analyzers with time domain capabilities can be used for both sweep testing and to simulate RF pulse and TDR testing. The advantage of this equipment is that one unit contains all the necessary transmission testing functions, and the time domain functions allow excellent control over the resolution. The time domain can be used to simulate an RF pulse by looking over only a small frequency range (channel bandwidth) or over the entire range of frequencies up to line cut-off. Using the equipment up to cut-off gives excellent resolution and allows smooth impedance variations to be displayed in time/length. Therefore, the analyzer can be used to locate problems that are not seen by an RF pulse but which could lead to eventual failures. The disadvantage of a network analyzer is cost.

An impedance plot of a transmission system using a network analyzer is shown in Fig. 30. This plot was taken for troubleshooting after multiple VSWR trips had occurred. The time domain information was automatically calculated from data taken in the frequency domain up to 900 MHz. In this mode the individual

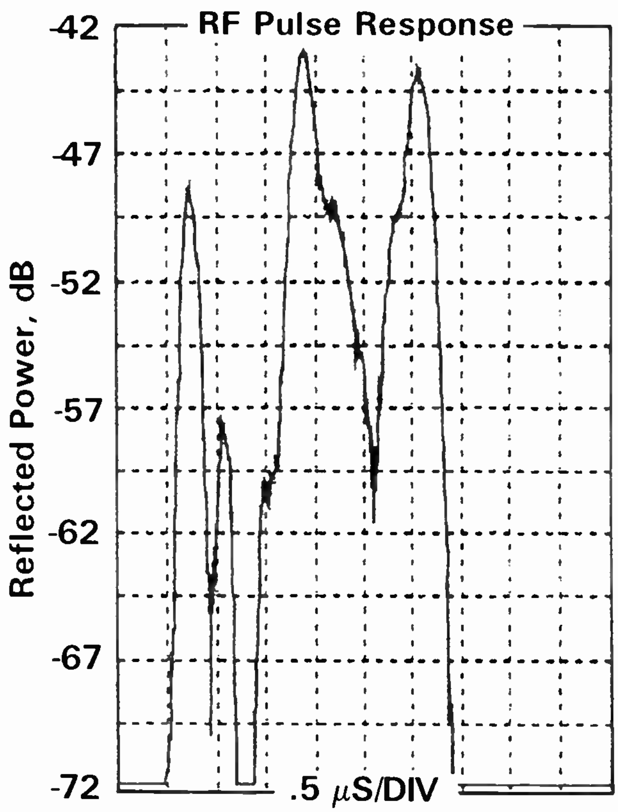

Figure 29. RF pulse test response of a 1,000 ft. 6⅛″ 75-ohm rigid line system and antenna.

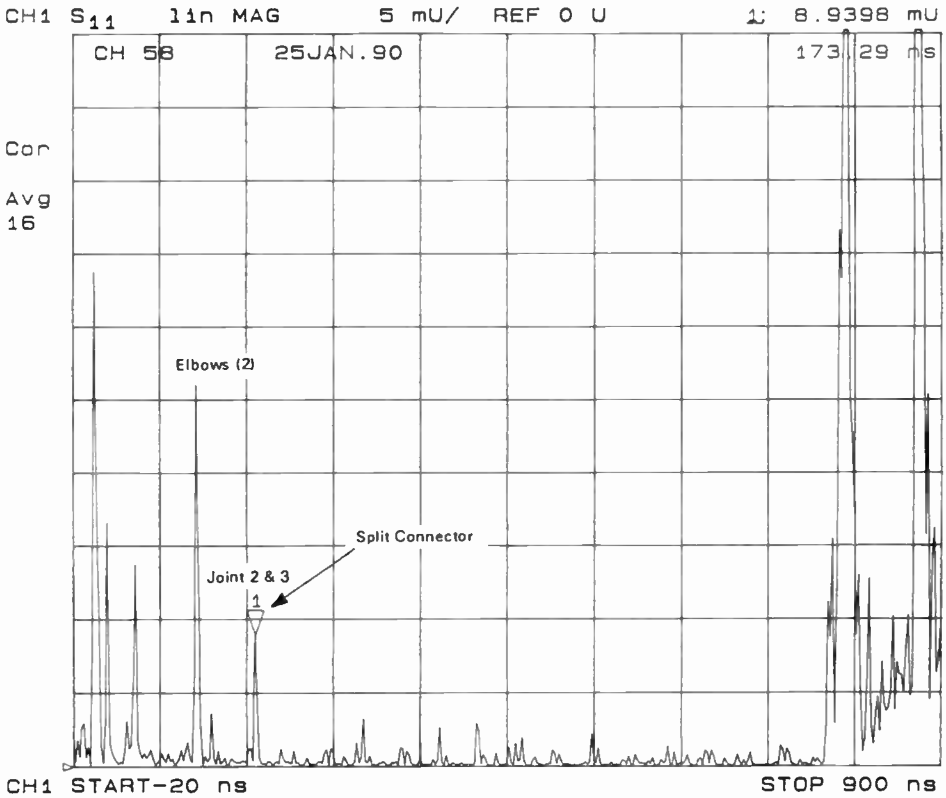

Figure 30. Time domain impedance plot of rigid line.

line components can be observed (adapters, elbows, flanges, insulators, and antenna). In Fig. 30 an impedance spike is seen in the vertical run of rigid line (this turned out to be a split inner connector). Fig. 31 is an impedance plot using only a small amount of frequency information (734 MHz to 740 MHz) to simulate an RF pulse. This test indicated a high impedance near the input to the antenna and around the horizontal-to-vertical junction at the tower base. The former turned out to be a bent inner conductor at the antenna input; the latter was an improperly tuned elbow used to connect the vertical to horizontal run. After replacing these items, the trace in Fig. 32 shows an improvement of approximately 11 dB at both locations.

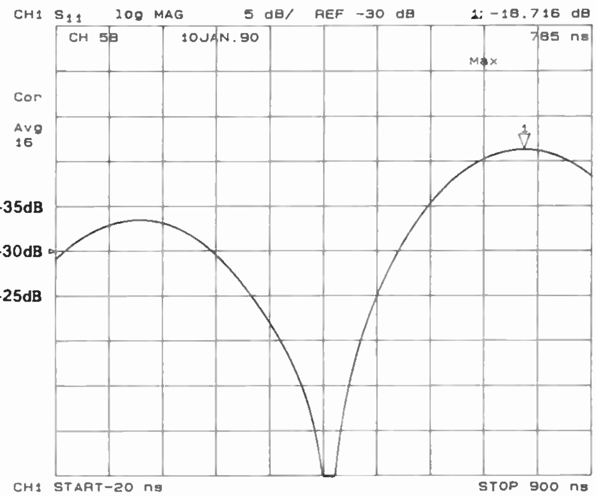

Figure 31. Time domain impedance plot before fix.

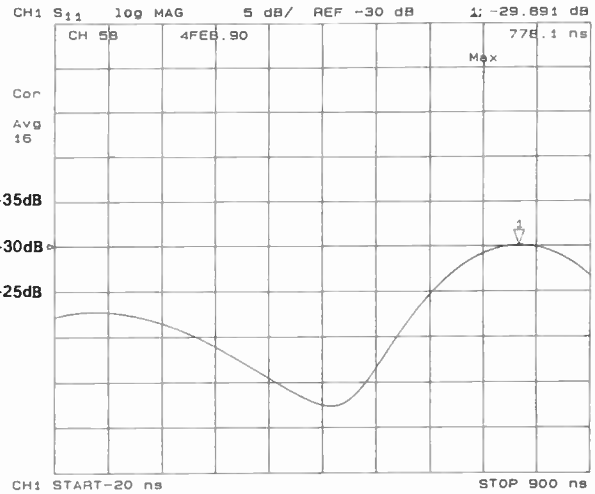

Figure 32. Time domain impedance plot after fix.

All of these tests were performed using an HP 8753C Network Analyzer with time domain analysis. This unit is excellent for performing complete system verification and debugging. A Systron Donner Model 5220 Transline Analyzer, which is made for field use, could also have been used.

Time-Domain Reflectometry (TDR) Test

A TDR (time-domain reflectometry) test can be used to examine a transmission line for faults. The TDR test set uses a fast rise time voltage step transmitted down the line, then measures the reflected signal. Since the signal will have significant frequency components up to 0.35 divided by the rise time of the pulse, the important thing to remember is to adjust the pulse rise time on the TDR test set to the cut-off frequency of the line. Because the TDR test set is a broadband device it cannot be used to determine the performance of the line over the channel bandwidth.

Insulation Resistance Test

An insulation resistance test can be performed on a rigid transmission line after purging with dry air to determine if it is sufficiently dry before applying power. This test should be performed after any line has suffered from moisture ingress. The insulation resistance between the inner and outer conductor should be greater than 100,000 Megohms. There are many inexpensive units available that can measure insulation resistance.

Operation and Maintenance

The following guidelines should be followed to ensure proper operation of a rigid coaxial transmission line system:

1. Establish a swept VSWR and time domain response of the transmission system before applying power.
2. Set and maintain the reverse power VSWR trip to an acceptable level for the method of broadcasting being used.
3. If possible, use an in-line power probe and meter to monitor actual forward and reverse power in the line and to compare with the transmitter meters.
4. Determine the cause of VSWR trips before overriding the system.
5. Always maintain a positive pressure in the line.
6. Do not exceed the pressure rating of the antenna or any other component in the transmission system.
7. Establish and record the dehydrator cycle pattern.
8. Record dehydrator cycle times and compare to the established pattern. Deviation from the established pattern may indicate a problem in the system.
9. Perform periodic maintenance checks on the pressurization system.
10. Always purge the line after an outside seal has been broken or when a positive pressure has not been maintained in the line.
11. Flanges and fittings can be examined for leaks using a soapy water solution.
12. Periodically feel for hot spots along the rigid line. The outer temperature is proportional to the inner temperature and excess outer temperatures may indicate an inner joint heating up.
13. Check the vertical and horizontal line sections for wear caused by thermal expansion and contraction.
14. Monitor the on-air signal and waveform monitor. Fluctuations in the signal could be the result of intermittent contact in the line which could lead to line failure.
15. Remeasure system VSWR and impedance periodically and compare to previous results to detect signs of deterioration.

WAVEGUIDE

General

Waveguide, as the name implies, "guides" the electric and magnetic fields of the travelling wave within its enclosed space. For UHF broadcast applications, the common forms of waveguide to be discussed in this section include (Fig. 33):

- Rectangular; generally aluminum with a width to height ratio of 2 to 1, ranging in size from 11.5" x 5.75" (WR1150) to 18" x 9" (WR1800).
- Circular; also aluminum with diameters ranging from approximately 13" to 18". A recent improvement provides single polarized operation by eliminating the cross polarized TE_{11} field (Fig. 33C).
- Truncated; an aluminum hybrid of the above consisting of a special interior shape (between circular and rectangular) surrounded by a cylindrical cover to reduce wind loading on the tower. Final diameters are comparable to those of a circular waveguide.

Because of the larger sizes which would be necessary at lower frequencies, waveguide is rarely used for broadcast applications other than UHF television.

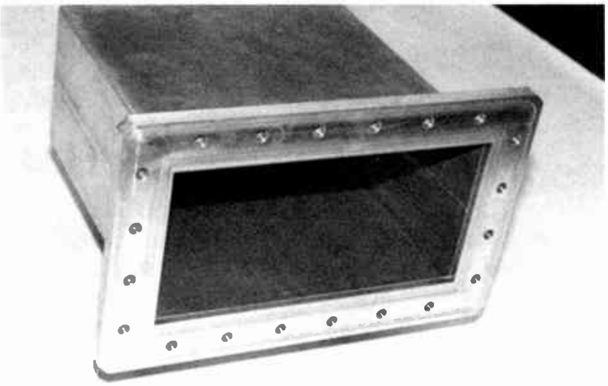
Basic Considerations

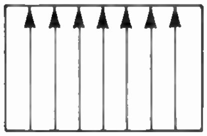
There are a number of important elements to be considered when evaluating the use of waveguide in a UHF broadcast application.
Following are descriptions of the most important.

Lower Attenuation

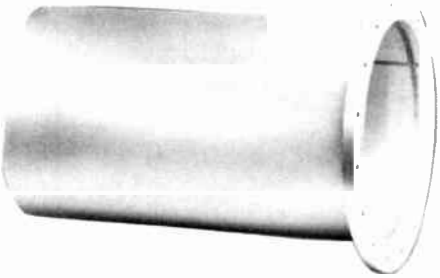
The absence of dielectric support materials together with propagation at waveguide modes reduces attenuation to values well below that of large rigid coaxial lines (Figs. 34 and 35). The lower attenuation of waveguide translates to high efficiency according to the formula:

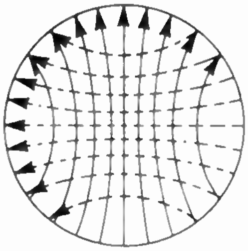
$$Eff = \frac{100\%}{10^{\left(\frac{dB}{10}\right)}}$$



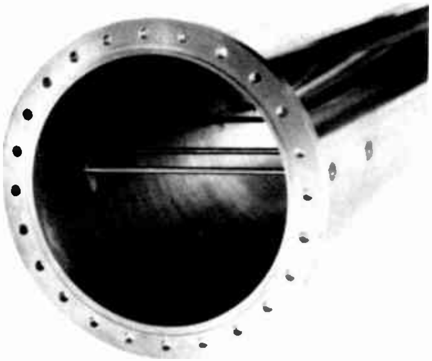


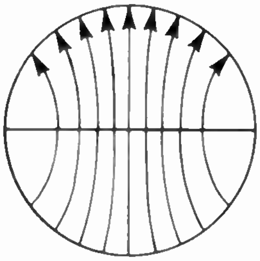
A) Rectangular



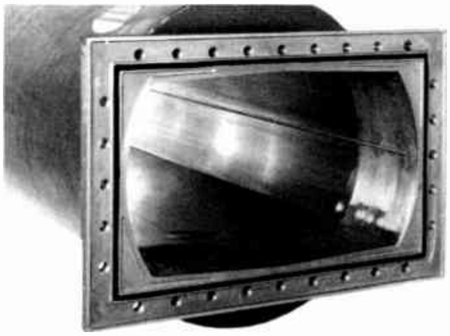


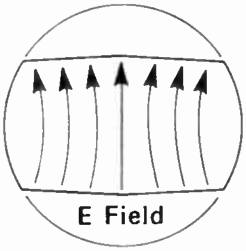
B) Circular





C) Circular with Cross-Polarization
Cancelling Rods





D) Truncated

Figure 33. Common broadcast waveguide types.

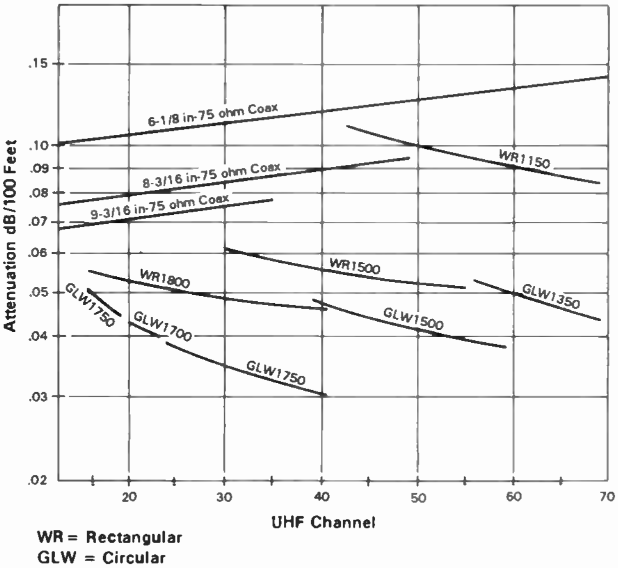


Figure 34. Relative attenuation of waveguide compared to large rigid line.

where dB is the total attenuation of the transmission line at the frequency of interest. The power lost in the line is dissipated as heat.

Table 21 lists the efficiencies of various transmission lines 2,000 ft long at channel 48. Manufacturers should be consulted to confirm attenuation/efficiency figures for actual system configurations.

Lower Operating Costs

Because of the increased efficiency compared to rigid line, desired ERP levels can be achieved with less transmit power; thereby reducing electricity bills. Table 21 shows the savings compared to 8³⁄₁₆″ rigid line assuming 20 hr/day transmission using a 50% efficient 120 kW transmitter with an electric rate of $0.10/kWH. Obviously, even higher savings would result if transmitter efficiency is less than 50%.

As a general rule, waveguide is more efficient than coaxial rigid line, with circular waveguide being the most efficient.

Possibility of Both Horizontal and Vertical Transmission

With increased efficiency of transmission, enough power may be available at the antenna to allow both full ERP in the horizontal polarization plane and additional ERP in the vertical polarization plane. In urban areas 5 to 20 miles from the tower, this vertically polarized signal may serve to improve reception for viewers using indoor antennas.

High Power Handling Capability

The single tube construction of waveguide provides high power handling capacity. There is no inner conductor to heat up, no dielectric support material to soften, and a large surface area over which the I^2R losses can be dissipated. Applications of 240 kW are common. Waveguide is the only practical way to deliver such power levels to the antenna.

Pressurization Requirements Must Be Carefully Evaluated

The large internal volume of a waveguide system should be pressurized. If left unpressurized, moist air may "breathe" in between the flanges under conditions of rapid barometric pressure or temperature change. If the pressure outside increases suddenly (i.e., quickly-moving warm air front), the interior volume of the waveguide acts like a vacuum and immediately tries to achieve pressure equal to the surrounding environment. Once stabilized with ambient air, the moisture now contained within the waveguide can, under dropping temperature conditions, condense and form water droplets. Gravity causes the droplets to accumulate at the bottom of the line, usually at the location of the bend between the vertical and horizontal runs. This moisture can, in some cases, act as a load and absorb a significant amount of transmitted power, thereby reducing efficiency. Alternately, it can raise VSWR high enough to cause transmitter shutdown.

Higher Wind Load

The larger size of waveguide causes more wind load on the tower. This limits the use of waveguide on many existing towers originally designed to support rigid lines only half as large in diameter.

Larger Elbow Complexes

Due to the physical size and electric field (E-field) orientation of waveguide, it is mechanically more complex to route and change direction of the transmission line system since there are no swivel flanges to facilitate compound bends. Consequently, routing waveguide in and around tower members may involve numerous components. Circular pin twist sections

Figure 35. Attenuation tables for broadcast waveguide types.

(described later) are used in single polarized circular systems to facilitate alignment of the polarization field with the components feeding the antenna and diplexer.

Shape Changes May Affect Performance

In a rectangular waveguide system, too high a pressure (typically anything above 0.5 psig) may cause the waveguide to "bulge" between flanges. This may cause the system VSWR to increase, thereby increasing the amount of reflected power and effectively reducing overall system efficiency. If the reflected signal becomes high enough (usually about 26 dB below the level of the main signal) a "ghost" signal may be evident at receiving locations. This occurs because the reflected signal has been delayed in time by its multiple trips through the system before being transmitted.

Truncated waveguide avoids this problem by enclosing the interior waveguide section in a circular jacket and pressurizing both equally. In this configuration, as in circular waveguide, the existence of higher pressures (2 to 3 psig) does not cause bulging.

However, if winds of high enough velocity distort the shape of any waveguide, overmoding problems can occur. Once additional higher order modes are generated by changes in shape, they reduce the efficiency of the waveguide, since some amount of power is not being delivered to the antenna in the desired mode. Also, this higher order mode energy may, as the shape "normalizes," reconvert to the desired mode. As in the case of a strong reflected signal, this reconverted higher order mode energy is transmitted on a delayed basis and, if strong enough, may also appear as a "ghost" at television receivers.

System Layout Considerations

General Information

Typical system configurations for different types of waveguide are shown in Fig. 36.

Because of the large size of bends, transitions, etc., and the differential expansion between waveguide and tower, careful coordination with the tower engineer and waveguide manufacturer is essential to prevent problems during installation and operation.

In addition, the horizontal run must be long enough to withstand the flexing caused by expansion in the much longer vertical run. Fig. 37 provides a guide to determine this length for circular waveguide systems. As can be seen, the horizontal run needs to be about 10% of the vertical for shorter systems and 5% for long systems. Always consult the manufacturer for confirmation prior to finalizing locations of the tower and transmitter building.

Horizontal and Vertical Straight Sections

Straight sections range from 11.5 ft to 12 ft depending on waveguide type and channel of operation. Follow the manufacturer's catalog recommendations.

The most common starting point for developing the list of required straight sections is the waveguide elbow located at the base of the tower. Working toward the building from the bend, the standard lengths recommended by the manufacturer are used back through the building opening. If the dimension of the final mating pieces cannot be determined accurately, specify a "length to be advised" piece. This will alert the manufacturer that a section must be made available based on last minute measurements.

The vertical run is laid out by stacking lengths end-to-end until the appropriate height is reached for positioning the top anchor plate. The same rule for a "to be advised" length should be applied as in the horizontal run.

Additional pieces will be needed between this point and the input to the antenna. As indicated in the figures, these will be a combination of waveguide-to-coax transitions, waveguide bends and special waveguide lengths. Since the waveguide is fastened rigidly at the top of the run, and the antenna is fastened rigidly at its mounting plate, the waveguide in between must also be allowed to grow and shrink due to thermal expansion and contraction. U-link bends or 90° elbows are the most common method for allowing the necessary "flexing" movement.

Tower Top

The vertical run is secured at the top end with an *anchor plate* or *milkstool* which must be carefully located on the tower to line up with the hangers for the vertical run and with the antenna interconnecting components. The milkstool hanger concept (Fig. 38A) provides adjustment in all directions to allow for minor field variations.

Hangers

Thermal expansion in both vertical and horizontal runs, depicted in Fig. 39, causes both to change positions. At the lower portion of the vertical run, lateral braces (Fig. 38B) are used to provide lateral support while allowing this shifting of position to occur. The supporting hangers for the horizontal run must also allow for an increased amount of movement at this area.

A spring hanger (Fig. 38C) is required on all other sections of waveguide in both the horizontal and vertical runs to provide the expansion/contraction capability necessary. For spring hanger and lateral brace mounting details, the manufacturer's installation bulletins should be thoroughly reviewed. With careful engineering and attention to all the necessary details, the hangers should attach to both the horizontal bridge and the vertical support structure with a minimum of difficulty.

Keep in mind that the coefficients of thermal expansion are 13×10^{-6} per degree F for the aluminum waveguide, and approximately 6.5×10^{-6} per degree F for the tower steel. This results in a relative differential movement of about 3/4" per 100 ft. for a 100°F temperature swing (2.5 cm per 40 m for a 56°C temperature swing). Also, the ambient temperature of the guide and the tower are different due to the additional heating effect of the RF power being transmitted. The resulting

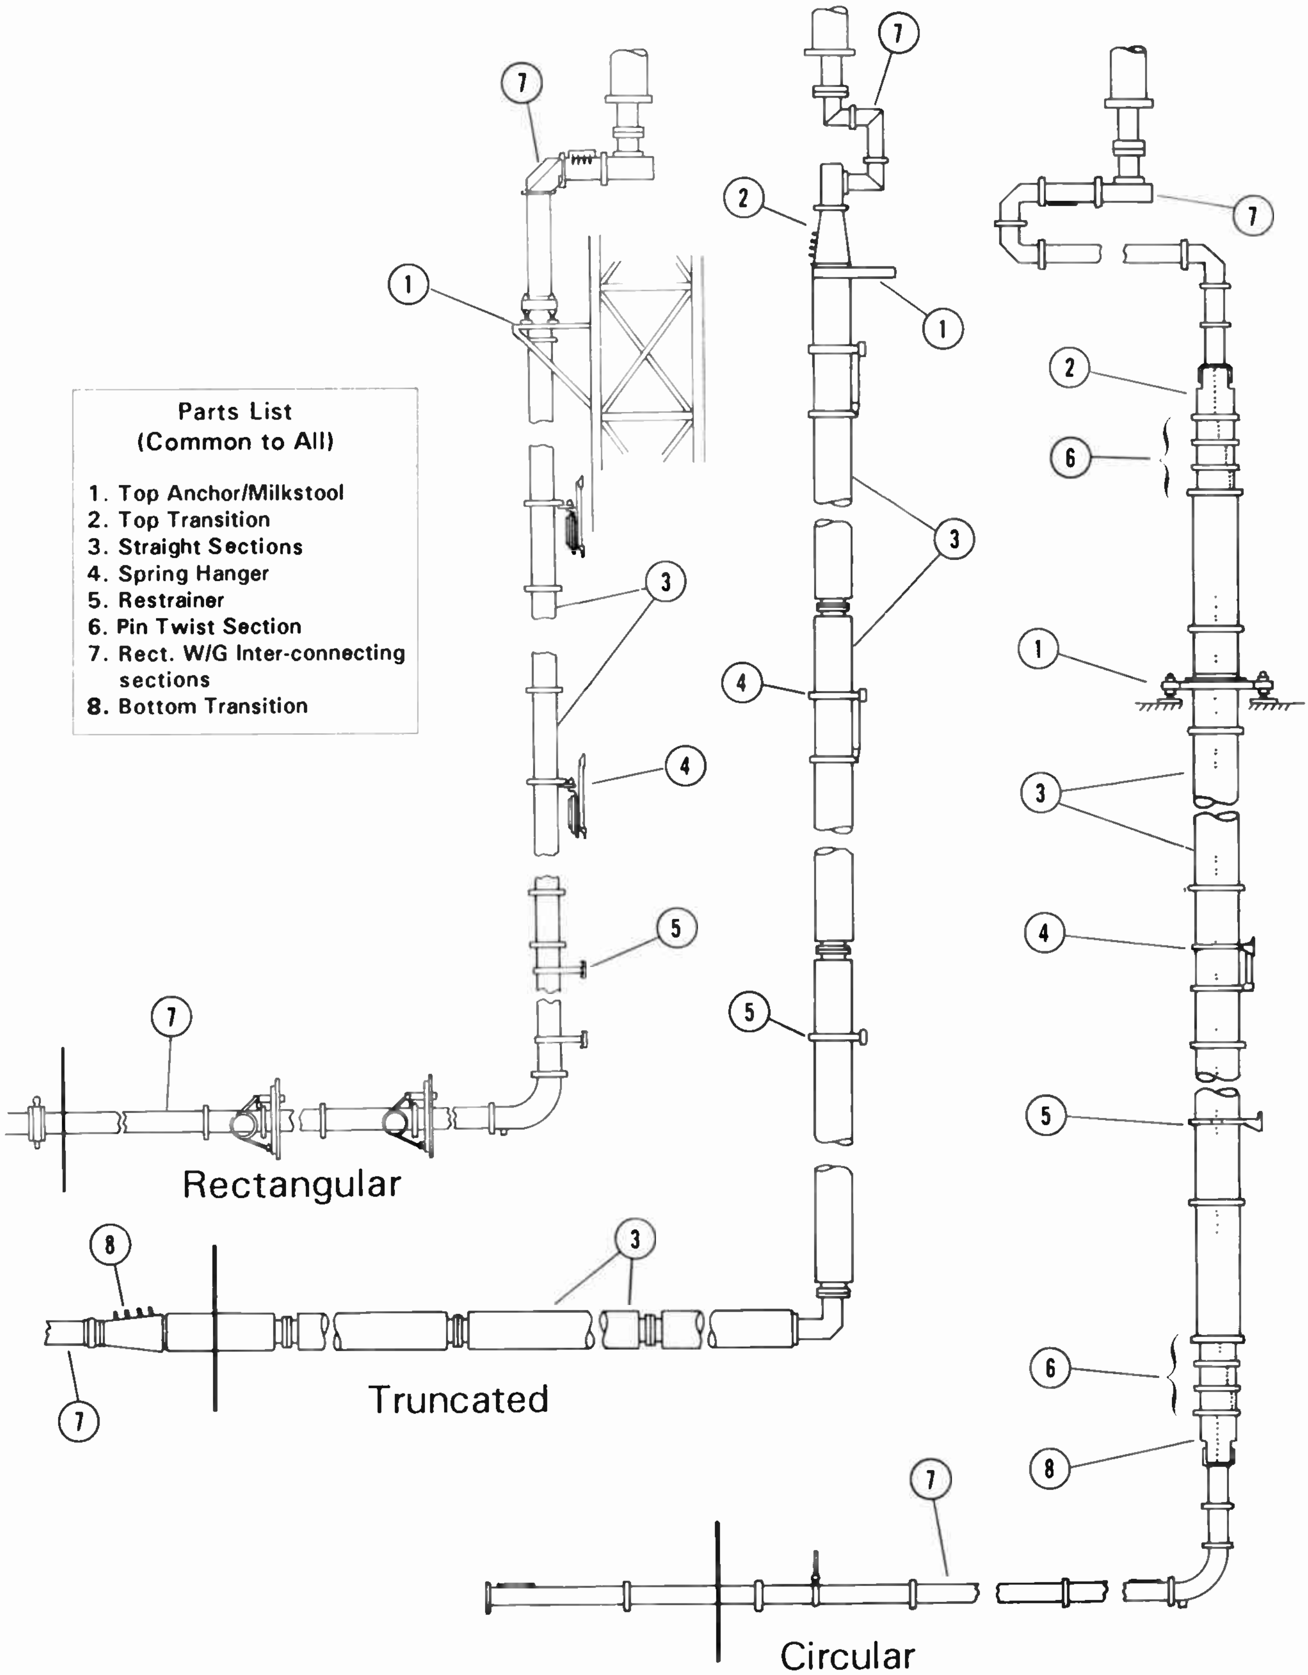

Figure 36. Typical waveguide system layouts.

Vertical Run Height (feet)	Minimum Horizontal Run Length (feet)					
	GLW			DTW		
	1350	1500	1750	1350	1500	1750
2000	75	90	100	72	84	120

1000	54	61	70	60	72	96
500	38	42	49	48	60	84

Figure 37. Typical manufacturer's recommendations for determining minimum length of horizontal run to provide for expansion of vertical run.

expansion/contraction must be accommodated by providing sufficient clearance between all waveguide components and the tower or bridge (Fig. 39).

Transitions and Associated Components

Rectangular waveguide systems may include transitions as shown in the typical layouts of Fig. 36. Rectangular to coaxial transitions are most commonly used to interface the main waveguide run to the antenna and, if equipped with a coax input, the diplexer. Single polarized circular and doubly truncated waveguide systems will also use transitions from their shape to standard rectangular waveguide at both ends (Fig. 38D).

Single polarized circular systems incorporate multisection pin twists (Fig. 38E) at the transitions to facilitate alignment of the electric field (E-field) with the mating rectangular waveguide feeding the antenna and transmitter. This simplifies both the layout of the waveguide system on the tower and the installation. In rectangular-only systems, special twist sections are needed to rotate the run as required for proper alignment.

Tuners

For final system VSWR adjustment, the manufacturer may recommend sections of waveguide with tuners to be located periodically in both the vertical and horizontal runs, especially in rectangular waveguide systems. A tuning section may also be located between the antenna and the anchor plate to facilitate matching the antenna to the waveguide run during final system testing.

Installation

General Considerations

Pages could be written about the handling and installation practices appropriate for waveguide sections. A summary of the major considerations is presented here.

The crew contracted to do the installation will play a major role in the success of the project. Select one with experience, credentials, and recent references. This is not a good place to try to save a few dollars.

If the waveguide will be stored at the site prior to installation, keep the interior surfaces dry and clean by covering the sections with plastic sheeting. Tape the sides and ends securely to keep out wind-driven rain and dirt.

Hanger Installation

Before uncovering any waveguide sections, install all the hangers on the tower and the horizontal bridge. Follow the detail drawings developed by the tower manufacturer to insure the proper interface between the hanger and the tower. Due to the significant windload which the waveguide run will place on the tower, it is important that these instructions be followed carefully.

As shown in the system layout drawings of Fig. 36, several types of hangers will be utilized—a fixed hanger at the top of the tower, spring hangers down the tower, lateral restrainers near the base of the tower and horizontal spring hangers beneath the bridge. Spring hangers with additional travel are provided with certain types of installations to accommodate the larger displacement near the base of the tower in both the vertical and horizontal runs. Be sure that the manufacturer's instructions are followed when installing hangers.

After installation, all hangers must provide the necessary movement to allow waveguide and flange displacement of the type shown in Fig. 39 with no interference at any tower member.

Waveguide Installation

Installation of straight sections usually starts at the base of the tower after properly locating the E-plane bend for clearance at both anticipated temperature extremes. However, single polarized circular waveguide is installed from the top down to eliminate the need for special field-cut circular sections in the vertical run.

Straight sections are normally provided with an O-ring groove in one flange only. This allows the sections to be installed with the groove facing up to provide a cavity for centering the O-ring and prevent "pinching" when bolting mating flanges together. Check for a uniform gap around the flange perimeter after torquing all flange hardware. A pinched O-ring will ultimately need fixing since it will cause VSWR changes, arcing, pressure leaks—or all three.

As mentioned above, be sure the bend at the base of the tower is placed in a location which provides freedom of movement for both the vertical and horizontal runs when differential thermal expansion occurs. As indicated, this differential amount can be approximated using the "¾ in/100 ft" (2.5 cm/40 m) guideline. Note that this will be true for both the vertical and horizontal runs, assuming steel is used for the tower and the horizontal bridge. This general rule is based on a 100°F (56°C) change in temperature. Thus, if the temperature is expected to increase 50°F (28°C) from the ambient at time of installation, the

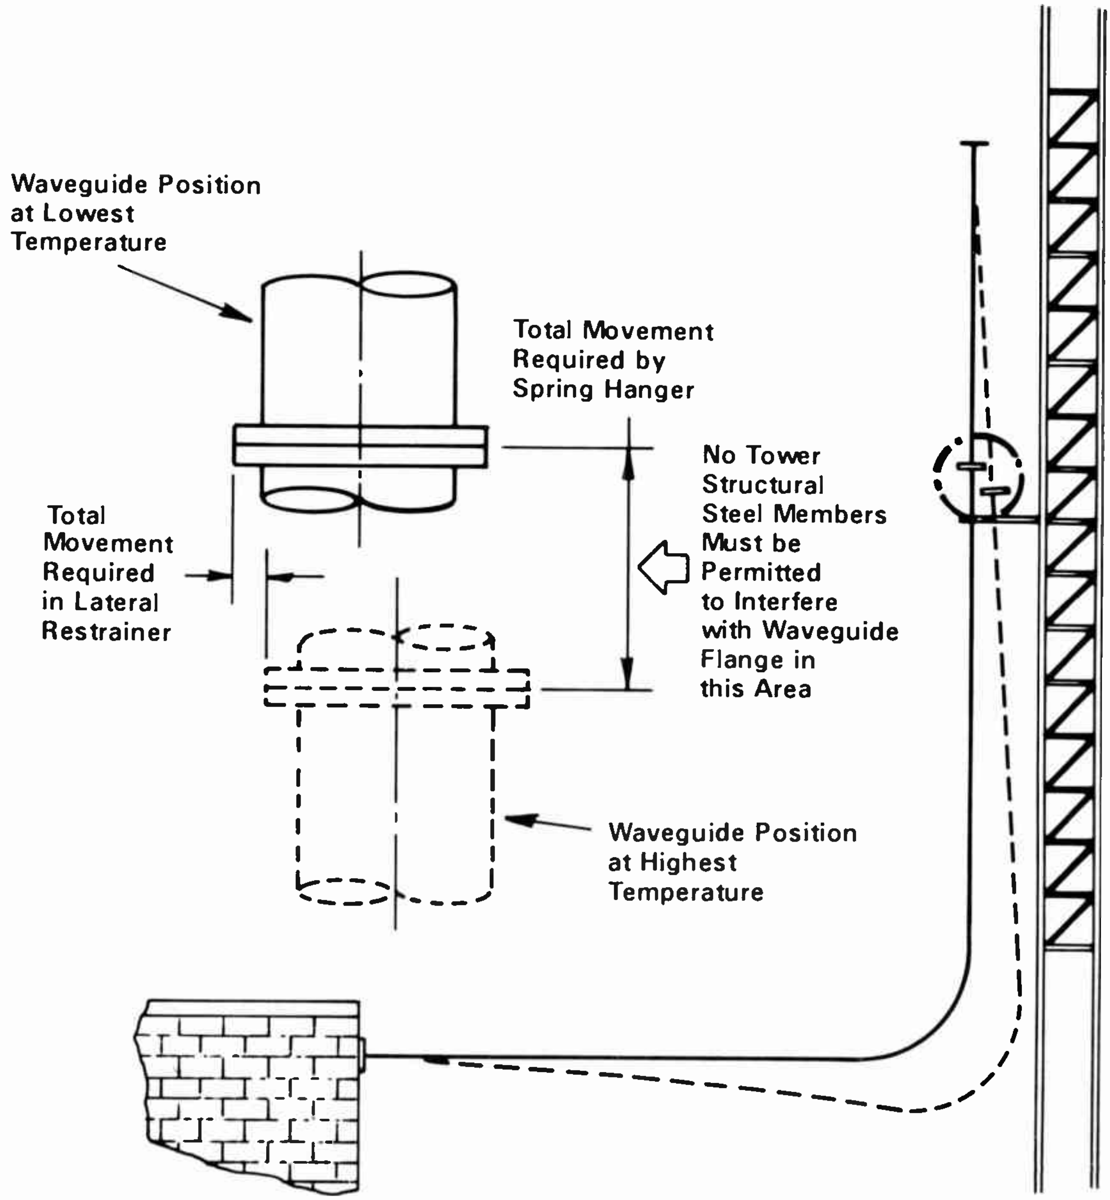

Figure 39. Effects of differential thermal expansion between transmission line and tower.

amount of differential *expansion* will be one-half that indicated above. However, remember that *shrinkage* will also occur as the temperature drops 50°F (28°C) from the ambient, so the same amount of "upward" movement must also be accommodated.

Waveguide flanges in mating sections are normally aligned by pins prior to tightening hardware. Make sure the installers attach these pins to their tool pouches using a long, strong cord. This will prevent the pins from inadvertently being dropped and, subsequently, not used. Misaligned flanges will cause power to be reflected at the point, adding to system VSWR and reducing transmission efficiency.

Pressurization

As mentioned earlier, positive dry air or nitrogen pressure should be maintained inside transmission lines to prevent "breathing." Ambient air can enter the line through the joints due to changes in atmospheric pressure. As the temperature drops, the moisture will condense on the internal surfaces of the waveguide. The accumulation of enough moisture in the waveguide can cause large changes in performance by increasing attenuation, system return loss, or both.

Rectangular waveguide, due to its shape, is usually not pressurized to levels greater than 0.25 psig to prevent distorting or bulging between the flanges.

Circular and truncated waveguides, on the other hand, can be pressurized at levels from 0.5 to 2 psig thereby reducing the likelihood of moisture penetration from the breathing process.

Due to the large volume of enclosed air and large surface area of the guide, sudden changes in ambient temperature and/or solar heating can cause fast changes in internal pressure. A pressure relief value is needed to bleed off rapid increases in pressure which can occur as the rising sun warms up the waveguide. When cooling occurs (due to clouds, sunset, etc.), the pressurization system must have the capacity to provide the required dry air volume quickly.

Due to the cyclic nature of waveguide pressurization systems (pressure relief followed by replacement of the purged volume), automatic dry air systems are more functional than nitrogen tank pressure systems since the latter would need regular replacement.

Testing

Electrical testing of waveguide systems should be performed after any of the following have occurred:

- Initial installation prior to applying power
- VSWR/reverse power trip
- Signal fluctuations of "in-line" waveform monitors or signal analyzers

The purpose of such tests is to verify that the overall performance of the system is as good as expected. Large amounts of reflected power reduce system efficiency, create the potential for "ghosting" and may even cause transmitter shutdown. It is advantageous to test new systems while installation personnel are still on site. Common tests performed are VSWR/return loss sweep and RF pulse test. Network analyzers with time domain capabilities can be used for overall system performance checks and are excellent devices for locating discontinuities not detectable by RF pulse testing. This section discusses such tests and presents actual data taken on waveguide systems.

Sweep Test

The sweep test is a frequency domain test that measures the return loss of the transmission line over the operating channel bandwidth. This will determine how efficiently energy is being transferred from the transmitter system into the transmission line. The measurement is typically performed at the gas barrier inside the transmitter building by applying a 6 MHz swept signal to the transmission line through a directional coupler or return loss bridge. A sample of the forward signal is compared to the reflected signal and the return loss or VSWR can be calculated. If a network analyzer is used, the calculation is done automatically, and the return loss/VSWR versus frequency is displayed on a screen. This test must be done with the end of the line terminated in either an antenna or load. Note that the effects of the terminating device will be included in the measurement.

Since power levels are highest at the visual carrier frequency, most waveguide systems are "optimized" for return loss at that frequency. The goal is at least 32 dB return loss (1.05 VSWR) which means less than a tenth of one percent of the transmitted power will be reflected back toward the transmitter. For a 120 kW UHF application, this translates to less than 120 watts of reflected power and a power transfer efficiency of greater than 99.9%.

A return loss sweep test of a circular waveguide system for a 240 kW application at channel 54 is shown in Fig. 40. This system included 900 ft of 15 in. circular waveguide in the vertical run, 100 ft of WR 1150 rectangular waveguide in the horizontal run, numerous bends and field cut sections, plus gas barrier and transmitting antenna. The maximum return loss level is about 23 dB to 24 dB (1.22 VSWR) at the edges of the band. At visual carrier, return loss is about 34 dB (1.04 VSWR).

The effects of discontinuities having repetitive spacing in a waveguide system, such as the flange joints, are shown clearly in Fig. 41A. The high VSWR "spikes" in this rectangular waveguide system occur at specific "reject" frequencies in the 200 MHz test bandwidth. A system utilizing different section lengths would cause these reject frequencies to change. For this reason, waveguide section lengths vary from about 11 to 12 ft depending on UHF operating channel in the same manner that rigid line lengths vary from 19 to 20 ft Selecting the correct length insures that no VSWR spikes will occur near the 6 MHz operating band.

Rectangular waveguide systems capable of broadband operation are now being provided for special applications. Fig. 41B shows the same waveguide system after adjusting flange tuners to reduce the effects of flange mismatch.

RF Pulse Test

An RF pulse test will display the performance of the line in the time domain. This test displays impedance changes versus time and allows the correlation of relative electrical performance of components to general location in the system when the propagation velocity is known. The test is performed by applying

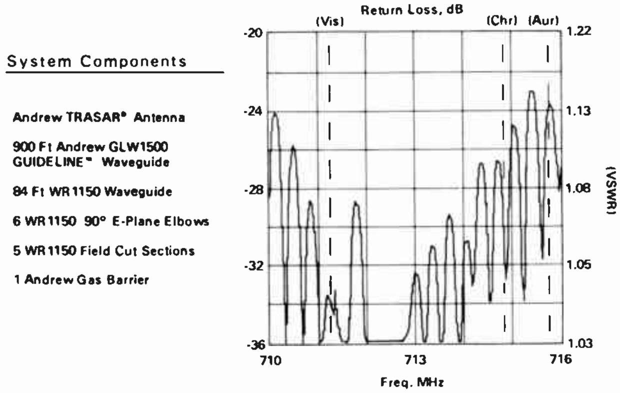

Figure 40. Sweep VSWR test results at channel 54 on 1,000 ft. circular waveguide system.

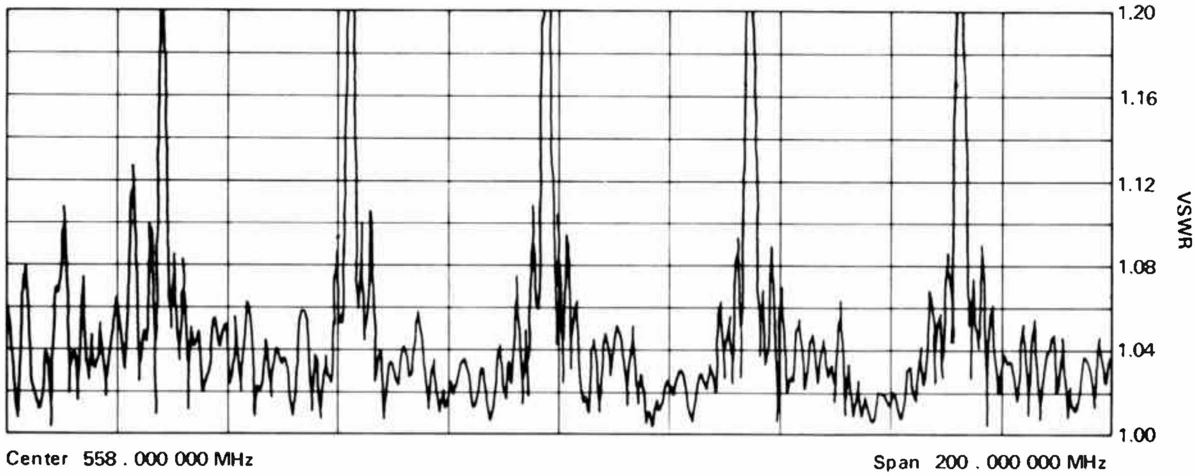

Figure 41A. Broadband (200 MHz) test of rectangular waveguide system to show high VSWR "spikes" at frequencies corresponding to flange joint spacing.

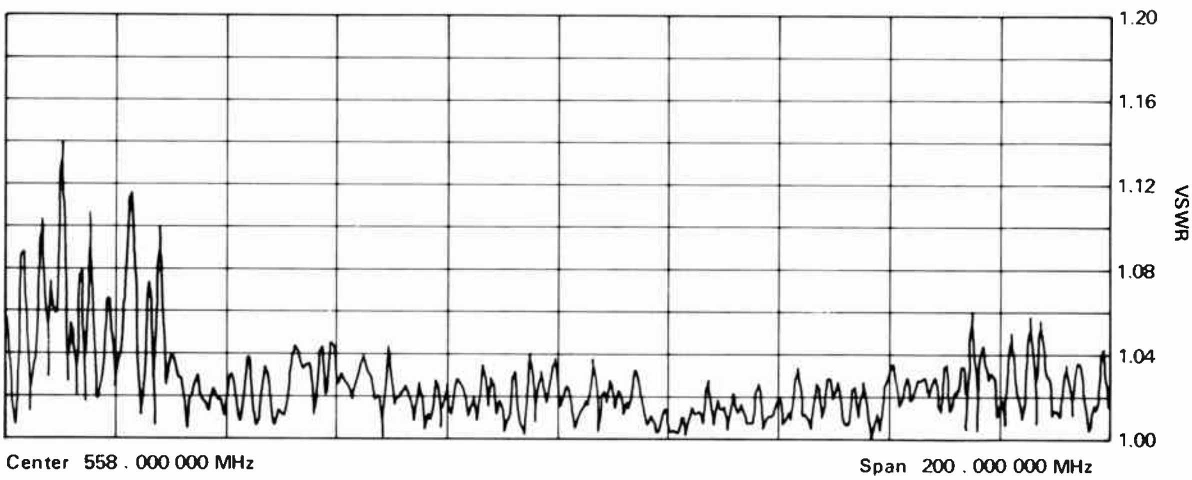

Figure 41B. Same waveguide system optimized for broadband application using tuners at flange joints to counteract flange mismatch.

CW signal bursts of various widths to the system and detecting the reflected signals versus time with a receiver having characteristics simulating an ideal video response. A 0.25 microsecond (2T) pulse has the spectrum of a normal video signal and is used to optimize the system for average picture content. The far end reflections are noted carefully to assure meeting the −32 dB return loss level in order to prevent noticeable ghosting. Because of the pulse width required to simulate the video information, this method does not have the positional resolution of a TDR. However, it provides excellent information regarding the system's transmission performance and can also detect gross problems such as misaligned flanges and pinched O-rings.

The main disadvantage of this test is that there is no standard "off-the-shelf" equipment package available. Therefore, correct interpretation of the test results is somewhat dependent on the skill and experience of the operator.

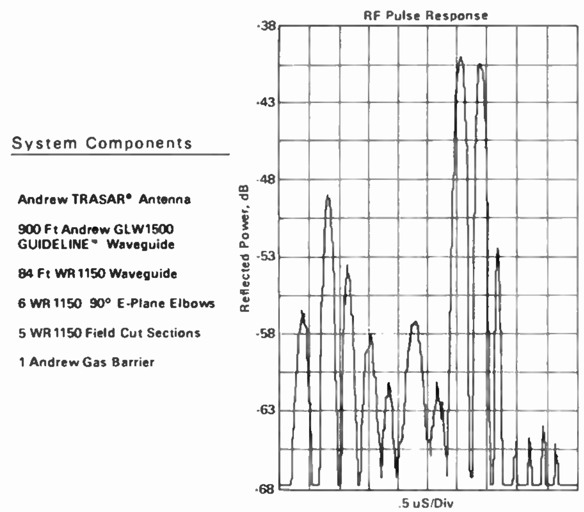

Figure 42. RF pulse test results on system shown in Figure 40.

An RF pulse test curve for the 15″ circular waveguide system described earlier is shown in Fig. 42. As can be seen, there is nothing between the bottom gas barrier up to and including the antenna with a return loss worse than about 40 dB (1.02 VSWR) at the visual carrier frequency of 711.25 MHz.

2.4 Diplexers, Combiners, and Filters[1]

William DeCormier
Dielectric Communications, Raymond, Maine

INTRODUCTION

In this chapter, several methods of connecting the output of the transmitter(s) to the external transmission line system, using either coaxial transmission line or waveguide, will be presented. Various components, ranging from the familiar (simple patch panels) to the recently-developed (circulators and switchless combiner-routing systems), their operation and integration into the transmitter system will be discussed. Filters and filter networks, such as diplexers and multistage multiplexers for FM, TV, and low-power TV, will also be covered.

SWITCHING

Every transmitter installation requires some type of switching in the transmission line system. The complexity of this switching will depend on the individual needs of the station. It can be as simple as a three-port patch panel to connect the output of the transmitter to the station load, or as complex as a multiple transmitter-antenna installation.

Patch Panels

Patch panels provide a convenient method of rerouting the interconnecting transmission lines between various inputs and outputs in the transmitter plant. Since they are manual devices and cannot be changed very rapidly, their use is limited to maintenance functions or as a secondary means of switching.

Coaxial Patch Panels

Coaxial patch panels can have any number of ports, but the more common have three, four, and seven-ports. They consist of the appropriate number of quick disconnect connectors mounted on a panel, and interconnecting transmission lines, usually in the form of U-lines.[2] The connectors are spaced so that the U-links may be used to interconnect any two ports (Fig. 1). For example: the connectors of a three-port patch panel would form an equilateral triangle.

Interlock switches are used to prevent transmitter power from being applied until the U-links are in the proper positions and properly seated. Power handling

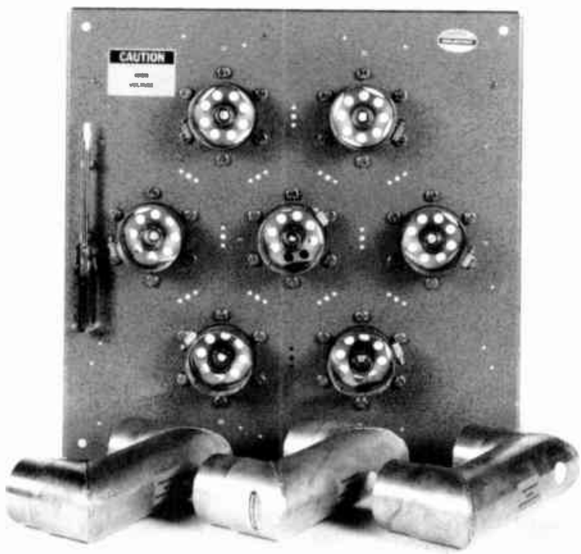

Figure 1. Seven-port patch panel.

[1] Portions of this chapter were retained from the 7th Edition.

[2] Short lengths of transmission line with connectors on both ends.

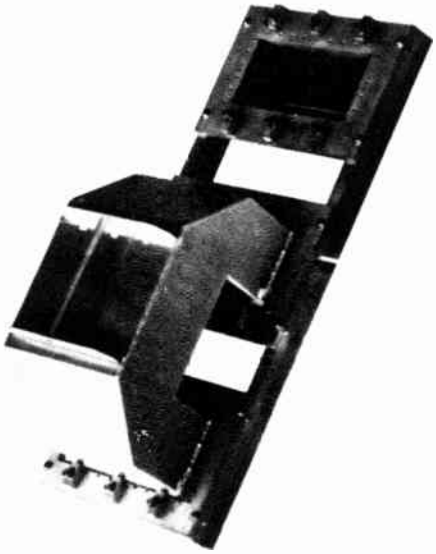

Figure 2. Three-port E-plane waveguide patch panel.

capabilities of the patch panels are essentially the same as the mating transmission lines.

Waveguide Patch Panels

Waveguide patch panels are used in much the same way as their coaxial counterparts. However, since waveguide is larger and inflexible, and most transmitter installations use rectangular waveguide inside the transmitter building, the patch panels are not quite as versatile. Generally, waveguide patch panels are only available as a three-port unit (Fig. 2).

Since the waveguide is rectangular, the ports must be in a straight line in either the broad wall or narrow wall plane.

Manual Coaxial Switches

Manual coaxial switches are generally available in either single-pole-double-throw (SPDT) or four-port transfer-type configurations. They have two distinct advantages over the manual patch panels: ease of operation and speed of switching.

Most manual coaxial switches have either a lever or knob that is turned to change positions of the switch (Fig. 3). This can be accomplished in a few seconds, compared to minutes to change a manual patch panel. Like patch panels, manual coaxial switches have interlock switches to turn off the transmitters during switching.

Power ratings of coaxial switches are approximately 80% of the equivalent coaxial transmission line. Since they are more complicated to build, they cost more than a patch panel. In order to accomplish the same functions performed by a seven-port patch panel, several switches will be required, because they are only available in three-port SPDT and four-port transfer configurations.

Motorized Coaxial Switches

Generally, motorized coaxial switches are very similar to manual switches. To reduce production costs, many of the parts are the same.

Usually, the RF portion of the switch is the same for either manual or motorized switches. The knob or lever is replaced with a motor drive assembly. The motor drive system requires some type of control system to start and stop the motor in the switching sequence.

Most motorized switches are available with a choice of motor voltages, with 115 vac being the more common, and various control circuit voltages. A small control relay isolates the switch from the control circuits of the transmitter system. Generally, both sides of the control relays are available in the electrical connector. Therefore, the user must supply a power source to energize the control relay.

Rotary motorized coaxial switches are available for 1⅝", 3⅛", 4$\frac{1}{16}$" and 6⅛" cable systems. These switches will change positions in approximately two seconds. Their frequency range is good up through the TV frequencies. Some of the larger switches are limited in their use in the UHF range because of possible moding problems.

For use at higher power levels and high frequencies, another type of switch was developed. This is a motorized U-link type switch (Fig. 4). Its power ratings are essentially the same as the comparable transmission line and its problems at the higher frequencies have, therefore, been greatly reduced. Sizes for 3⅛", 4$\frac{1}{16}$", 6⅛", 8$\frac{3}{16}$", and 9$\frac{3}{16}$" cable systems are available. Because of the mass of the moving parts of the larger switches, switching time is increased to approximately 10 seconds.

Figure 3. Coaxial rotary switch.

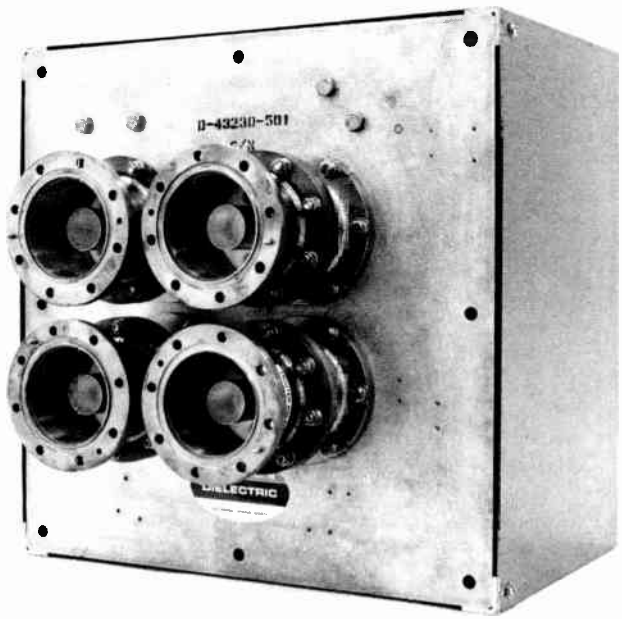

Figure 4. High power coaxial switch.

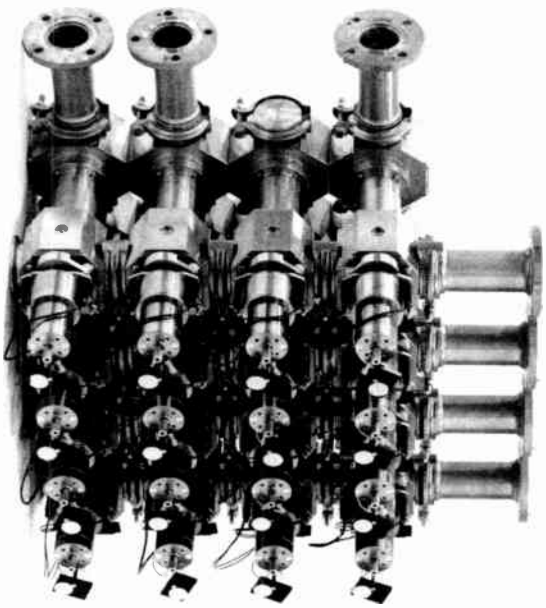

Figure 5. Coaxial crosspoint matrix.

Switches for Shortwave and AM Applications

Open wire switches can be used in lower frequency applications, such as the AM and shortwave bands. These switches often resemble high-power relays or contactors. The major differences are the type of dielectric material and the spacing between the contacts. Various types and sizes are available for use with powers from a few watts to several hundred kilowatts.

In addition, coaxial crosspoint switches are commonly used for AM and shortwave applications. A crosspoint switch consists of two SPDT switches in a single case. When used in a matrix, the transmitters are each connected to the end of a column and the antennas or load are connected to the end of the rows. In the inactive position, each switch passes the energy from one transmitter along its column while simultaneously passing another channel, highly isolated along a perpendicular row. When a switch is activated, its signal along the column is diverted to the row either to the right or the left. In this way, output from any transmitter can be routed to any antenna.

Coaxial sizes in excess of 10 inches in diameter may be switched in this manner, handling average power levels in excess of 1 megawatt. Fig. 5 depicts 1⅝" coaxial cross point matrix (4 rows × 4 columns). Newer designs, such as the one shown, feature >80 dB isolation, modular construction and auxiliary interlocks.

Waveguide Switches

Waveguide switches are available in three-, four-, and five-port versions. The RF sections of both manual and motorized switches are usually the same. Manual units will have a knob or handle to change the positions of the switch. Motorized units have the manual drive replaced with a motor drive assembly. Some type of motor control circuits will also be required.

The four-port transfer switch shown in Fig. 6 is an E-plane type of switch. Both E-plane and H-plane units are available. The four-port units usually take the form of crossed waveguide, with the ports 90° apart. Within the switch is a metal back plate that has

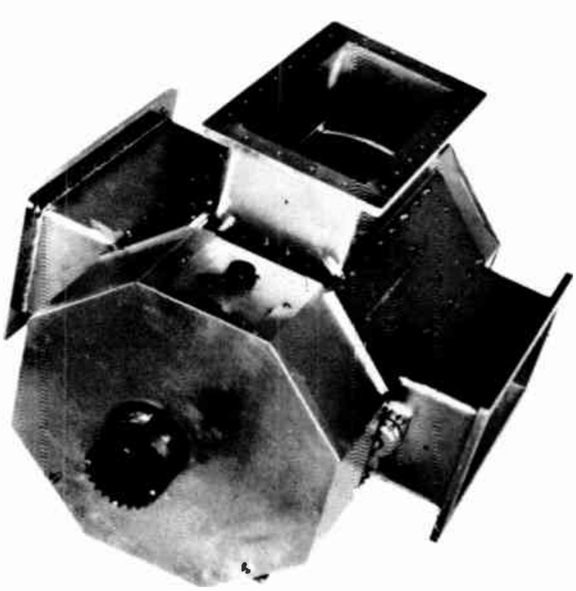

Figure 6. Port E-plane waveguide switch.

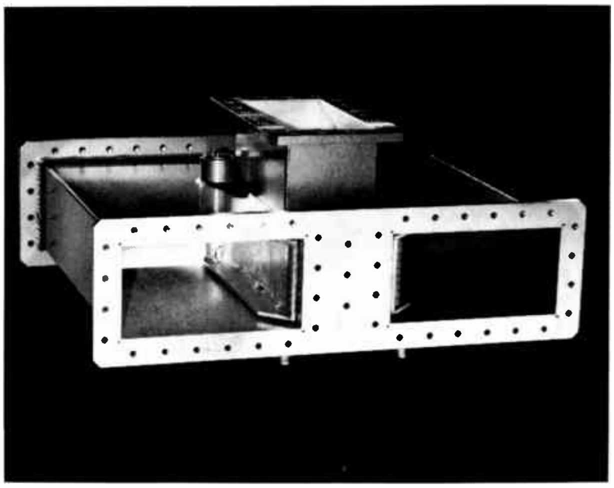

Figure 7. Five-port waveguide switch. (Courtesy Micro Communications, Inc.)

fingerstock around the four sides which contact the waveguide case. The back plate is positioned at a 45° angle to the ports of the switch. Thus, two ports of the switch will be connected together in the form of an elbow. In one position, the top port is connected to the right hand port, while the bottom port is connected to the left hand port. In the other position the opposite is true.

The control circuits of the waveguide switch are very similar to those in the coaxial switches. Various motor and control voltages are available. The waveguide switch is equipped with some type of interlock switches to turn off the transmitters during the switching process.

FILTERS

Filters are used in broadcasting to limit the undesirable emissions from transmitters. More specifically, it is necessary to limit the harmonic content of transmitters to prevent interference at higher frequencies with other services. In addition, it is necessary to limit the intrusion of other RF signals into the final stage of transmitters as a result of antenna coupling.

The FCC addresses these requirements for the FM broadcaster in Volume III, Subpart B, Section 73.317, Paragraph 14 of the Regulations by stating that "any emissions appearing on a frequency removed from the carrier by more than 600 kHz shall be attenuated by 43 dB + 10 log (power) dB below the level of the unmodulated carrier or 80 dB, whichever is the lesser attenuation." If a broadcaster is operating above 5 kW, the 80 dB requirement applies. For comparison, a broadcaster operating at 100 watts would be required to meet a 63 dB requirement under these rules.

The TV requirement is addressed in Volume III, Subpart D, Section 73.687, Paragraph (i)(1). In part, it states ". . .all emissions removed in frequency in excess of 3 MHz above or below the respective channel edge shall be attenuated no less than 60 dB." It goes on to say that this requirement should be considered temporary and that the state of the art might be the more appropriate limit. Broadcasters are encouraged to seek this limit in order to meet future rule making requirements.

Harmonic Filters

Harmonic filters are commonly used on the output of all transmitters used for broadcast applications. They can be built for use with either coaxial or waveguide. The decision to use one form over the other is a matter of convenience (i.e., size), performance, and cost.

The coaxial form is used in the lower portions of the broadcast spectrum, namely VHF, FM, and portions of UHF bands. For low band VHF and FM, where the maximum ERP is limited to 100 kW, coaxial harmonic filters are used since the common EIA line sizes from 3⅛" to 6⅛" coaxial can handle these power levels without degradation due to higher order modes. Waveguide would have to be greater than 60" to operate in the fundamental mode at these frequencies.

Harmonic filters will pass the fundamental frequency with efficiencies of about 98% or −0.1 dB insertion loss. They will reject the second through the fifth harmonic with attenuation of −40 to −50 dB. By virtue of their function of attenuating harmonics they are, by necessity, designed to handle a limited segment of the band (less than one octave). Table 1 lists the typical way the band is divided.

The skirt of the attenuation curve must have a slope sufficiently large to pass the highest fundamental frequency and reject the lowest frequency in the second harmonic. A filter with nine to eleven stages will normally provide 40 to 50 dB rejection at the low end of the second harmonic.

A waveguide harmonic filter is normally used at frequencies on the high end of the UHF band. This is necessary for several reasons. Larger coaxial sizes will support the generation of higher order modes near the high end of the frequency spectrum for UHF-TV. Higher order modes will be sustained at a frequency where

$$\text{wavelength} = \pi\,(a+b)$$

TABLE 1

Channel	Fundamental	2nd Harmonic	Typical Construction
2–3	54–66 MHz	108–132 MHz	Coaxial
4–6	66–88 MHz	132–176 MHz	Coaxial
FM	88–108 MHz	176–216 MHz	Coaxial
7–13	174–216 MHz	348–432 MHz	Coaxial
14–43	470–650 MHz	940–1300 MHz	Coaxial
44–52	650–698 MHz	1300–1396 MHz	Coaxial or Waveguide
52–69	698–806 MHz	1396–1612 MHz	Waveguide

where a and b are the radii of inner and outer conductors. Larger coaxial sizes are also needed to handle the power levels authorized in the UHF band. 8³⁄₁₆", 75 ohm line will support higher order modes at frequencies just above channel 56; and 9³⁄₁₆", 75 ohm cable at frequencies just above channel 40. But the construction of a coaxial filter is a cascade of larger and smaller diameter inner conductors. The larger inner conductors essentially cause moding to occur at longer wavelengths or lower frequencies. This phenomenon lowers the effective frequency at which coaxial filters can be used.

Waveguide filters must therefore be used above channel 40 when transmission line power levels exceed the rating of 6⅛" coaxial. One type is commonly called a waffle iron filter because the broad walls of the waveguide resemble the top and bottom plate in a waffle iron. A waffle iron harmonic filter in WR 1150 waveguide can be used between channels 40 and 69.

Harmonic filters are usually supplied with transmitters since the transmitters cannot meet FCC Rules with regard to harmonic content without a filter. The broadcaster will seldom need to buy a harmonic filter unless he has experienced a severe transmission line failure or acquired a used transmitter.

Band-Pass and Band-Stop Filters

Band-pass filters are used sometimes in combination with band-stop filters to control another class of spurious emission problems. The transmitter (with its harmonic filter) is capable, in the absence of other RF signals, of producing transmissions which are free of any emissions. Potential problems arise, however, when the transmission facilities of two or more broadcast channels are located very close to one another.

Assume, for example, that Channel A and Channel B use antennas on the same tower. This is common today. Channel A's antenna, in addition to transmitting its primary signal, also receives some of Channel B's signal. The magnitude of this received signal depends on the gain and bandwidth of Antenna A at the frequency of Channel B as well as the distance between the two antennas. Several spurious signals can be generated in Transmitter A and transmitted on the air as a result of the presence of RF from Channel B. The transmitter will usually, because of its limited bandwidth, provide several dB turnaround losses for this spur. The most troublesome spur will occur at a frequency which is

$$F = 2A - B$$

A comparable problem could occur in Transmitter B where

$$F = 2B - A$$

The magnitude of the spur will be equal to the power level of the coupled signal minus the turn-around loss. So, if Channel B is present in Channel A's transmission line at a level of −40 dB down from Channel A's power level, and Transmitter A provides −10 dB turn-around loss, then a spur will likely exist at (F = 2A-B) with an amplitude of −50 dB from Channel A's amplitude. In order to comply with FCC Rules for FM, therefore, a filter would have to be installed in Channel A's transmission line which would pass Channel A with minimal insertion loss (usually −0.15 dB) and provide −30 dB rejection at Channel B. This would lower the spur level to −80 dB below Channel A's transmission line level.

Another example of spurious emissions occurs when a channel 14 or channel 69 system is located in close proximity to land mobile communications. Two types of interference have been noted in this situation:

1. An intermodulation product of visual, aural, or color signals mixing to produce a spur at a frequency used by the land mobile system.
2. The power generated by the TV station simply overloads the front end of land mobile receivers although the carrier signals of each are at different frequencies.

The first situation must be addressed by providing filters in the TV station's system to reduce the resulting intermodulation. Fig. 8 illustrates how the intermodulation was suppressed at Home Shopping Network's Channel 69 in Hollywood, Florida.

The second situation must be addressed by installing a filter in the land mobile receiver system. This can generally be achieved with much smaller hardware when required.

The decision to use band-pass versus band-stop filters should be based on the nature and extent of the problem. Each type has virtues and limitations which make them suitable for certain problems.

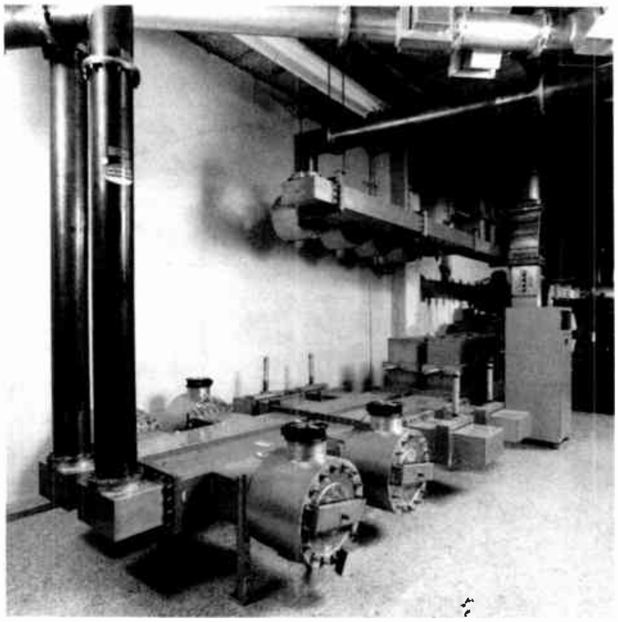

Figure 8. Notch filters at visual and aural inputs in Hollywood, Florida. (Courtesy Home Shopping Network.)

The typical response curves for several combinations are presented in Figs. 9 through 12. The band-stop (as depicted in Figs. 9 and 10) is characterized by rapidly rising skirts which make these filters particularly suited to rejecting frequencies that are extremely close to the desired frequency (i.e., frequencies displaced by as little as 0.8%). However, due to their sharp response, they are more prone to drifting with temperature than the band-pass configuration. They can be built so that drifting does not affect their desired performance, if manufacturers design them to minimize this tendency. Band-stop cavities are commonly used in the FM band. They are also used in VHF or UHF diplexers, but are not used to protect one TV channel from another since their band-stop widths are generally too narrow to reject an entire TV channel.

The notch responses shown were plotted in the FM band near 100 MHz. The center frequency can be scaled to anywhere in the VHF or UHF band, and similar percentage bandwidth would be obtainable. Fig. 9 depicts the response of a single-cavity notch. Fig. 10 shows a dual-cavity response.

Band-pass filter responses for a four-cavity and five-cavity filter are shown in Figs. 11 and 12. Again, these were measured near 100 MHz and their percentage bandwidth would be obtainable at any other frequency in VHF or UHF spectrum. The skirt selectivity is not as sharp for band-pass cavities as for band stop cavities. This suggests that more stages will be needed in band-pass cavities to obtain the same attenuation as a band-stop cavity. The band-pass cavity, however, has some advantages; since the pass band is broad, it is not affected by drifting due to temperature changes. The reject curves are also located symmetrically about the pass band.

The formula for locating the spur,

$$F = 2A - B$$

will always place the spur at exactly the same distance, frequency-wise, from the pass-frequency, but on the opposite side of the pass band. So the band-pass filter attenuates the incoming RF on one side and the resulting spur on the other side of the pass band. It also has the advantage of attenuating all frequencies sufficiently removed from the pass band. This is especially useful when multiple interferences are detected.

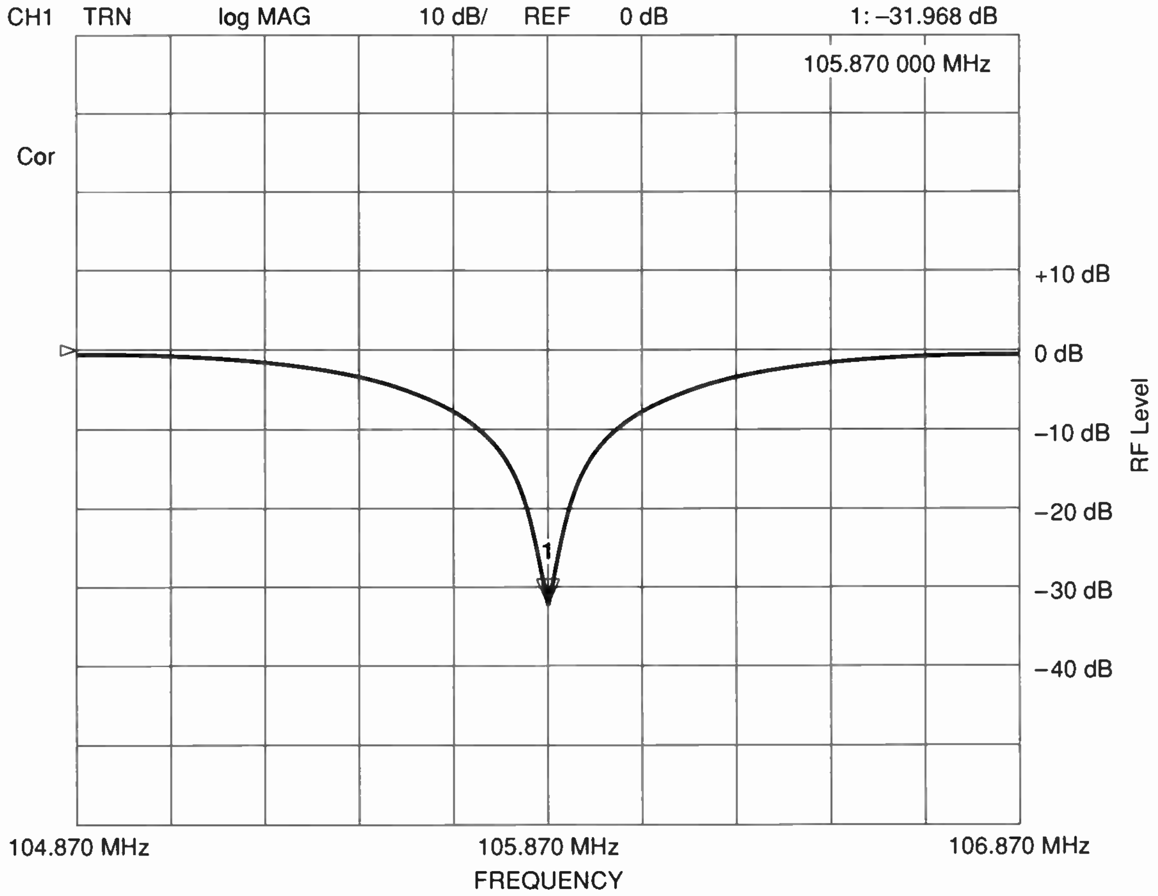

Figure 9. Single-cavity notch filter response 31.9 dB.

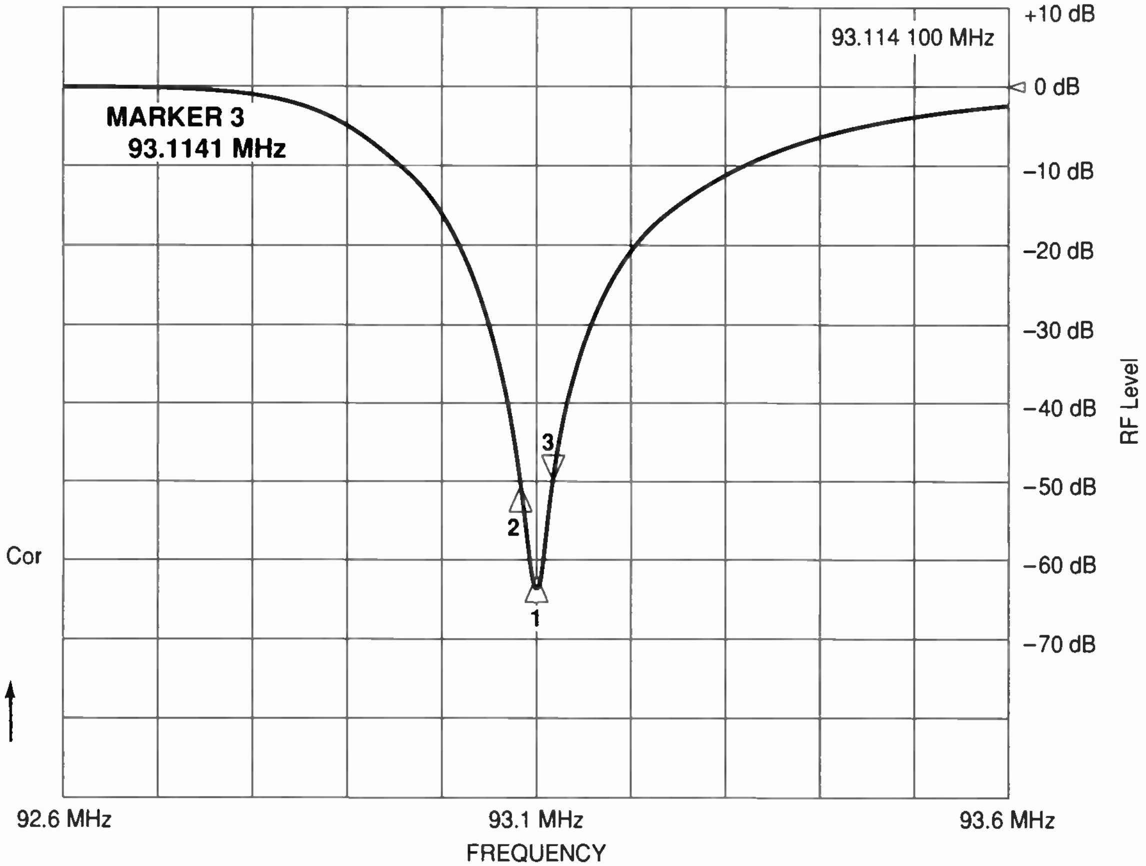

Figure 10. Dual-cavity notch filter response 64 dB.

Combinations of band-pass and band-stop are also available in a single filter. They can be visualized by superimposing a band-stop and a band-pass filter response with the notch located at the edge of the pass band. These filters are useful when interference is caused by a combination of one frequency close to the desired frequency and multiples further removed from it.

All of these responses in the VHF and FM bands can be achieved with coaxial cavities approximately ⅜-wavelength long and 12″ to 24″ in cross section. (See Fig. 13.) In the UHF band they can be produced by using coaxial cavities or waveguide cavities. These filter systems also serve as building blocks for the diplexing and multiplexing systems discussed in the next section.

Once a decision is made to use a band-pass, band-stop, or combination of both filters for a particular application, it is important to specify a few additional parameters to insure that the filter does not degrade the audio or visual content of the broadcast signal.

For example, if a filter is used to prevent Channel B from entering the transmitter of Channel A, the filter will pass Channel A and reject Channel B. But the reject curve for Channel B must not infringe upon the bandwidth of Channel A. Therefore, an insertion loss variation must be specified across the operating bandwidth and perhaps beyond. At FM, where these filters are commonly used, insertion loss variation can be kept within

$$< 0.1\ \text{dB},\ \pm 200\ \text{kHz}$$

when either the notch is sufficiently removed in frequency or the pass band is broad enough. The edge of the reject skirt in either configuration is also characterized by a large deviation in group delay. Group delay is defined as a change in phase divided by a change in frequency.

$$\text{Group delay} = \frac{\text{Change in phase}}{\text{Change in frequency}}$$

The standard for group delay at FM seems to be

$$\pm 25\ \text{ns}\ \pm 150\ \text{kHz}$$

This specification approaches state of the art limits when two FM channels are separated by only 800 kHz. Since group delay can exceed either of the above specifications at frequencies well inside the 3 dB points of a band-pass filter if improperly tuned, specification of group delay is desirable in order to assure proper audio performance.

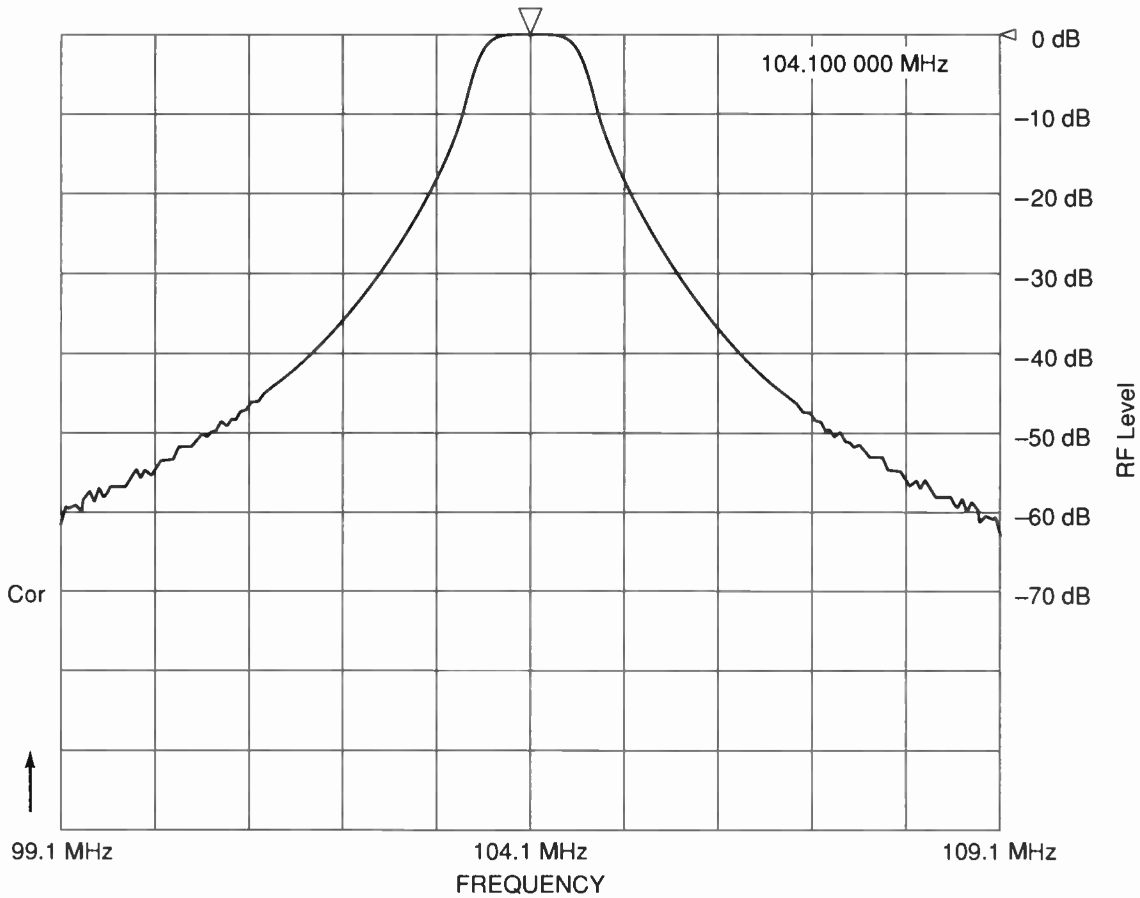

Figure 11. Four-cavity band-pass filter response.

Group Delay Correctors

The group delay response of a band-pass filter is U-shaped. A device which uses a hybrid in conjunction with two notch cavities produces a group delay response shaped like an inverted U. Since group delay is additive, the positive group delay of the bandpass added to the negative group delay of this corrector causes cancellation at the band edges relative to center frequency. The group delay correctors thereby produce a relatively flat group delay. These were first developed as high power devices used in multiplexers. They have since been developed for low power applications and are now used in FM applications and in the aural input of TV diplexers.

Diplexers and Multiplexers

Diplexers and multiplexers are devices which allow broadcasters to combine two or more frequencies in a common transmission line while providing the isolation needed to prevent either transmitter from generating spurious emissions. Figs. 14, 15, 16, and 17 provide schematic examples of configurations which can provide, in varying degree, the necessary response.

In the tee diplexer (Fig. 14) each input leg contains either a band-pass or a band stop filter. Each of these filters is characterized by a good voltage standing wave ratio (VSWR) and low insertion loss within the pass band. The slope of the reject curve away from center frequency is completely dependent on the number of cavities in each leg. Therefore, F1 and F2 must be separated sufficiently in frequency to allow the reject skirt to reach a rejection sufficient to obtain the desired isolation. All of this isolation (other than the 3 dB split of the tee) must be provided by the filter cavities. Figs. 11 and 12 show rejection to be expected with deviations from center frequency. In general, F1 and F2 must be widely separated for band-pass legs, and each operating band must be narrow for band-stop legs. In addition, this configuration has limitation when multiple frequencies must be combined.

Fig. 15 illustrates the branch combiner for three or more channels. This device is not generally used for inputs greater than 10 kW since the VSWR's and bandwidths are not as good as those in the constant impedance units shown in Figs. 16 and 17. Broadcasters with tight budgets may still consider these units if they are willing to accept some performance degradation.

Figs. 16 and 17 respectively are band stop and band-pass versions of a constant impedance diplexing configuration in common usage today at VHF, UHF,

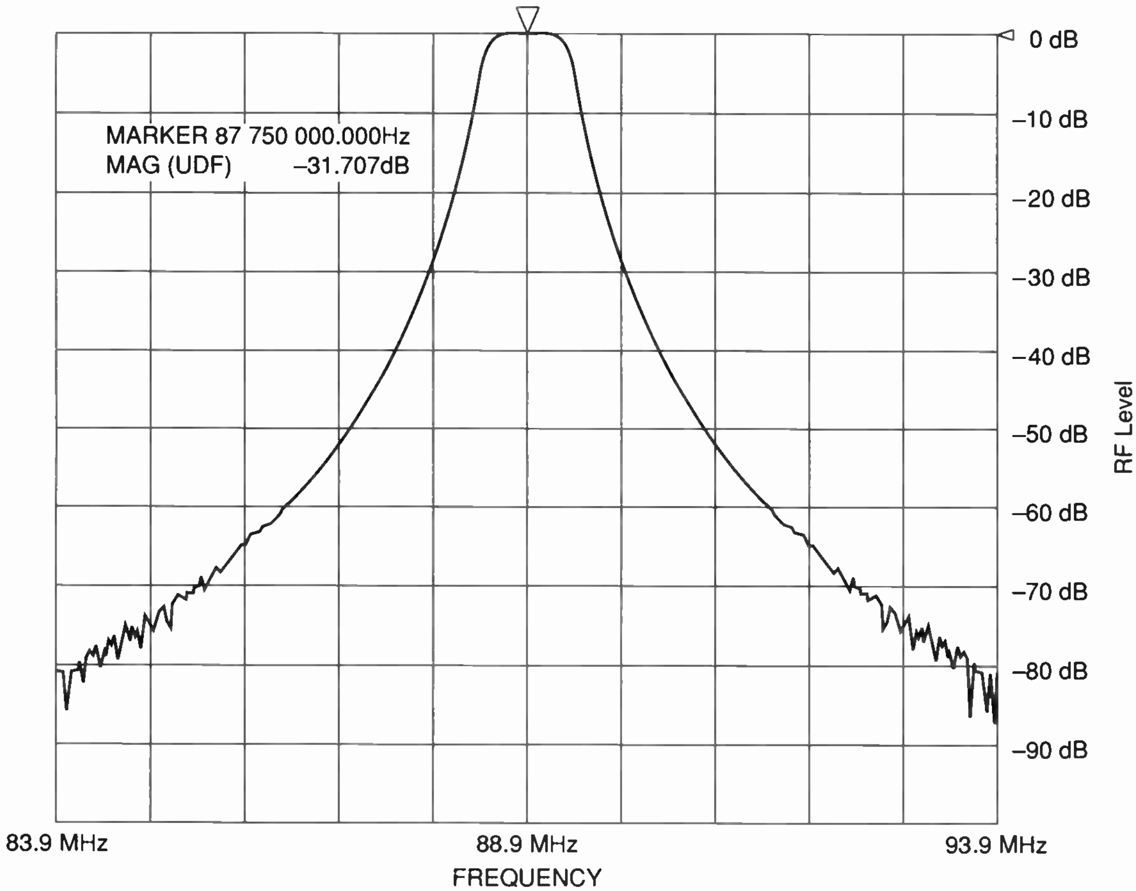

Figure 12. Five-cavity band-pass filter response.

and FM frequencies. In both configurations 3 dB hybrids are used on both ends of the system and there will be an equal number of cavities in each leg between the hybrids. With the exception of the load on the isolated port and possible differences in line size, each system is electrically symmetrical about lines running through the center, both vertically and horizontally. These systems have similar response in both coaxial and waveguide configurations.

The band-stop system of Fig. 16 is typically used for visual to aural diplexers in television applications. F1, in that case, would be aural and F2 would be visual. Aural would enter at F1, be split into both legs of the hybrid, and then be reflected by the notch cavities. The reflected signal would pass through the

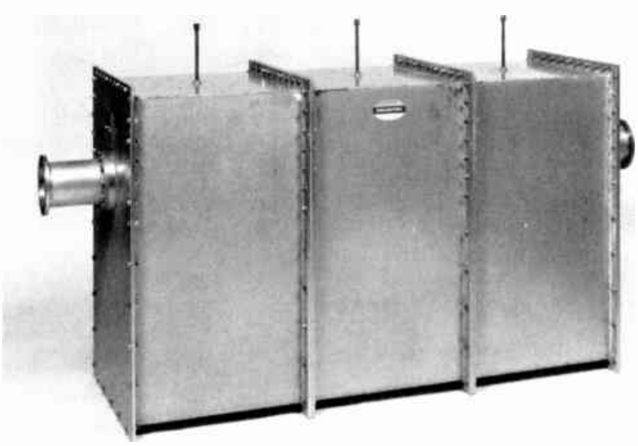

Figure 13. Three-cavity band-pass filter.

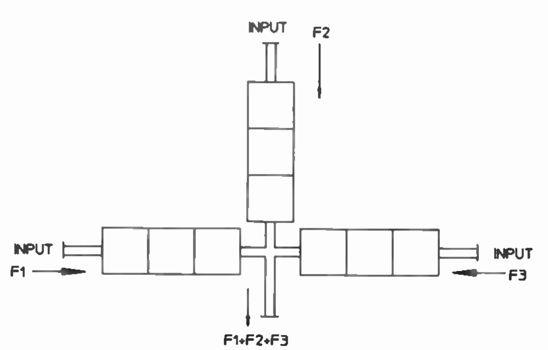

Figure 14. Schematic tee diplexer.

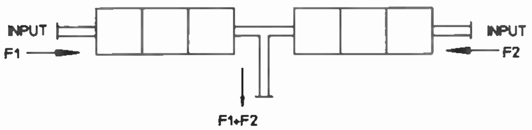

Figure 15. Schematic branch diplexer.

same hybrid as before but recombine in the output port.

The visual signal (F2) would enter the rightmost hybrid, split into the two lines with cavities, pass the cavities unattenuated, and recombine into the output. In most TV diplexers, the second cavity in each leg would be tuned to 3.58 MHz below the visual carrier. This is the lower sideband of the visual color signal. The signal enters F2 with the visual signal and is reflected, in a manner similar to the aural signal, except that this signal is reflected into the load and absorbed.

An analysis would show the isolation of visual (F2) to aural (F1) would be due solely to the isolation inherent in the leftmost hybrid. Over a 6 MHz bandwidth, this is typically 35 dB, but can be as high as 45 dB with special care. The isolation from aural (F1) to visual (F2) is due to two components. The notches produce 27 dB typically and the rightmost hybrid about 35 dB, for a total of 62 dB.

In previous years, this type of diplexer has been used at FM frequencies, but the poor isolation in one direction required the addition of supplementary cavities on the F1 input. In addition, the group delay for this approach was four times higher than achievable with a band-pass system and the lack of symmetry and inverted shape made group delay compensation more difficult. The bandwidth, while adequate for the aural component of a TV system, has proven to be too narrow for FM applications resulting in incidental amplitude modulation.

The notch type constant-impedance diplexer has been widely used for TV applications with excellent results.

The band-pass constant-impedance diplexer, shown in Fig. 17, is widely used for high-power diplexing or multiplexing applications in FM. It is occassionally used for diplexing complete TV signals, each containing visual plus aural. Several units can be cascaded together, each module providing a separate station's

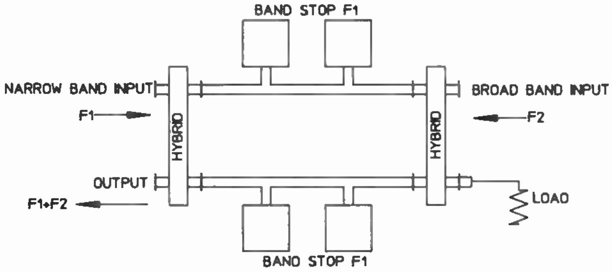

Figure 16. Schematic band-stop constant impedance diplexer.

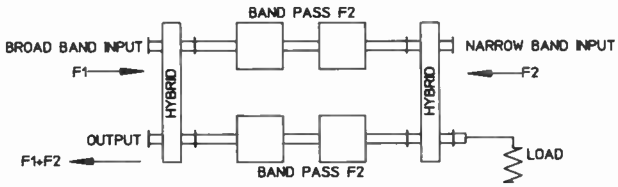

Figure 17. Schematic band-pass constant impedance diplexer.

input. Since the cavities are band-pass units, only one channel passes through them and all others are reflected. For this case F2 becomes an individual-station input. The signal is split by the hybrid and passes with minimal attenuation through the cavities to recombine in the output. Any channel (other than F2) sufficiently spaced to be rejected by the cavities will be injected at F1, be split by the hybrid and then reflected by the cavities. The reflected signal recombines in the hybrid to exit through the output port.

An analysis of isolation in this case shows a deficiency in isolation from F2 to F1. The isolation is entirely that inherent in the hybrid. Across a 20 MHz bandwidth at FM that isolation is typically 35 dB. The isolation from F1 to F2 is very good since it is due to the combined effects of the rejection of the cavities (which is >25 dB) and the hybrid (which is 35 dB) for a combined total of 60 dB.

If a module is used for each channel, then the adjacent module provides the additional rejection to increase the deficient isolation from F2 to F1 to 60 dB.

Fig. 18 shows a four station multiplexer that is using band-pass modules to combine three FM stations with a channel 6. The taller module passes channel 6. Two supplementary notches are shown to the left of the channel 6 module to supplement the isolation from channel 6 (aural) to a closely spaced FM channel.

Fig. 19 shows a VHF notch diplexer used to combine visual and aural. It functions as the schematic in Fig. 16 shows.

Fig. 20 shows a UHF waveguide notch diplexer. It also functions as shown in Fig. 15.

In the UHF portion of the band, where the visual transmitter is actually capable of amplifying the audio if diplexed low level, special motor-driven devices may be used in waveguides to detune the notch so that the entire content of the TV channel can be amplified by the visual transmitter, fed into the broadband port and recombined into the output without being attenuated by the notches. This is an emergency configuration for use when an audio transmitter fails.

TRANSMITTER SYSTEMS

In the following section, several methods of connecting one or more transmitters to the antenna system will be discussed. It would be impossible to cover all of the possible combinations. Therefore, only some of the basic configurations will be discussed. These can

Figure 18. Four-channel multiplexer: Ch. 6, plus three FM's. Corpus Christi, Texas.

be modified or expanded to suit the individual station's requirements. Most broadcast equipment manufacturers will be happy to assist in designing custom systems.

A Caution About Interlocks

When designing an RF output system with motorized coaxial switches, it is essential to make sure that the transmitter cannot produce RF power when the switch contacts open. Most coaxial switches are constructed so that the interlock kills the transmitter before the RF contacts open. However, this timing will vary between different types of switches. Also, the time it takes a transmitter to stop producing RF in response to the interlock signal will vary. Therefore, it is a good idea to check this timing. It may be necessary to turn off the transmitter a short time before commanding the coaxial switch to change positions. If the transmitter is still producing RF power when the RF contacts open, the contacts switch will be burned.

Single and Alternate Main Transmitter Systems

Fig. 23 illustrates a single TV transmitter system utilizing a seven-port patch panel. The patch panel would allow the visual or aural component or the diplexer output to be terminated in station load. If the transmitter has multiplex capability (amplifying both the visual and aural signals in the visual amplifier), the visual amplifier could be connected directly to the antenna, bypassing the diplexer.

An alternate main transmitter with a coaxial switch is shown in Fig. 24. A single ended transmitter (such as an AM or FM unit) would connect as shown. A TV transmitter would require two switches.

Parallel Transmitters

Parallel transmitters are two complete transmitters whose output is combined to double the available output power. In addition to the increased output

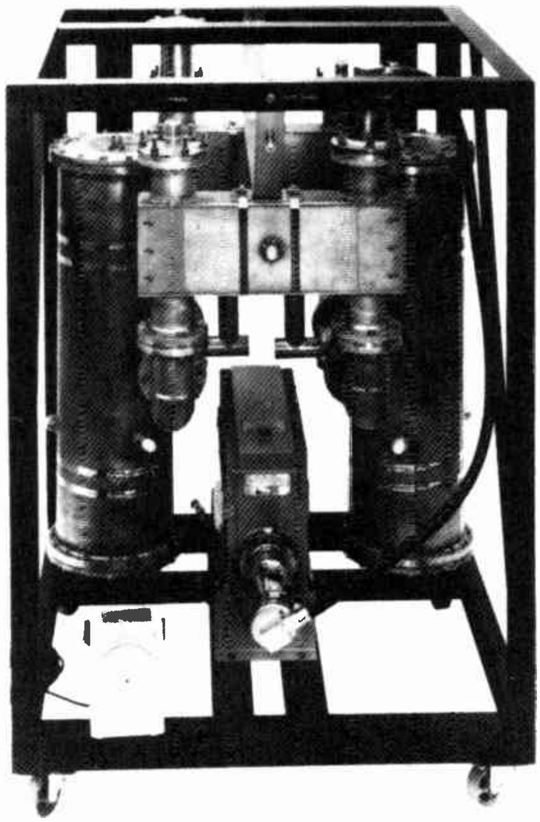

Figure 19. High band VHF notch diplexer.

power, the parallel transmitter has additional advantages, such as redundancy and reduction of ghosting in TV applications.

When one of the transmitters fails, the output power will drop to quarter power. If switching is provided in the output system, the output power can be increased to half power by bypassing the output combiner. This switching can take place at any convenient time after the failure.

In its simplest form, a parallel transmitter consists of an exciter-modulator, input power divider, two amplifier sections, output power combiner, and reject load. (Fig. 25.) In order to properly combine the input signals, they must be of the proper phase and amplitude. These relationships vary with the different types of combiners.

AM and Short Wave Parallel Transmitters

Parallel transmitters are not as common in the AM, and shortwave broadcast bands are not as common as in the higher frequency bands. They are generally used only to double the output power available.

Combiners used at these lower frequencies are usually a bridge circuit. The bridge is usually made of four circuits with a characteristic impedance of 70.7 ohms and constructed with lumped elements (capacitors and inductors). The bridge circuit is shown in Fig. 26A. The phase shifts produced by each leg can either be positive or negative 90°, depending on the elements used. If the shunt elements are capacitors, a negative phase shift will be produced. Using inductors will produce a positive phase shift for the shunts. If the

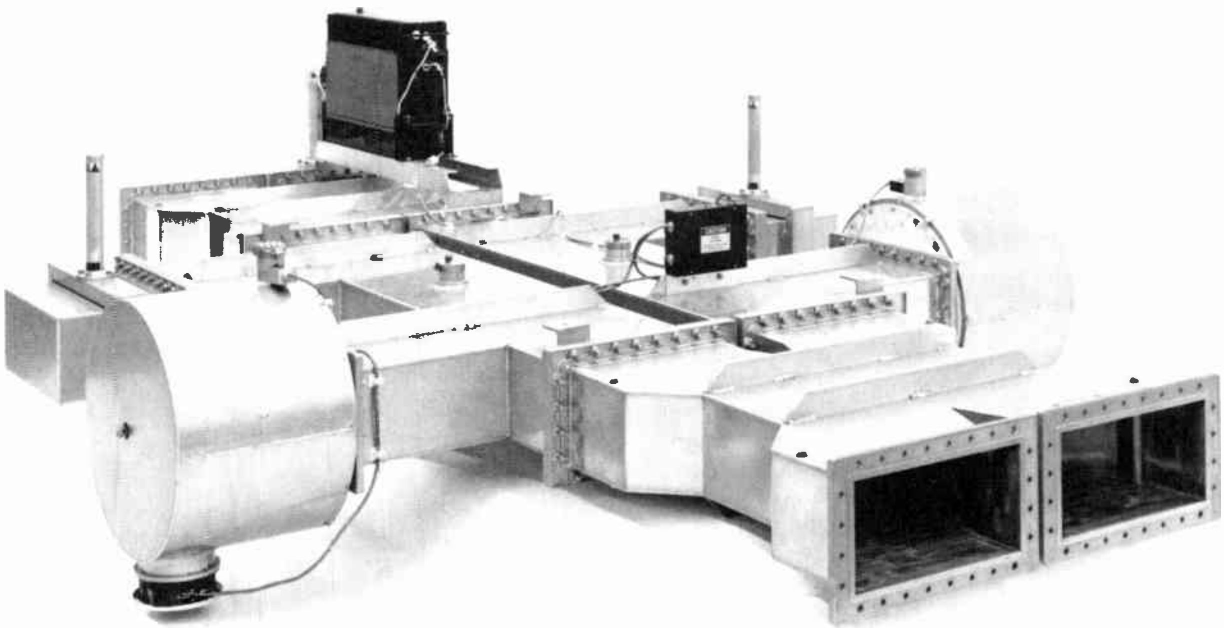

Figure 20. WR1500 waveguide notch diplexer.

Figure 21. UHF low-power TV notch diplexer. (Courtesy Micro Communications, Inc.)

two transmitters are fed to the two inputs in phase, the two signals will be in phase at the antenna output, they will combine. The two input signals will be 180° out of phase at the reject load output, therefore, there will be no power dissipated in the load. When one of the transmitters stops producing power, the power from the remaining transmitter will be split equally to the reject load and the antenna.

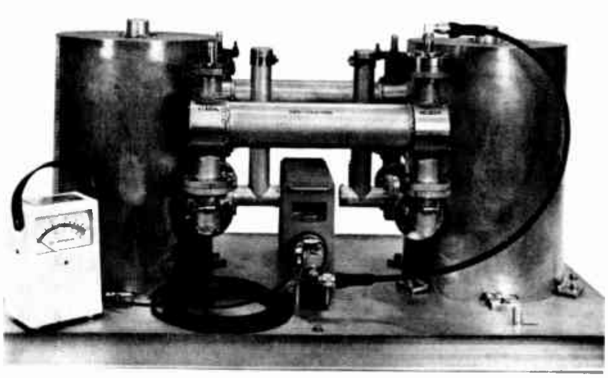

Figure 22. High band low-power TV notch diplexer.

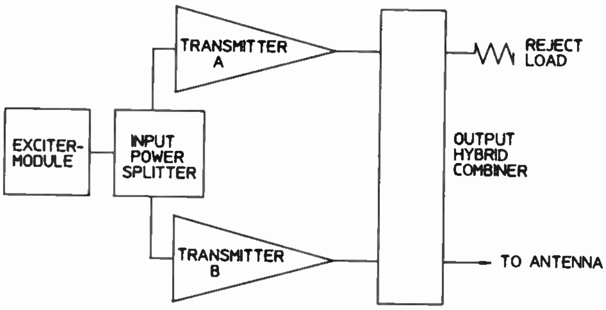

Figure 23. RF flow diagram TV transmitter with seven-port patch panel.

By making three of the legs of the bridge a positive phase shift, the number of circuit components can be reduced. This simplified circuit is shown in Fig. 26B. The two parallel capacitors across the antenna output and Transmitter 1's input can be combined so that only one capacitor is required at each point. The capacitor and inductor that are in parallel across the reject load and Transmitter 2's input will have equal reactance and thus cancel, so neither are required. The bridge combiner can be built with only three capacitors and three inductors, thereby reducing costs. An added advantage of high current carrying devices is that, of the series elements, three are inductors.

Ferrite core transformers may be used as combiners in lower power applications. One parallel transmitter using such a device is shown in Fig. 27. This unit is used to combine two 5 kilowatt transmitters.

The combiner can be thought of as a center-tapped autotransformer that operates at radio frequencies. If equal-amplitude signals that are in-phase are applied to the ferrite combiner, with a common ground, the sum of the two will appear at the center tap signals. Since the two signals are in-phase, there will be no voltage differential across the reject load resistor.

If each input power is 200 watts, for example, there will be 100 volts at 2 amperes across the 50 ohm input of the ferrite transformer. When the two signals are added, current will total 4 amperes. Since the center tap of the transformer has an impedance of 25 ohms, the 4 amperes will produce 400 watts of power. An "L" network is used to match the 25-ohm center tap of the transformer to the 50-ohm output.

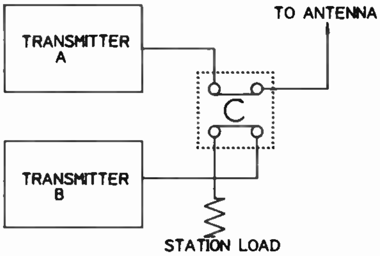

Figure 24. RF flow diagram with alternate main transmitter.

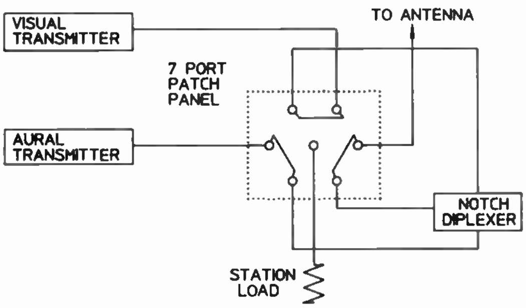

Figure 25. Basic parallel transmitter.

When only one transmitter is operating, the power it produces will be split equally between the antenna and the reject load. The operating transmitter will produce 200 watts, or 100 volts at 2 amperes in the example above. Therefore, there will be only 2 amperes at the center tap of the transformer, which will produce 100 watts of power. Since the other transmitter is not operating, there will be 100 volts across the 100 ohm reject load, which is the remaining 100 watts produced by the operating transmitter.

VHF Parallel Transmitters (Coaxial)

In VHF parallel transmitters, the output combiner is usually a 3 dB, 90° hybrid. In order to properly combine the two transmitter signals, the hybrid requires that the signals be of equal amplitude and phased

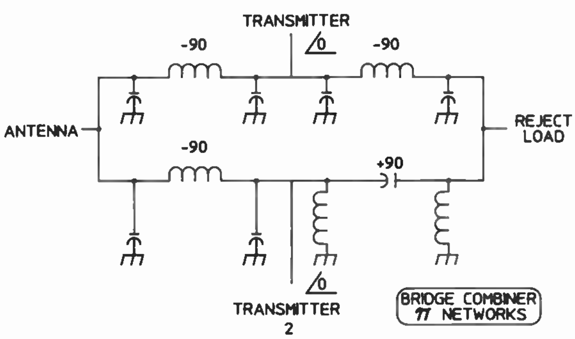

Figure 26A. Bridge combiner PI network.

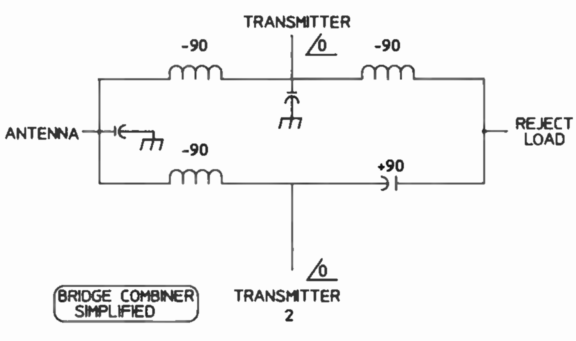

Figure 26B. Bridge combiner simplified.

in quadrature (90°). If we assume that the amplifier sections of the transmitters are identically tuned and that the electrical path lengths and gain are the same, then the input power divider must provide two signals that are of equal amplitude and phased in quadrature. A 3 dB hybrid will provide this type of power division, but other types could be used. An in-phase power divider with a 90° delay in one output would work just as well.

Fig. 28 shows the relationship of phase error to output power of the parallel transmitter system. With no phase error (input signals to the output hybrid in quadrature) 100% of the available transmitter power will be delivered to the antenna. If there is a 90° phase error, both signals in-phase, the power will be divided equally between the antenna and reject load. All available transmitter power will be dissipated in the reject load if the phase error is 180°. A phase error of 20° will only result in an output power reduction of approximately three percent. This would indicate that the phasing is not critical for output power considerations.

The relationship between relative amplitude of the two transmitters and output power is shown in Fig. 29. The graph assumes that one of the transmitters is operating at full power and that output power of the second transmitter is varied from zero to full power. If only one transmitter is operating, the output power will be only 25% of the normal combined output power. With only one input signal, the output hybrid acts as a power divider, applying half the power to the antenna and the other half to the reject load. The power being fed to the antenna is 25% of the normal combined transmitter power. If one of the transmitters is operated at half its normal output power while the other transmitter is operated at full power, the combined output power will be approximately 73% of the normal combined power. Since the two transmitters are only generating 75% of the normal combined power, only about 2% of the power is being dissipated in the reject load. Therefore, not much power is wasted in the reject load. The maximum power that the reject load should be required to dissipate is half of one transmitter's power.

Thus far only the basic parallel transmitter system has been discussed. It was assumed earlier that the amplifier sections of the transmitters were identically tuned, having the same electrical path lengths and gain. From a practical viewpoint this could be done, but with difficulty. Therefore, most parallel transmitter systems provide a means of controlling the phase and gain of the transmitters that is independent of the tuning. This usually means an attenuator for gain and a phase shifter for the phase. Some transmitters use a gain control within the amplifier section and one of the input matching controls of the power amplifier to accomplish these adjustments. This practice is probably more common in FM than TV since the FM bandwidth is smaller.

One of the major advantages of parallel transmitters in television is the reduction of ghosts or reflections

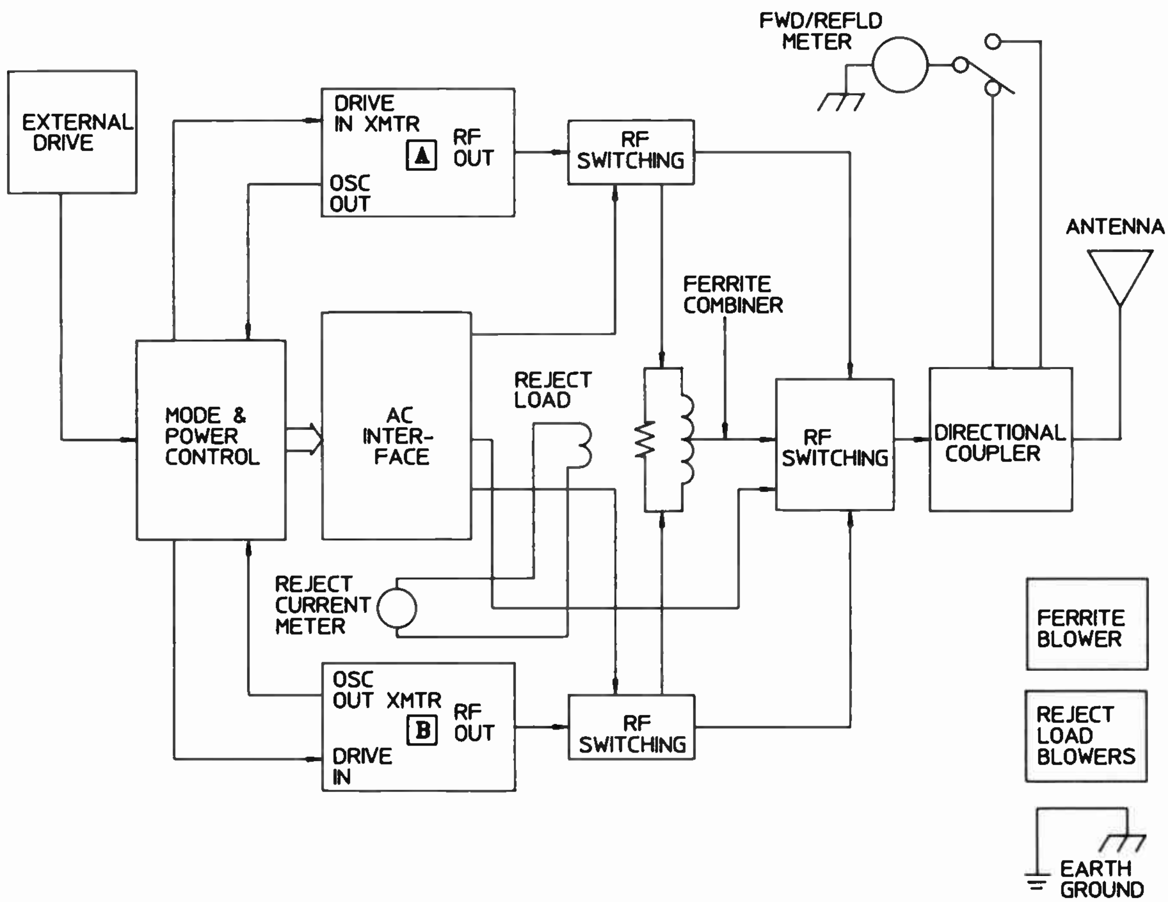

Figure 27. Simplified block diagram of combiner and RF switching using a ferrite core transformer. (Courtesy Harris Corporation.)

from the antenna. Ghosts occur when a portion of the power is reflected from the antenna back to the transmitter, re-reflected, and finally radiated. The distance between the original image and the ghost as shown on a TV receiver can be used to determine the approximate location of the reflection in the transmitting antenna system. Since the horizontal frequency of the TV is 15,734 kHz, the full horizontal line would be equal to 63.6 microseconds. The length of the visible portion of the horizontal line is 53.1 microseconds. Therefore, the time between the image and the ghost can be measured. This time, when compared to the speed of light, will yield the distance the reflected signal had to travel to produce the ghost.

It must be kept in mind that the reflected signal had to travel from the point of origination down the

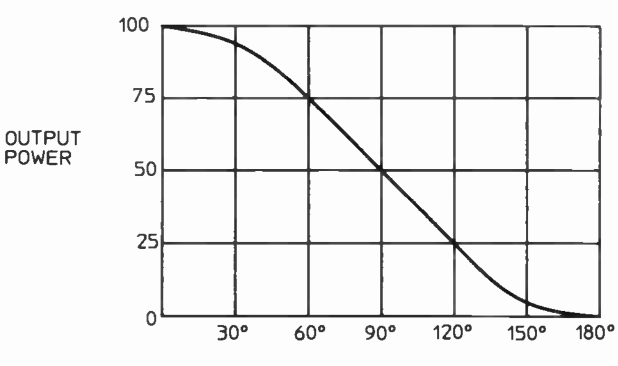

Figure 28. Relative output power versus phase error.

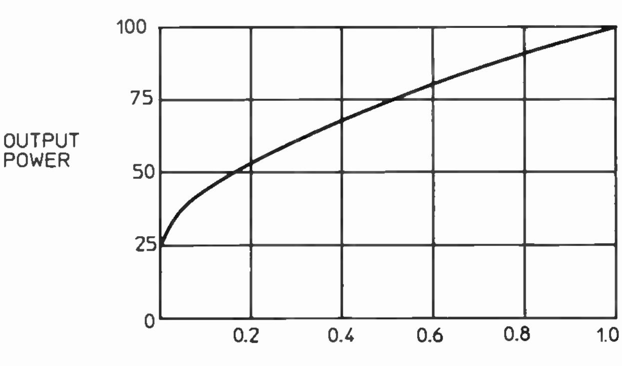

Figure 29. Relative output power versus amplitude ratio.

transmission line to the transmitter and back up the transmission line to the antenna to be radiated. The velocity of propagation of the transmission line must also be taken into account.

The use of the 3 dB hybrid in the parallel transmitter will reduce the reflected signals that produce the ghosts. When the reflected energy from the antenna is applied to the output of the 3 dB hybrid, it is split into two signals at the two transmitter inputs. These signals will be phased 90° apart and will continue until they are re-reflected by the output circuitry of the transmitters. The signals will then be applied to the inputs of the 3 dB hybrid. However, their phases are such that instead of combining in the antenna output, they will combine in the reject load of the parallel transmitter. For optimum ghost reduction the electrical path lengths between the hybrid and transmitter inputs must be the same. The use of slugs or other tuning devices can upset the phase balance or electrical length of the system.

One method to measure the effectiveness of a system for ghost reduction is to measure the reverse VSWR of the system. This is accomplished by placing open or short circuits on the transmission lines that would connect to the transmitter outputs and measuring the VSWR at the output of the combining system. Thus, the path of the ghost signal is being measured. Ideally, this path should be as good as the forward VSWR of the system. However, from a practical standpoint, a VSWR of 1.1:1 or better will reduce the ghosting. It should be noted that equal electrical line lengths are needed for quadrature type combining networks. For systems using in-phase type combining networks, there must be a 90° delay in the proper input. To offset this delay, a 90° delay can be inserted in the input circuitry of the opposite transmitter.

Fig. 30 shows a complete output switcher for a parallel television transmitter. For single-ended transmitters such as used in FM, only half the system would be required. This figure shows the switching options of the output hybrid combiner. There are normally four modes of operation:

1. A and B combined to the antenna.
2. A and B combined to the station load.
3. A to the antenna and B to the station load.
4. B to the antenna and A to the station load.

As drawn, the diagram is shown in the A&B to the antenna mode. By rotating S3 and S6, the system is changed to the "A and B combined to the station load" mode. If S1, S2, S4, and S5 are changed, Transmitter A will be connected to the antenna while Transmitter B will be connected to the station load. If S3 and S6 are rotated, the transmitters will switch Transmitter A to the station load while Transmitter B is connected to the antenna.

Since a parallel transmitter is really two complete transmitters, there should ideally be two exciter-modulators. Some manufacturers may offer the second exciter-modulator as an option. By adding a switch on

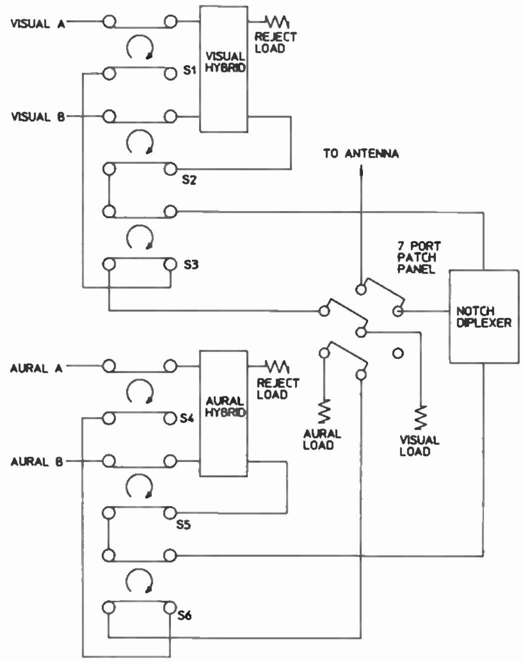

Figure 30. RF flow diagram for output switcher.

the input of the input power divider, either exciter-modulator could be selected. This would provide redundancy, should the active exciter-modulator fail. Since the power level of the exciter-modulator is usually fairly low, the switching could be done under power, which would allow the switching to be automatic. By using relatively fast switches, the transfer could be done with only a small carrier interruption.

Automatic operation of the output switching system is not usually done. Stations would rather choose when the carrier break occurs, since it will be noticeable to the audience. In lower power installations, the carrier break will be two seconds or less. With higher power switches the break could be up to ten seconds.

Again referring to Fig. 30, the combined output of the visual hybrid must pass through S2 and S3. Therefore, these switches must be sized to carry the combined power. Some systems will add another coaxial switch (S7) on the output of the visual hybrid as shown in Fig. 31. This higher power switch will allow the other three switches to be of a smaller size, since the combined power will only be applied to S7. It would then be necessary to add another station load for the combined signal at S7. Generally, this will reduce both the physical size and the cost of the parallel transmitter system. A television system requires a diplexer of some type in order to combine the aural and visual signals. The output switching system usually contains a patch panel which allows the output of the diplexer to be routed either to the antenna or the station load. The output switching system must also contain the necessary monitoring points for combined power and reject power.

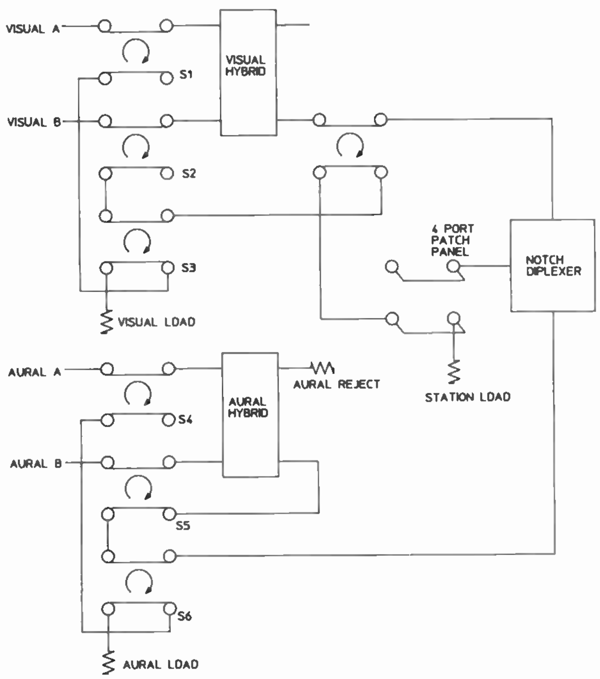

Figure 31. RF flow diagram for high power output switcher.

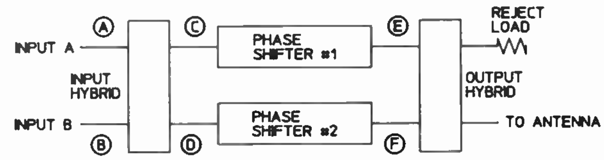

NOTES:

1. INPUTS A+B ARE IN PHASE
2. PHASE SHIFTER #2 WILL USUALLY CONTAIN A FIXED 90° SECTION AND A VARIABLE 90° SECTION.

MODE	PHASE SHIFTER #1	PHASE SHIFTER #2
A+B ANTENNA	0	90
A-ANTENNA B-LOAD	90	90
B-ANTENNA A-LOAD	0	180

Figure 32. Schematic of basic switchless combining system.

VHF Switchless System (Coaxial)

The switchless system also combines the outputs of two transmitters operating in parallel.

As with the switch method, it provides four modes of operation:

1. A and B combined to the antenna.
2. A and B combined to the station load.
3. A to the antenna and B to the station load.
4. B to the antenna and A to the station load.

There are several methods to accomplish these mode changes without the switches. A basic system is shown in Fig. 32 and consists of two 90° hybrids, a reject load, and some type of phase shifting device. The method used to shift the phases defines the various options. Therefore, the basic system will be presented here, and then the different methods of accomplishing the phase shift will be discussed.

Since the switchless system contains two hybrids, one must understand how the hybrid operates. The 90° hybrid can be used as either a power divider or a power combiner. In the switchless system both are used.

When used as a power combiner, the hybrid will combine two signals that are equal in amplitude and phased in quadrature. Again referring to Fig. 32, if two equal amplitude signals are applied to points E and F, with the signal at F lagging in phase by 90°, the signals will be combined into the antenna. Conversely, if the signal at point E is lagging by 90°, the signals will be combined into the load.

If a signal is applied to the A input of the hybrid (now being used as a power divider), it will be split into two signals of equal amplitude that are phased 90° apart. The signal appearing at Point C will be in phase with the input signal (Point A), while the signal at Point D will lag the input signal by 90°.

The converse is true for a signal being fed into the B input. The signal at Point D will be in-phase, while the signal at Point C will lag 90°. If two signals that are in-phase are applied to inputs A and B, then each of the outputs (Points C and D) will have two signals, one in-phase with the inputs and one lagging by 90°.

If the switchless system is set in the A and B to the antenna mode, phase shifter #2 must have 90° more phase shift than phase shifter #1. The two signals at Point F will lag the two signals at Point E. In this situation, the signals will combine in the antenna output.

If either of the phase shifters are set for an additional 90° of phase shift, the system will be in one of the single transmitter modes of operation. If phase shifter #1 is changed, then Transmitter A will be routed to the antenna, while Transmitter B will be terminated in the station load. Should phase shifter #2 be changed, Transmitter B will be routed to the antenna, while Transmitter A is terminated in the station load.

There are three methods of sending output from the combined transmitters to the station load:

1. A coaxial switch or patch panel could be used at the antenna output to route this output to a separate station load.
2. The combined transmitters could be routed to the reject load by moving the additional 90° phase shift in phase shifter #2 to the #1 phase shifter.
3. The transmitter outputs could also be combined into the reject load by changing the input phases to the switchless system. By adding 180° delay to

the A input, the combined transmitter output will be routed to the reject load.

The latter two methods will require that the power rating of the reject load be increased to the combined power level instead of that of a single transmitter. They also require that the antenna receive any power that is not absorbed in the reject load.

There are several methods of changing the phase of the RF signals in the switchless system.

1. Probably the most familiar method of changing the phase at higher power levels is the line stretcher. It is a piece of transmission line whose length can be changed. For convenience, it often takes the form of a U-link, or trombone, so that the connectors can be mounted and the U-link moved to change the length.
2. Another method uses a 90° hybrid with movable short circuits on two of the arms (Fig 33). If a signal is applied to the input (Point A), the hybrid will divide it into two equal signals that are phased 90° apart. The signal at Point D will lag by 90°. The short circuits attached to Points C and D will reflect the two signals back to the hybrid. The phase of the two signals will be delayed by twice the electrical length of the short circuits. If the two short circuits are the same length, the relative phases of the two signals will still be 90°. Since the signal at Point D is lagging by 90°, the two signals will combine into the output (Point D). By changing the length of the short circuits, the delay or phase shift through the circuit will change. If the short circuits are moved 90°, the phase shift through the circuit will change. If the short circuits are moved 90°, the phase shift through the circuit will be 180°. The signal must travel from the hybrid to the short circuit and then return to the hybrid, twice the distance of the short circuit. The two short circuits must be moved together in order to make the hybrid combine the reflected signals properly.
3. Fig. 34 shows several methods of making a short circuit needed in the above circuit. It could be the traditional short (i.e., a piece of movable metal contacting the inner and outer conductors of the transmission line).
4. A *deep short* could be used which moves the ringer contacts one quarter wavelength away from the short. This greatly reduces the amount of current that the fingers are required to carry. A *noncontacting short* may be used. It is a pair of cylinders that are a quarter wavelength long and shorted at one end. The sizes of the cylinders are such that they fit between the inner and outer conductors of the transmission line. The shorted cylinders are insulated from the transmission line, thus forming a capacitor. The capacitor is large enough to have very little impedance at the operating frequency, therefore, it appears as a short circuit.
5. Another method of creating phase shift is to use an open circuit. A short section of the center conductor is removed from a shorted piece of transmission line. The transmission line appears as an open circuit, since there is very little capacitance between the two pieces of cut center conductor. By moving an insulated metal probe across the gap in the cut center conductor, a large amount of capacity is created. This causes the transmission

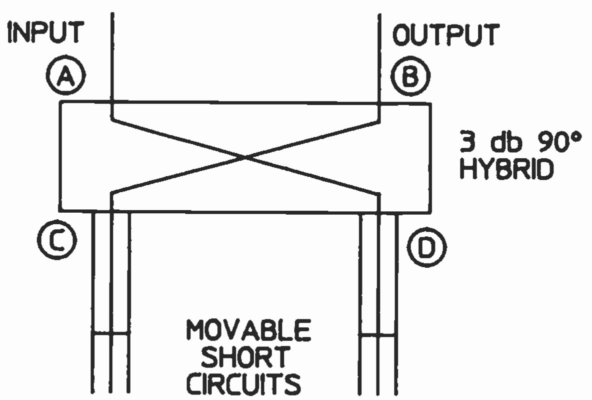

Figure 33. Variable phase shifter assembly.

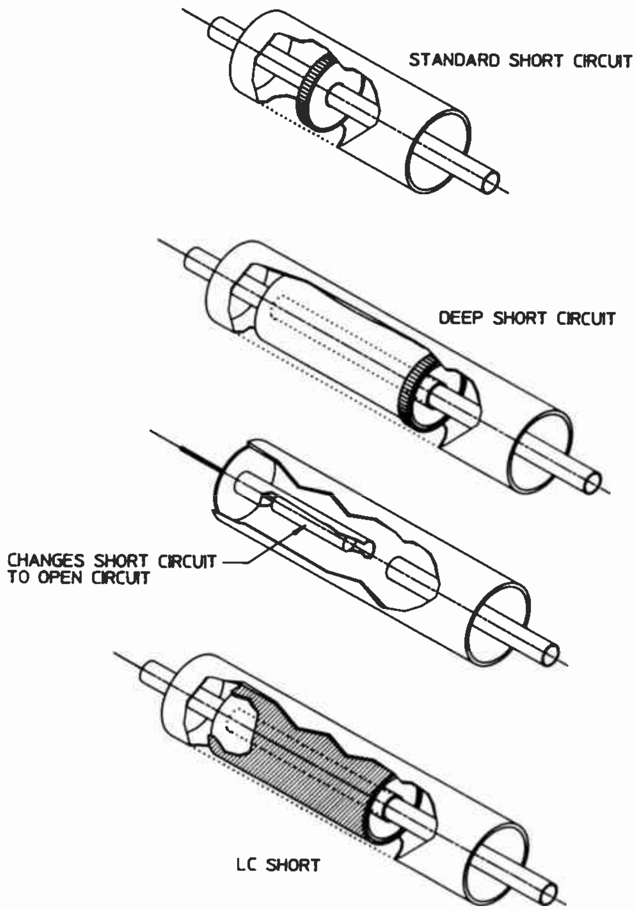

Figure 34. Variable phase shifter options.

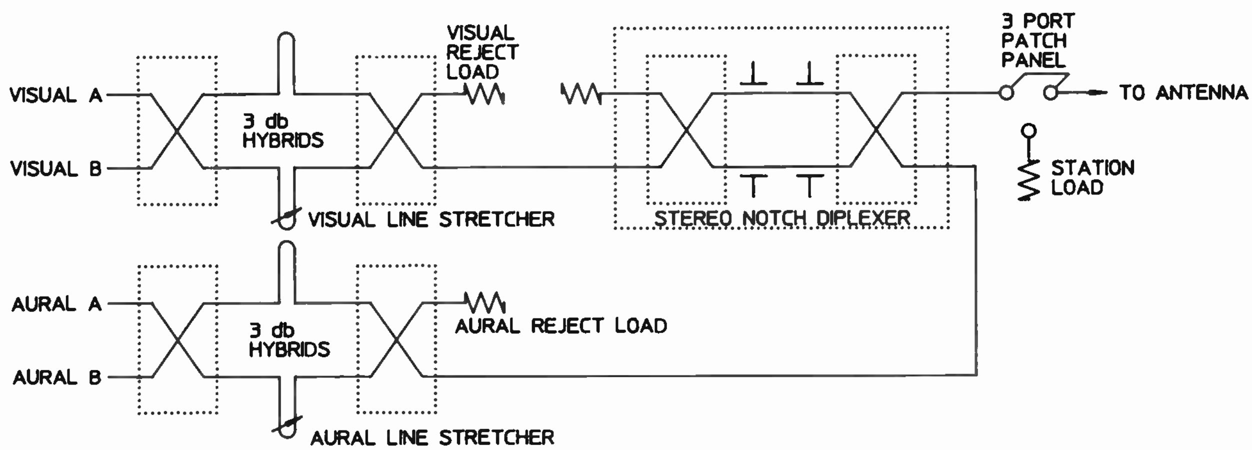

Figure 35. RF flow diagram VHF switchless system with diplexer.

line to appear as a short circuit, thus changing the phase.

All of the above methods will change the phase and allow the switchless system to operate. Each method has advantages and disadvantages that should be taken into consideration upon purchasing a switchless system.

A typical flow diagram for a VHF switchless system is in Fig. 35, and a diagram for a coaxial Opto-SX is shown in Fig. 36.

The switchless system does not require that the transmitters be turned off during the switching process. Since there is no carrier break, the length of switching is not important. Switching may be be done with no regard to program content.

The switchless system will offer the same ghost reduction capability as other types of parallel transmitters. Since the two signals from the transmitters are applied to the switchless system in-phase, there must be an external phase shift to take advantage of the ghost reduction feature. A 90° phase shift must be added between the output of one of the transmitters and the switchless system. This will delay the reflected signal in that path 90° as it passes from the output system to the transmitter, and another 90° as it passes from the transmitter back to the output system. The two reflected signals will now be 180° out-of-phase, and thus be combined in the reject load. Since a 90° delay was added to one of the transmitter signals, it will be necessary to add an equal phase shift to the other transmitter so that the two signals will combine in the antenna output. This delay can be added to the input circuits, allowing the ghost reduction circuit to operate properly.

Safety Considerations

There are some safety aspects of the switchless system that were not present in the switch type

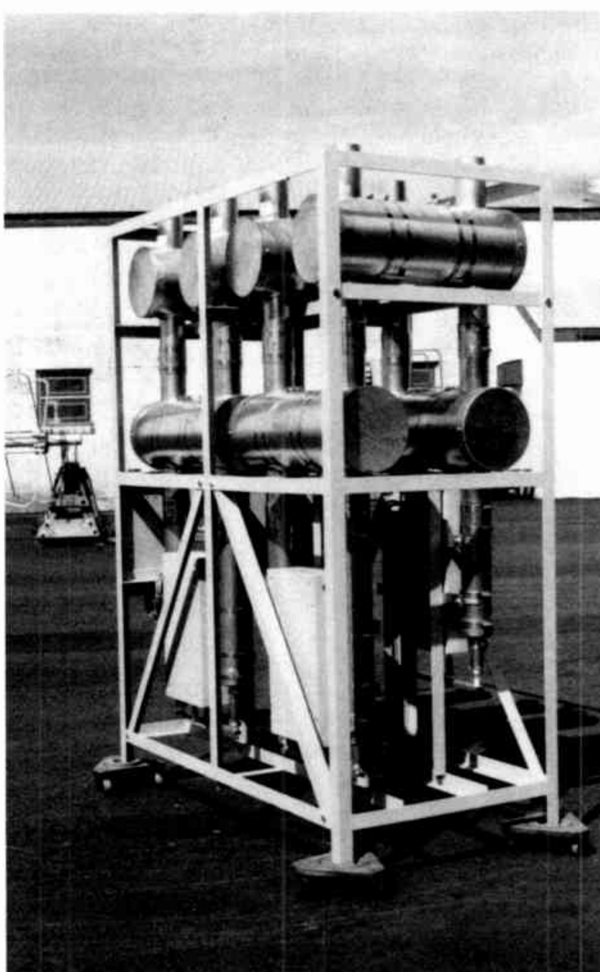

Figure 36. VHF switchless "Opto-SX" switcher. Includes aural and visual inputs.

systems. In a switch type system, the transmitters were isolated by the mechanical switch when operating in the single transmitter mode. The switchless system does not have that isolation. Its isolation is provided only by the two hybrids. Therefore, the 60 dB or better isolation provided by the coaxial switches, is not present in the switchless system. It is possible that voltages could be present on an input, even through the transmitter driving that input is turned off. It is necessary to make sure that safety devices are used to protect technicians. It would be a good idea to delay maintenance on the system until both transmitters could be turned off.

UHF Parallel Transmitters (Waveguide)

UHF parallel transmitters are different from their VHF counterparts. Because of the power rating of the klystron (30 kW to 60 kW), purely parallel transmitters are not as common as in VHF. While there are quite a few 110 to 120 kW transmitters operating, these are not true parallel transmitters, as only the visual klystrons are operating in parallel. A 220 to 240 kW transmitter is the more common parallel UHF transmitter. The UHF transmitters also have aural multiplex capabilities, which reduce the need for parallel aural amplifiers.

A typical RF flow diagram for a waveguide output switching system is shown in Fig. 37. It contains four waveguide transfer switches, a hybrid combiner, and a reject load. S1 and S2 switch the input of the system around the hybrid for single transmitter operation. S3 determines whether the transmitter signals will be routed through the diplexer, while S4 routes the output of the diplexer to the antenna or station load. The aural amplifier is routed directly to the diplexer. This system would have the four basic modes of operation:

1. Visual A and B combined to the antenna.
2. Visual A and B combined to the station load.
3. Visual A to the antenna and visual B to the station load.
4. Visual B to the antenna and visual A to the station load.

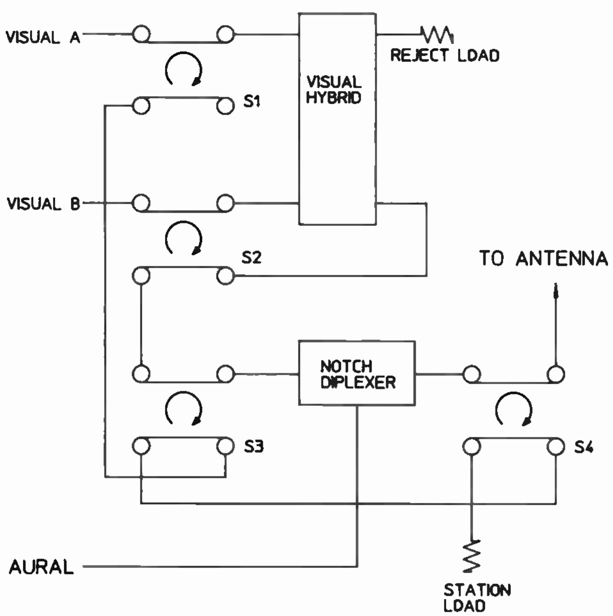

Figure 37. RF flow diagram of output switcher with parallel visual amplifiers.

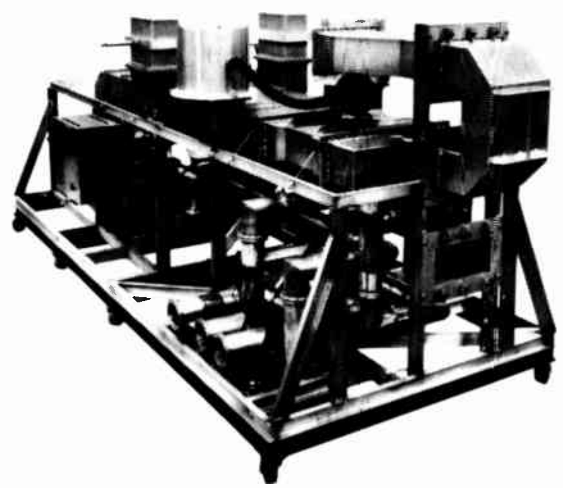

Figure 38. Output switcher 100 kW UHF transmitting system.

In addition, each of the modes could be operated either multiplexed or normal.

Recent developments in diplexers have simplified the switching systems. Aural notch detuners allow the multiplexed signals to pass through the notch diplexer rather than being switched around it. The detuners will raise the aural notch cavity's frequency so that it is above the aural carrier. This allows the multiplexed visual carrier to pass through the diplexer, just as the visual signal does normally.

A station's RF output switching system is usually unique. Either the RF layout of the system will be slightly different, or the mechanical layout of the system must be adapted to the transmitter building. Since this is usually the case rather than the exception, most manufacturers are equipped to handle these situations. Fig. 36 shows a system with coaxial patch panels and switches on the input and a waveguide patch panel on the output of the diplexer.

UHF Switchless System (Waveguide)

One of the more recent developments in RF switching is the switchless phase-shifter systems. These combine the outputs of higher power UHF amplifiers and can be used for either aural or visual service. This system consists of a 3 dB, 90° hybrid, a dual phase-shifter, a reject load, and a magic tee (180° hybrid) and is shown in Fig. 39. To better understand how the system operates, it is essential to examine the individual components.

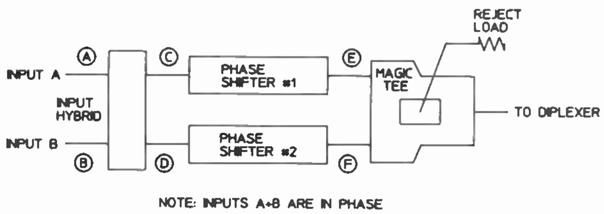

Figure 39. Block diagram UHF switchless switcher.

The magic tee (180° hybrid) works much like a 90° hybrid. The difference is the amount of phase difference which it provides. When it is used as a splitter, the outputs will either be in phase or 180° out-of-phase, depending on which input is being driven. When used as a combiner, the magic tee will combine signals that are in phase into the main output; if the signals are 180° out-of-phase it will route them to the coupled output.

Each phase shifter consists of a movable piece of dielectric material inside a section of waveguide. When the dielectric material is against the side wall of the waveguide, the phase shift will be at the minimum. As the dielectric material is moved toward the center of the waveguide, the phase shift of the signal going through the waveguide will increase. By choosing the type and amount of dielectric material, the device can be adjusted to produce 90° of phase shift. The amount of phase shift with the dielectric material against the side wall is not important in this instance. The critical element is that the phase shifts through the two units be equal.

Assume that there is no phase shift through the unit when the dielectric material is against the side wall and 90° when it is in the center of the waveguide. If a signal is applied to the A input of the hybrid, it will be split into two signals of equal amplitude that are phased 90° apart. The signal appearing at Point C will be in-phase with the input signal (Point A), while the signal at Point D will lag the input signal by 90°. The relationship of the signals at C and D will be reversed for inputs at B. If the result of each of these scenarios is superimposed on one another to simulate the normal mode of operation with signals at both A and B, the outputs C and D each contain two signals at equal amplitude and 90° phase difference. The hybrid effectively causes these signals to be vectorially summed with an equivalent output of amplitude = 2, and phase = −45°. Although these signals have been delayed 45° with respect to the input, they are now in phase with one another at ports C and D.

With the assumption that the phase shifters have no phase shift when set to the minimum position, the signals at the output of the input hybrid (Points C and D) would be applied to the input of the magic tee (Points E and F). There will be signals present at both Points E and F that are in phase with the input signal. The signal at Point E was produced by amplifier A, while the signal at Point F was produced by amplifier B. Since these signals are equal amplitude and in phase

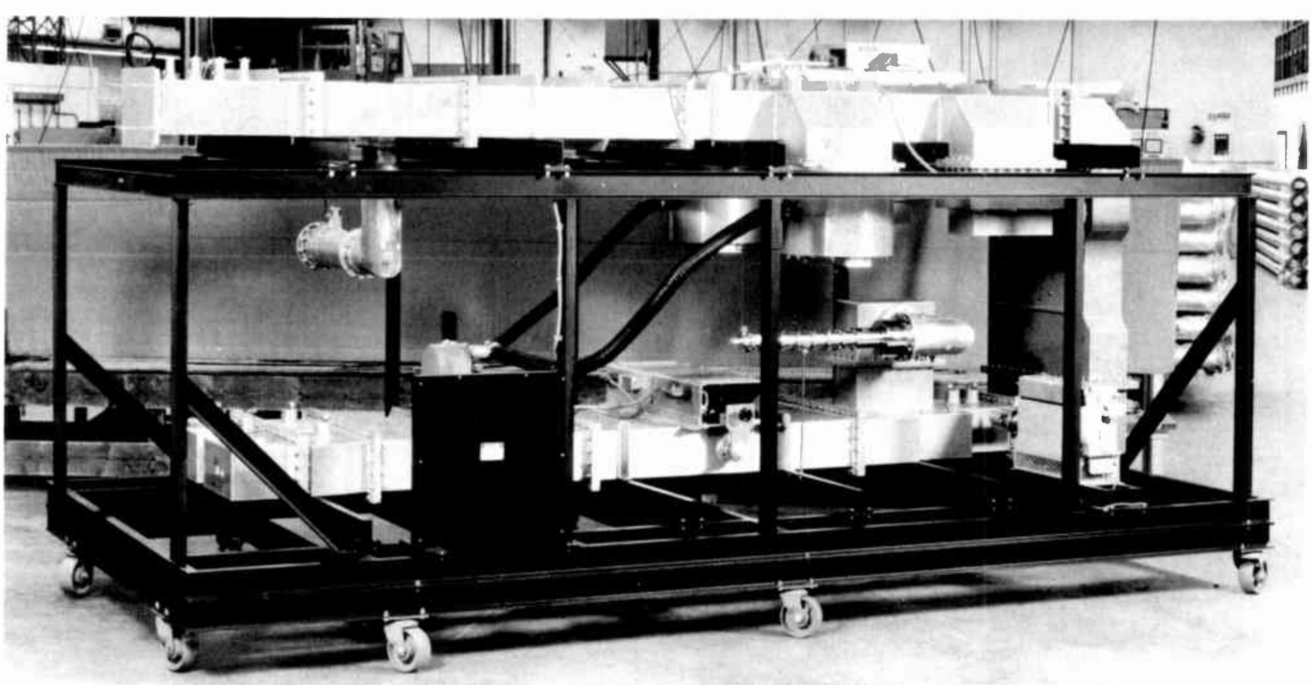

Figure 40. UHF 120 kW switchless diplexer.

they will combine into the main output of the magic tee. At the same time, the other two signals at Points E and F are equal in amplitude and in phase they will combine into the main output of the magic tee. At the same time, the other two signals at Point E and F are equal in amplitude and in phase, therefore, they will combine just as the other signals did. Since these signals are not in phase at the output of the magic tee, the resultant signal will be the vector sum.

By inserting 90° of shift in phase shifter #1, a new mode is created. The phases at the output of the hybrid (Points C and D) will be the same as before. Since 90° is added between Points C and E, the phases at E will now be 90° for the signal from input A and 180° for the one from input B. Therefore, on the inputs of the magic tee, the signals from input A are in phase, while the signal from the B input are 180° out-of-phase. The in phase signals will add at the main output of the magic tee while the signals that are 180° out-of-phase will add in the coupled output.

If phase shifter #1 is returned to the minimum position and phase shifter #2 is set for 90° of phase shift, the signals from the B input will add in the main output, while the signals from the A input will add in the coupled output. By adding the phase shift in the #2 phase shifter, the signals at Point F will be 90° for the one from input B and 180° for the one from input A. Thus the signals from input B will be in phase at the inputs of the magic tee, while the ones from input A are 180° out-of-phase.

Thus far three modes of operation have been accomplished within the switchless system. The fourth mode, both transmitters combined to the station load, can be done two ways. If the phase of the input signals are changed from in phase to 180°, the combining that takes place will be applied to the coupled output (reject load) rather than to the main output. The second method is to add a switch to the output of the system to allow the output to be connected to the antenna or the station load. The latter seems to be the more common method at the present time.

The switchless phase shifter can be changed under power, since there are no contacts to break and make. The only part that is moving is the dielectric material

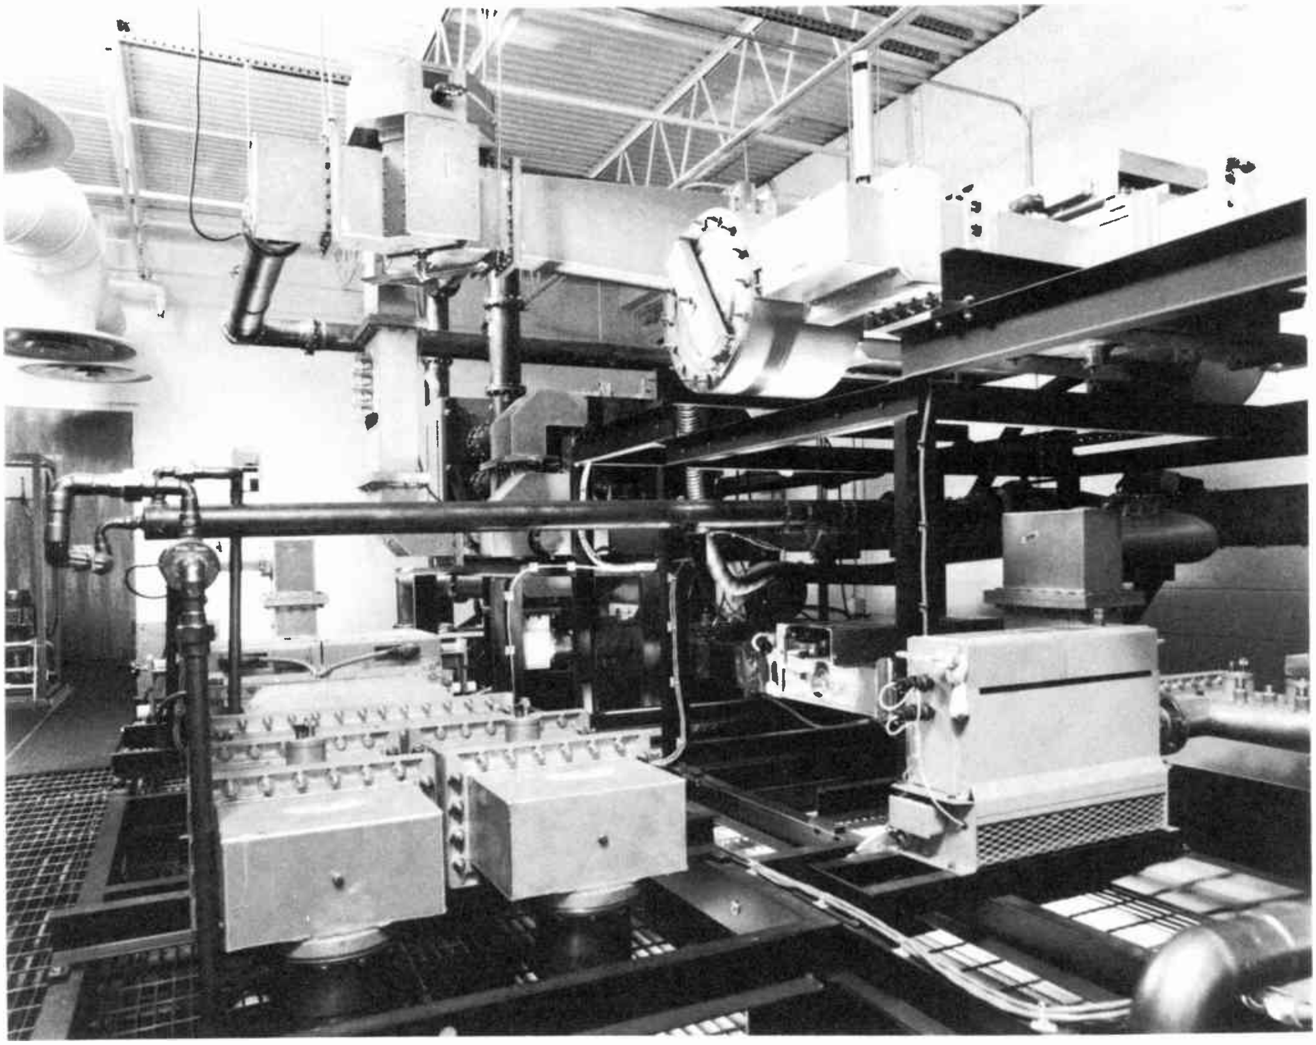

Figure 41. 180 kW three-tube switchless at channel 50 in Tampa, Florida. (Courtesy of Home Shopping Network.)

in the phase shifter section. Since the full power of one transmitter can be applied to the reject load, the load must be capable of handling that power.

In the past, switching systems changed the RF path by mechanically moving the parts of a switch. A typical switch will have around 60 dB of isolation between the paths of the switch. In the switchless system there is no mechanical isolation. Isolation is provided by the the hybrid and by the magic tee within the system. Typically, this isolation will be on the order of 35 to 45 dB, which is sufficient for good performance. However, the operator must be aware that the isolation that he provided in a switch-type system is not there in the switchless system. Therefore, when maintenance is being performed on the system of one transmitter, there may be a small amount of power present from the other transmitter.

Three-Tube Switchless Combiner

A recent addition to UHF switchless systems is the three-tube switchless combiner, introduced by Dielectric in 1988 and covered by U.S. Patent #4,951,013. Until this time, it was not recognized that widely different amplitude of visual inputs could be combined with a switchless system. Once two tubes of a 180 kW system have been combined, the resulting 120 kW must be combined with the remaining 60 kW. The three-tube switchless enables other phase choices in addition to 0°, 90°, and 180° from the phase shifters as shown in Fig. 39. By allowing for 19°, for example, the high efficiencies of a two-tube system may be obtained with the three-tube system. (See Fig. 41.)

This approach is also usable at VHF should the need arise.

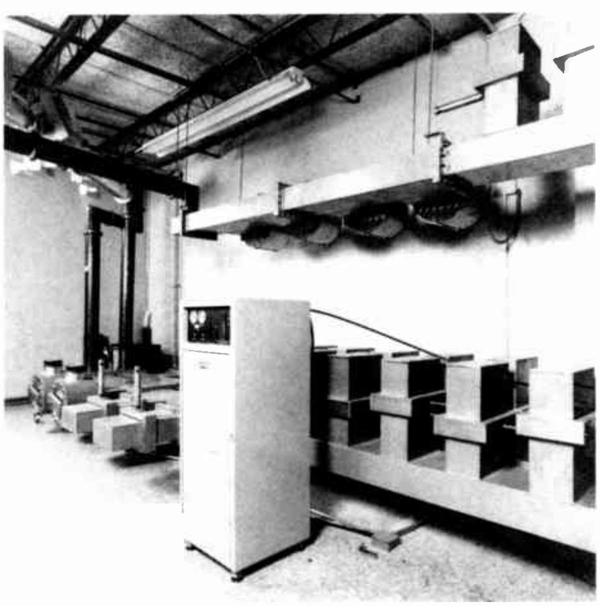

Figure 42. Aural and visual filtering at channel 69 in Hollywood, Florida. (Courtesy of Home Shopping Network.)

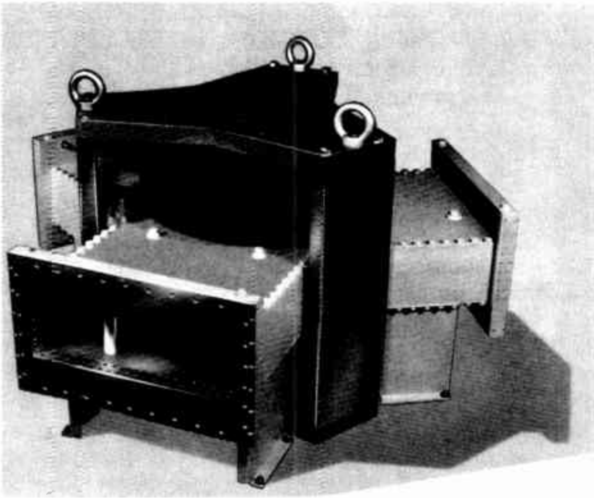

Figure 43. High-power UHF isolator. (Courtesy of Micro Communications, Inc.)

Special Filtering for UHF

The industry is aware of potential problems channels 14 or 69 are installed in localities where land mobile services must coexist. Recent success in planning and installing a channel 69 system in Hollywood, Florida, may allay the fears of those contemplating such an installation. An extensive review was provided by Beifus, Harbaugh, and DeCormier in *Channel 69 Filtering for Land Mobile Compatibility* in the 1990 44th Annual Proceedings of the NAB.

High power filters were provided on the visual and aural inputs to supress intermodulations. (See Fig. 42.)

The super power isolator has also been introduced recently to the broadcast community. (See Fig. 43.) The isolator is a nonreciprocal three-port device. A wave entering at port 1 appears only at port 2 and a wave returning from port 2 appears only at port 3. This circulating action occurs because of the deflection of the wave by a nearby magnetized ferrite cylinder. It is promoted to offer impedance stabilization, ghost elimination, hot switching, and harmonic rejection. The performance is temperature-dependent, requiring a closed loop cooling/heating system.

Multi-Transmitter Different Frequencies Coaxial System

Within the FM band there is a growing demand for multiplexing systems that provide more than the capability of simply combining several stations. They also provide a spare broadband port for emergency use should any module in the system fail and either dual outputs with switching should either half of the antenna fail and extended monitoring capabilities or both.

The basic functions of a multiplexer module have been discussed earlier in this chapter as a category of filters. Here the peripheral features will be explored in

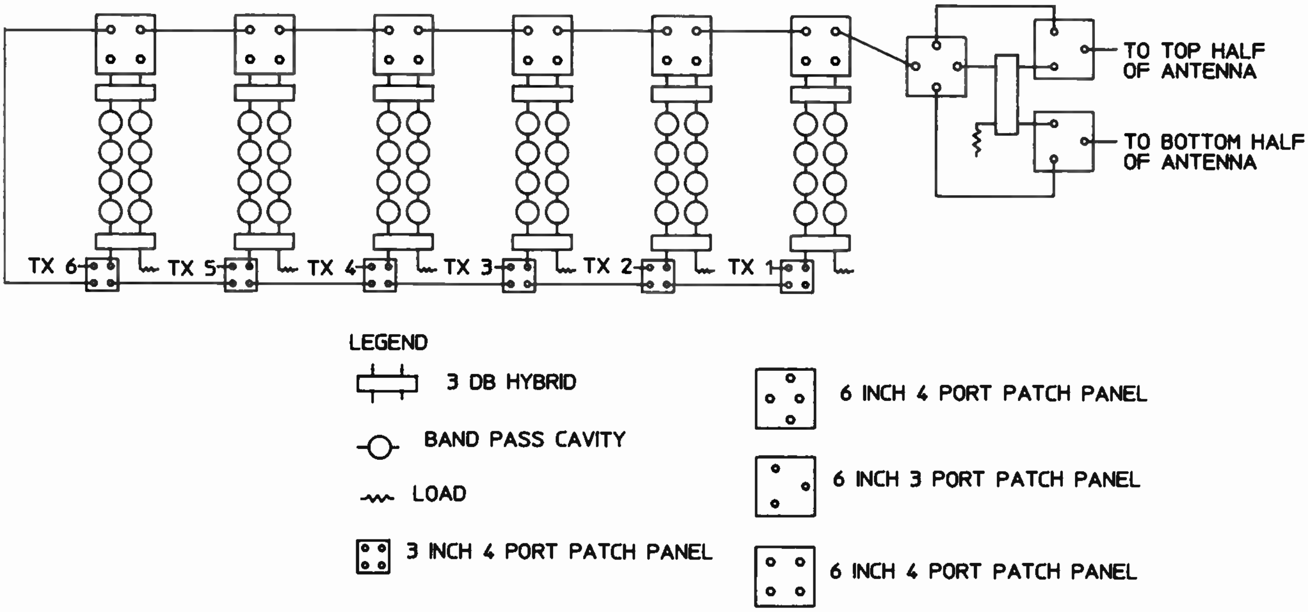

Figure 44. Schematic for six-station FM band-pass constant impedance multiplexer.

Figure 45. Six-station FM band-pass constant impedance multiplexer at St. Louis. (Courtesy EZ Communications, Inc.)

an effort to examine additional benefits of a multiplexer system.

Whether the diplexer modules in the system are made of band-pass or band stop cavities, the system can be built with N modules or N-1 modules where N is the number of channels to be combined. Building the system with N-1 modules is the most economical way while N modules provide a spare broadband input. The spare input can be used as an emergency input if any of the modules fail for any reason. A switch or patch panel is needed both on the input side and output side of each module. See Fig. 44 for a typical schematic of this system.

The band-pass system for FM applications has demonstrated superior performance; in particular, with regard to amplitude response, group delay, and intermodulation rejection. The following are nominal performance characteristics:

- Group Delay +25 ns +150 kHz
- Amplitude Response < 0.1 dB +200 kHz
- Intermodulation Rejection > 80 dB

Fig. 45 depicts a six-station band-pass FM combiner in St. Louis.

The sharing of costs for a system among all participants often makes it possible to consider monitoring systems that one station might have considered too costly. At a minimum, each station must have individual fail-safe power to trip the transmitter. Some broadcasters may consider a computer monitor system superimposed on the fail safe. The computer can monitor forward and reflected power; status of interlocks and heat sensors; and can be programmed to transmit status hourly, daily, or upon an unusual event through a modem to a responsible individual.

All of the features mentioned need to be addressed with the philosophy of the participants in mind. These systems are all custom-made using components that have been standardized over years of use in the industry. Extensive discussions with manufacturers or suppliers are necessary to specify sizes, power capacity, VSWR, insertion loss, bandwidth response, group delay, patch panels, switches, monitoring, interlocks, heat sensors, cooling, and layout to meet individual requirements. When seeking bids, it is prudent to specify all of the above parameters so that all bidders are quoting the same system. These systems can be built with all the bells and whistles or stripped to a bare minimum.

Figure 46. RF monitor and control system in St. Louis. (Courtesy of EZ Communications, Inc.)

Fig. 46 depicts a six-station monitor and control system. The system monitors forward and reflected power for each station, and the combined forward and reflected power on each of the dual outputs to the antenna. The system provides local and remote warnings when VSWR rises to 1.25:1 and trips at 1.50:1 VSWR. It also generates reports at prescribed time intervals and on the occurrence of an event. This makes analysis easier in the event of a failure.

2.5
AM Broadcast Antenna Systems
Part I: System Design

Carl E. Smith
Carl E. Smith Electronics, Cleveland, Ohio

INTRODUCTION

Standard broadcast (AM) antenna systems can reach a high degree of sophistication, much of which is based on advanced mathematics. The purpose of this section is to provide the station engineer with an understanding of some of the basic concepts of antenna design and an appreciation for the complexities of this specialty. An extensive bibliography is included for those who wish to pursue further study.

The chief purpose of a broadcasting antenna system is to radiate efficiently the power supplied to it by the transmitter. A simple antenna can do this job quite well. This is often a single vertical tower that radiates its signal equally in all directions along the ground in a so-called nondirectional or omnidirectional pattern. A second purpose of an AM antenna system is often to concentrate the power in desired directions to cover populated areas, and to suppress it in other directions to protect the coverage of other stations sharing the same or closely-adjacent channels. This directionality may require a very complicated antenna system with several towers if the requirements are stringent.

The antenna is the last point in the system under the control of the broadcaster. The signals radiated from the antenna are propagated through space to each receiving antenna. The factors affecting the strength of the received signal include the strength of the signal radiated by the broadcasting station in a particular direction, the distance to the receiving site, losses incurred by the less-than-perfect conductivity of the ground along the propagation path, terrain obstructions (large hills cast shadows even at AM frequencies), and in the case of skywave transmission, the ionospheric conditions that determine how much of the radiated signal will be reflected back to each distant receiving location. Signal strength in a particular direction can also be affected by the presence of structures such as buildings or towers near the radiation system.

The polarization of the transmitted waves is also a factor; for standard broadcast stations vertical polarization is used because of its superior groundwave propagation and the simplicity of antenna design. The FCC has established maximum transmitter power limits for each of the three classes of AM channels (clear, regional, and local) so the only variables available to the design engineer attempting to maximize the coverage of a radio station involve the antenna location, the pattern design, and a limited choice of power levels. These factors go hand in hand when designing a directional antenna system. Severe constraints are usually imposed on transmitter site selection because of aeronautical, zoning, environmental, and coverage requirements. The constraints encountered in the pattern design relate to the size and shape of the transmitter site; the extent to which the necessary signal suppression can be achieved at the desired transmitter power level; and the cost of design, construction, adjustment, and maintenance of multitower systems. The pattern design can also seriously affect the stability, efficiency, and bandwidth of the completed system. These factors will be discussed later.

RADIATION VERSUS FIELD STRENGTH

Two independent factors determine the signal strength at any given point within a station's service area. First is the strength of the signal radiated in that direction; and second is the path attenuation between the transmitting and receiving antennas. Attenuation is determined by both distance and ground conductivity. It is customary to express the radiation in units of millivolts-per-meter at one kilometer (km) unattenuated. This is the field that would exist at one kilometer over perfectly conducting earth. In this case the field strength would be inversely proportional to the distance from the transmitting antenna; hence, the radiation is also described as the "inverse distance field." The unattenuated radiation cannot be measured directly but can be inferred with great accuracy if sufficient field strength measurements are made to determine the ground conductivity. Field strength measurements are always dependent on radiation, distance, and ground conductivity.

THE SINGLE TOWER NONDIRECTIONAL ANTENNA

Current and Voltage Distribution

The majority of single-tower antennas are neither top-loaded nor sectionalized, and most of them are insulated from ground. For such simple towers, the current is a maximum 90 electrical degrees down from the top (or at the base if the tower is shorter than 90 degrees in height). A typical guyed tower that is 90 degrees high physically is about 95 degrees high electrically, because the velocity of propagation is less in the tower than in the air and is a function of the tower cross-section, slowing down as the cross-section is increased. The approximate shape of the current distribution on a thin tower of uniform cross-section is given by

$$i_a = I_a \sin(G - y)$$

where: i_a = Current in amperes at height y
I_a = The maximum current in amperes
G = The tower height in degrees
y = The height in degrees of the current element i_a

As an example, the general shape of the current and voltage distribution on a thin tower 210 electrical degrees high is shown in Fig. 1. For shorter towers, the distribution would approximate that shown, but with the lower portions cut off; there always being a current node and a voltage maximum at the top of any such tower that does not employ top loading. It is important to visualize the shape of the voltage distribution along the tower because of the need of good insulators at the high-voltage points. Otherwise corona or arc-overs may result to disrupt broadcasting service.

The tower current and voltage are not zero at the nodes shown along the tower. Rather, they reach minimum values and shift rapidly, approximately 180 degrees in-phase in traversing the node region. When towers considerably taller than 180 degrees in height are considered, the current near the base is in the opposite direction from that in the upper portion of the tower. Under these conditions, when viewed in the horizontal plane, the radiation from the lowest part of the tower is canceling a portion of the radiation from the part above the current minimum. Any increase in tower height above the optimum would actually reduce horizontal plane radiation.

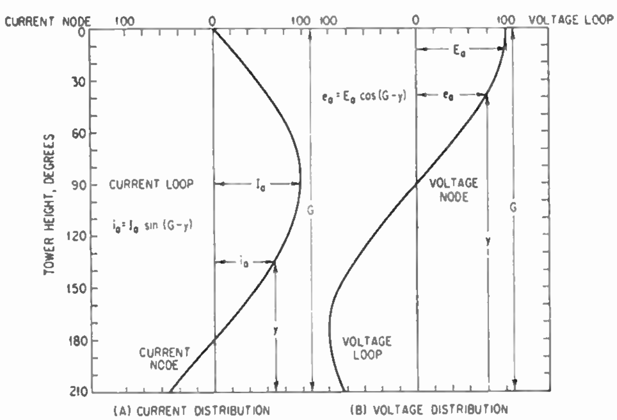

Figure 1. Theoretical current and voltage distribution on a vertical radiator.

VERTICAL RADIATION CHARACTERISTICS

Maximum groundwave radiation for a given transmitter input power occurs when a tower is 225 electrical degrees high (five-eighths wavelength). The variations in tower current distribution with increasing tower height defines the shape of the radiation characteristic in the vertical plane. Fig. 2 shows the size and shape of the vertical plane radiation patterns for a single tower of various heights atop a perfect ground system, fed with one kilowatt of power.

Insulated Tower Base Impedance

The base impedance of a single nondirectional tower is determined principally by its electrical height, its cross-section, the extent of the ground system, and the elevation of the feed point above ground. For typical guyed towers of uniform cross-section, which are base insulated and fed four or five feet above ground level, the resistive and reactive components of the base impedance approximate the values shown in Fig. 3. The base impedance of self-supporting towers departs radically from the values shown, not only because of their large and tapering cross-section, but also because of the capacitance of the base insulators necessary to support each leg of the tower.

Electrically short towers are inefficient radiators, not only because of the shape of their vertical radiation characteristics as shown in Fig. 2, but also because of

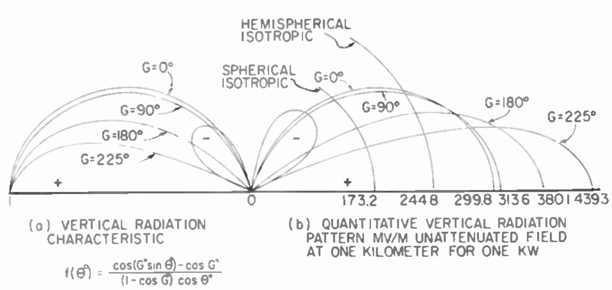

Figure 2. Radiation characteristics in vertical plane.

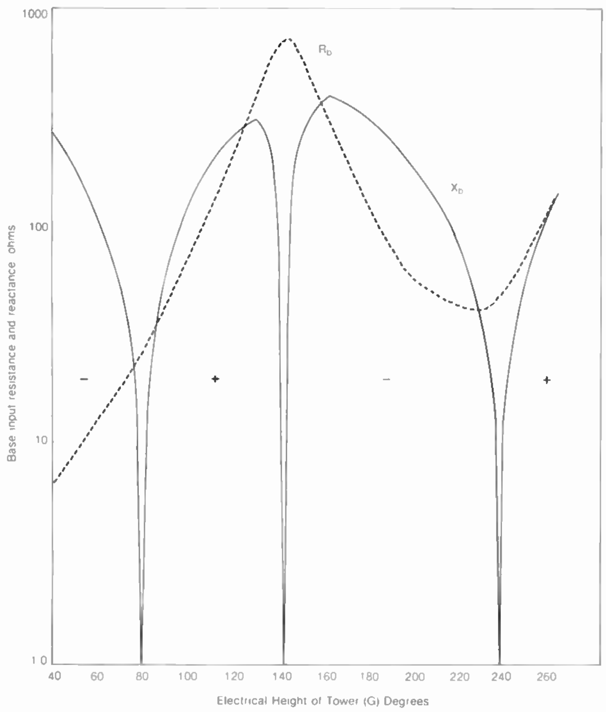

Figure 3. Typical base input resistance and reactance of a uniform cross-section base insulated guyed tower.

proportionately higher ground losses. For example, a tower 48 degrees high with a base resistance of only 9 ohms will have approximately 10% of the available power wasted in ground system resistance losses (typically one ohm).

Grounded Towers, Shunt Fed and Folded Monopoles

Occasionally towers without insulated bases must be used as AM radiators. Such structures include FM or TV towers, water tanks, and ornamental flag poles. Although the impedance at the base of such a tower is necessarily essentially zero, the impedance rises with increasing height of the feed point. It is a simple matter to determine experimentally the height at which a shunt fed tower must be driven to provide a desirable input impedance. A common technique is a *slant-wire* feed in which a wire is attached to the tower at a selected height above ground, and brought down to near ground level at an angle approximating 45 degrees, to serve as the antenna input terminal. A slant-wire feed distorts the otherwise omnidirectional pattern of a single tower and tends to suppress radiation over the sector on the side where the slant-wire is attached. This effect can be avoided if, instead of the slant-wire, the feed conductors are insulated at the base, brought up outside of the tower, and bonded to the tower; for example, 90 degrees above ground to form a folded monopole. The conductors, in this concentric arrangement, in effect form the outer conductor of a coaxial transmission line with a short to the tower at the 90-degree point and an open at the base insulators. This quarter-wave open circuit transmission line in effect puts an insulator at the tower base. The current up on the outer conductors and down on the tower essentially cancel so far as radiation is concerned. The tower with this insulated skirt performs like a base insulated tower. The concentric arrangement of conductors, usually six, are tied together above the conductor base insulators and fed like a base insulated tower. There is a small amount of power loss in the 90-degree concentric transmission line shorted at the top and used to produce the open circuit at the bottom. The radiation current is up on the outer conductors, to where they are connected to the tower at the 90-degree point, and then on up to the top of the tower where the current is zero, as on a base fed insulated tower.

Folded Conical Monopole

The folded conical monopole shown in Fig. 4 broadbands the input impedance. For a 90-degree tower, the vertical radiation characteristic is that of a 75-degree tower, but with an increased value of input resistance and reactance of about 50%. These results were obtained by applying the method of moments to compute the base impedance, current distribution, and vertical pattern.

Top Loading

The performance of an electrically short tower (significantly less than 90 degrees) can be improved, both as to radiation efficiency and bandwidth, by means of top loading. This consists of increasing the capacitance

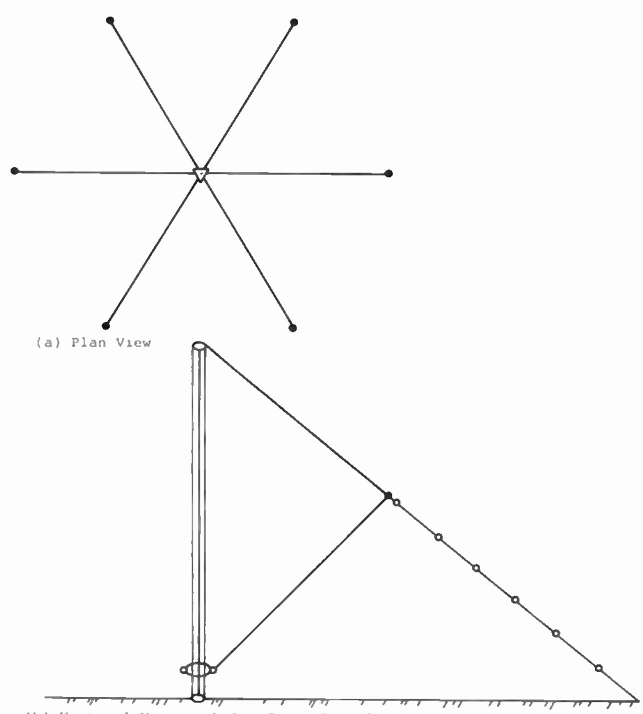

Figure 4. Sketch of folded conical monopole antenna.

to ground from the top of the tower. This loading can take the form of either a flat, more-or-less circular horizontal disk attached to the top of the tower (called a top hat), or as sections of guy wires bonded to the top of the tower and extending down a useful distance before encountering the first of the guy wire insulators. Many variations are possible. Some installations use 3, 6, or even 12 nonstructural guys for top loading that are very effective. By interconnecting the lower ends of the top loading cables, the capacitive loading is increased some, but both this method and spider web connections between the top loading cables increases the construction and maintenance problems. These problems can be eliminated by simply increasing the top loading cables a small amount to give the same increase in capacity effect. Top loading is electrically less desirable than increased tower height, but is useful where towers must be electrically short due to either extremely low carrier frequencies or to aeronautical limitations. Top loading increases the base resistance and lowers the capacitive base reactance, thus reducing the Q and improving the bandwidth on towers less than 90 degrees high. When the tower height is of the order of 130 degrees, top loading can be used to increase the tower's electrical height to give maximum groundwave radiation and minimum skywave radiation.

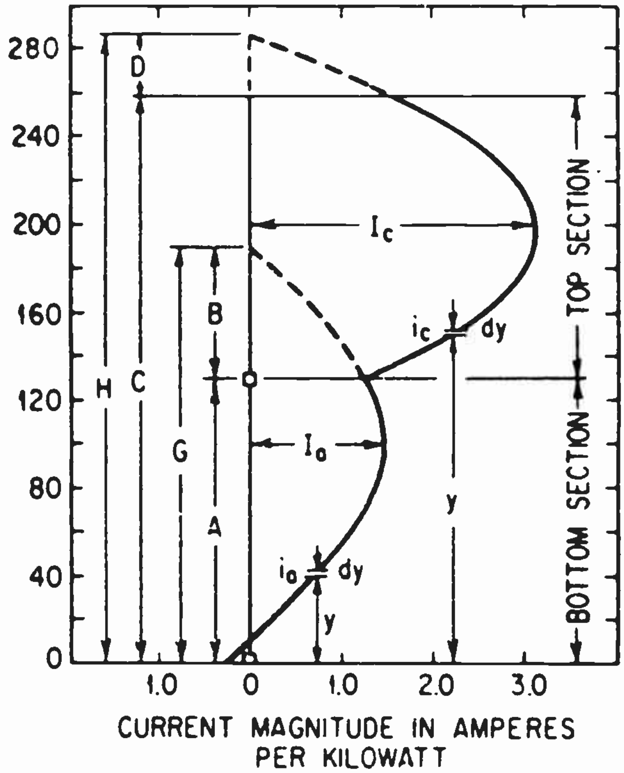

Figure 5. Theoretical current distribution on top-loaded sectionalized tower.

Sectionalized Towers

A utopian vertical radiator would have a constant current throughout its height, but in real life the current must ultimately reduce to zero at the tower top or at the end of the top loading cables. The current can be made to diminish less rapidly by inserting an inductance in series with the tower at a point part way up its height. This is the same technique as using the familiar "loading coil" near the center of the vertical whips often used in mobile radio systems.

Top-Loaded Sectionalized Tower

For a simple vertical radiator, the radiation characteristic can be improved either by increasing the tower height up to 225 degrees for maximum groundwave or by top loading. This in effect raises the position of the current loop with respect to the ground. This principle can also be applied to the top section of a sectionalized tower.

The purpose of top loading a sectionalized tower is to provide a means of further controlling the current distribution on the lower section only. Considering efficiency and stability, it is usually possible to achieve a more favorable radiation characteristic of the whole tower by employing top loading and sectionalization. See Fig. 5. In the case of tall towers used to support FM or TV antennas, it may not be practical to employ top loading.

Depending on the height of tower in wavelengths, the tower can be sectionalized at one or more points to accomplish the highest efficiency consistent with good operating stability. (See Fig. 6.)

Short Low-Loss Antenna with Insulated Counterpoise

Short low-loss antennas are useful for standby use and regular use where height is limited. By using optimum top loading and a tuned counterpoise, the field strength is maximized by adjusting the counterpoise inductor in Fig. 7 to minimize the top hat field through the counterpoise to the lossy ground.

Ground Systems

The current on a tower does not simply "disappear", rather it returns to earth through the capacitance between the earth and each incremental element of the tower or the top loading. For towers not exceeding 90 degrees in height, the tower current is greatest at the base. For such towers the radial ground current is greatest near the tower and decreases with increasing distance from the tower. For single towers the ground currents are radial from the tower base. The ground losses are greatly reduced if the tower has a radial copper ground system, so the ground current will be in the low-loss copper ground system rather than in the earth which has a much higher resistance. A solid copper sheet of infinite radius would be the ultimate ground system, but experiments and experience have defined the dimensions of an adequate ground system. A system of 120 radial ground wires, each 90 degrees

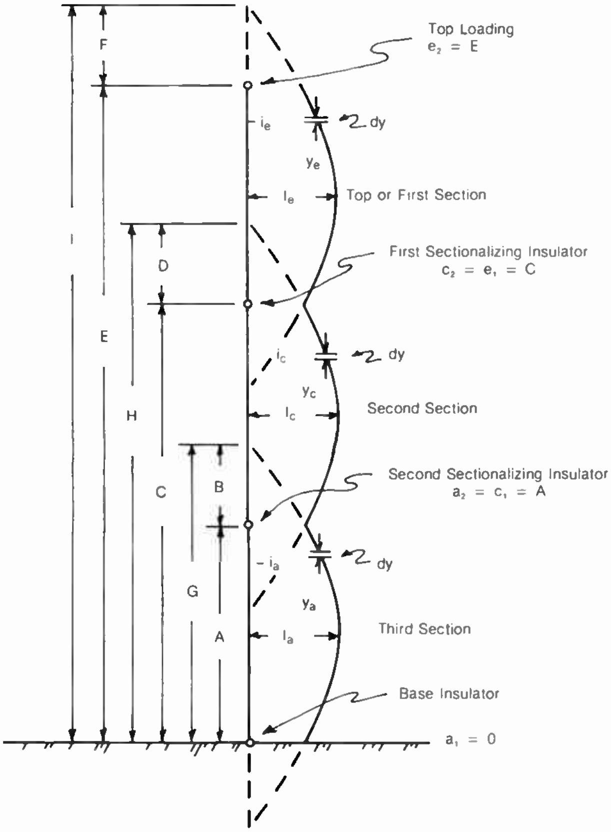

Figure 6. Theoretical current distribution on three section top loaded tower.

long (140 degrees is considered optimum), and equally spaced out from the tower base, constitutes a "standard" ground system. This is often augmented with an additional 120 interspersed radials 50 feet long, or an expanded copper mesh ground screen 25 to 50 feet square centered at the tower. A superior ground screen material is the copperweld, mesh ground mat often utilized by power companies for lightning protection under electrical substations.

Where the antenna site is too small to accommodate all the ground radials at full length, a compromise often used, if easement can not be obtained beyond the property line, is to increase the number of radials by

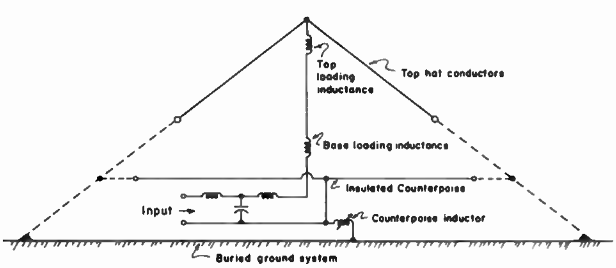

Figure 7. Short, low-loss antenna with counterpoise.

placing them 1 or 2 degrees apart rather than the standard 3 degree separation.

There is no magic in a standard ground system for nondirectional towers; it simply represents a reasonable balance between cost and radiation efficiency.

The antenna system loss including the tower and ground system is normally assumed to be one ohm and is added to the tower base resistance.

Most ground systems under directional antenna arrays consist of the usual 120 radials per tower truncated and bonded to traverse copper straps where the radials from the several towers would otherwise intersect. Stability considerations may dictate larger than standards ground systems under critical directional antenna arrays; changes in soil conditions beyond the ground system can result in small changes in tower base impedance.

Ground system losses are minimized if the radial wires are placed above ground, thus the E-field voltage from the tower and top loading cables terminate on these radial conductors so the H-field current can return to the tower base without penetrating the lossy earth. Ground radials are usually buried 6 to 8 inches for mechanical protection. Burial up to 24 inches is feasible where necessary to permit deep plowing for agricultural crops. However, the ground system should be very near the earth surface in the immediate vicinity of the tower. The earth losses are greater for the buried ground system. Ground systems laid on the earth surface, or tundra in the far north, has the highest loss and least stability of the base impedance. Changes in weather conditions change the dielectric constant and conductivity of any unshielded earth to the detriment of base current stability.

TWO-TOWER DIRECTIONAL ANTENNA

Radiation Pattern Shape

When a nondirectional antenna, with a given power, does not radiate enough field strength to serve the community of interest and/or fails to protect other radio stations, then it is logical to resort to a directional antenna system to achieve these objectives. FCC Rules spell out the protection requirements to be provided to the various classes of stations, both daytime and nighttime on the same and adjacent channels. These limits, which must be met in the directional antenna design, tend to define the shape and size of the most desirable antenna pattern. Since the distances and directions to the other stations requiring protection are rarely the same, most directional antenna patterns are tailored to meet the specific requirements. A directional antenna functions by carefully controlling the amplitude and phase of the radio frequency currents fed to each tower. The resulting field in any direction is the vector sum of the individual tower radiation components. To visualize the resulting pattern in the horizontal plane, one must consider the individual tower radiation components when viewed from distant points in different directions. The relative amplitudes from the individual towers remain unchanged, but the relative phases shift with azimuth because the signal from the closest tower arrives first. In a directional antenna system, one tower is usually defined as the reference tower, and the amplitude and phase of each other tower is measured relative to this reference. The reference tower usually has the greatest current, thus the ratio of the current in each other tower relative to the reference tower current is a fractional number often expressed as a percent of the reference tower current. The relative amplitude and phase of the tower currents is measured by means of an antenna monitor.

The phase of the field, radiated by each tower relative to the reference tower, has two components when viewed from any distant point of observation. The relative electrical magnitude of the current fed to the tower is one component, and is adjustable. The second component is the phase which appears to lead or lag the reference tower by virtue of being more distant or closer than the reference tower to the point of observation. This is termed the space phase component and varies continuously for each tower in a sinusoidal manner as the observation point is moved in azimuth along a distant circle around the array.

Fig. 8 shows three simple directional antennas and their resulting patterns which are easy to visualize. Fig. 8A shows two towers arranged along a north-south line separated by 180 degrees and fed with equal currents in phase. When viewed from the east or west, the fields from the two towers are in phase and the maximum field strength results. When viewed from the north or south, the field from the more distant tower is delayed by the 180 degrees of additional distance, thus canceling the field of the closer tower so as to result in a minimum or null. The deepest minimum or null occurs only when the fields are exactly equal in amplitude and opposite in phase.

Fig. 8A is termed a broadside array because the maximum radiation is broadside to a line through the towers. Fig. 8B shows a similar arrangement, but with the phase of the current in the north tower shifted by 180 degrees. The fields from the two towers cancel each other when viewed from the east or west, but would produce maximum radiation from the north or south. This would be termed an end-fire array, because maximum radiation coincides with a line through the ends of the array. Fig. 8C alters the spacing to 90 degrees and phasing to 90 degrees so as to produce a cardioid pattern. Other combinations of tower spacing and phasing can produce a great variety of pattern shapes. (See Appendix B.)

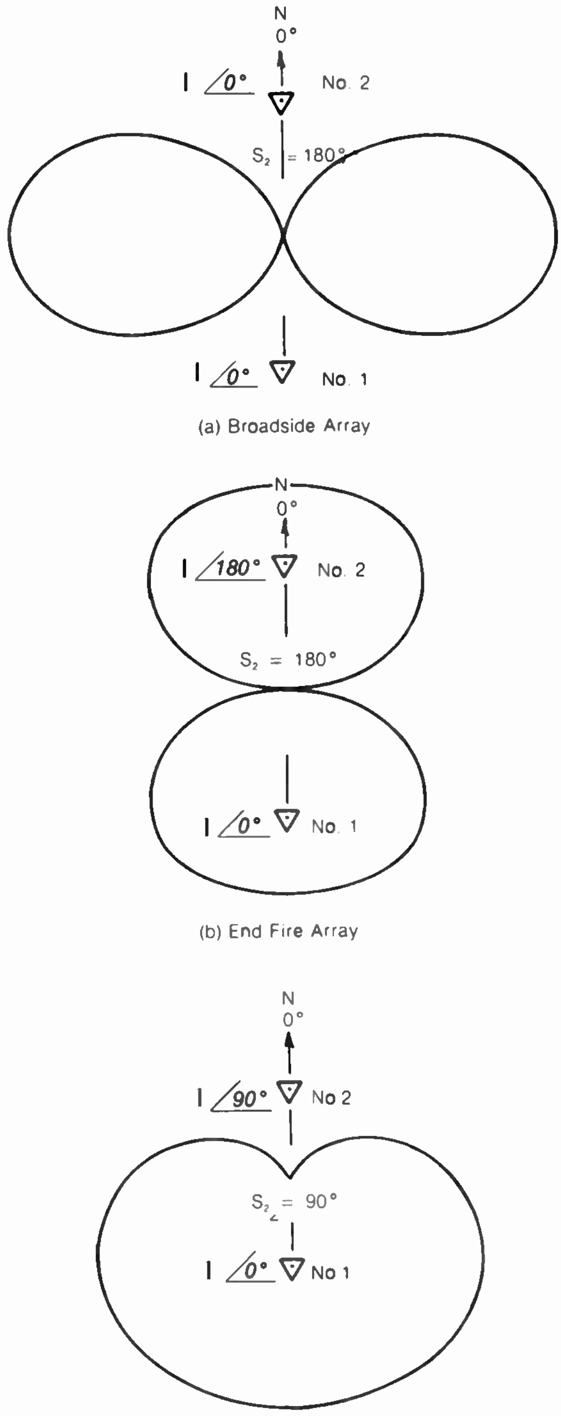

Figure 8. Three simple directional antenna patterns.

Multiplication of Two-Tower Patterns

Perhaps the most widely used method of controlling pattern shape involves the multiplication of two-tower patterns. This is illustrated in Fig. 9. When a two-tower pattern such as pattern No. 1 with nulls at $\pm\theta_{n1}$ is multiplied by pattern No. 2 with nulls at $\pm\theta_{n2}$ the result is pattern No. 3 in a three-tower array. The directions of all of the two-tower array nulls are maintained in the three-tower array. This is a very powerful design technique for protecting other stations and still serving a desired service area. In this special case, the spacings S_2 and S_3 are equal, resulting in an in-line array with fields of towers No. 2 and No. 3 being added in the center tower, and the end tower of

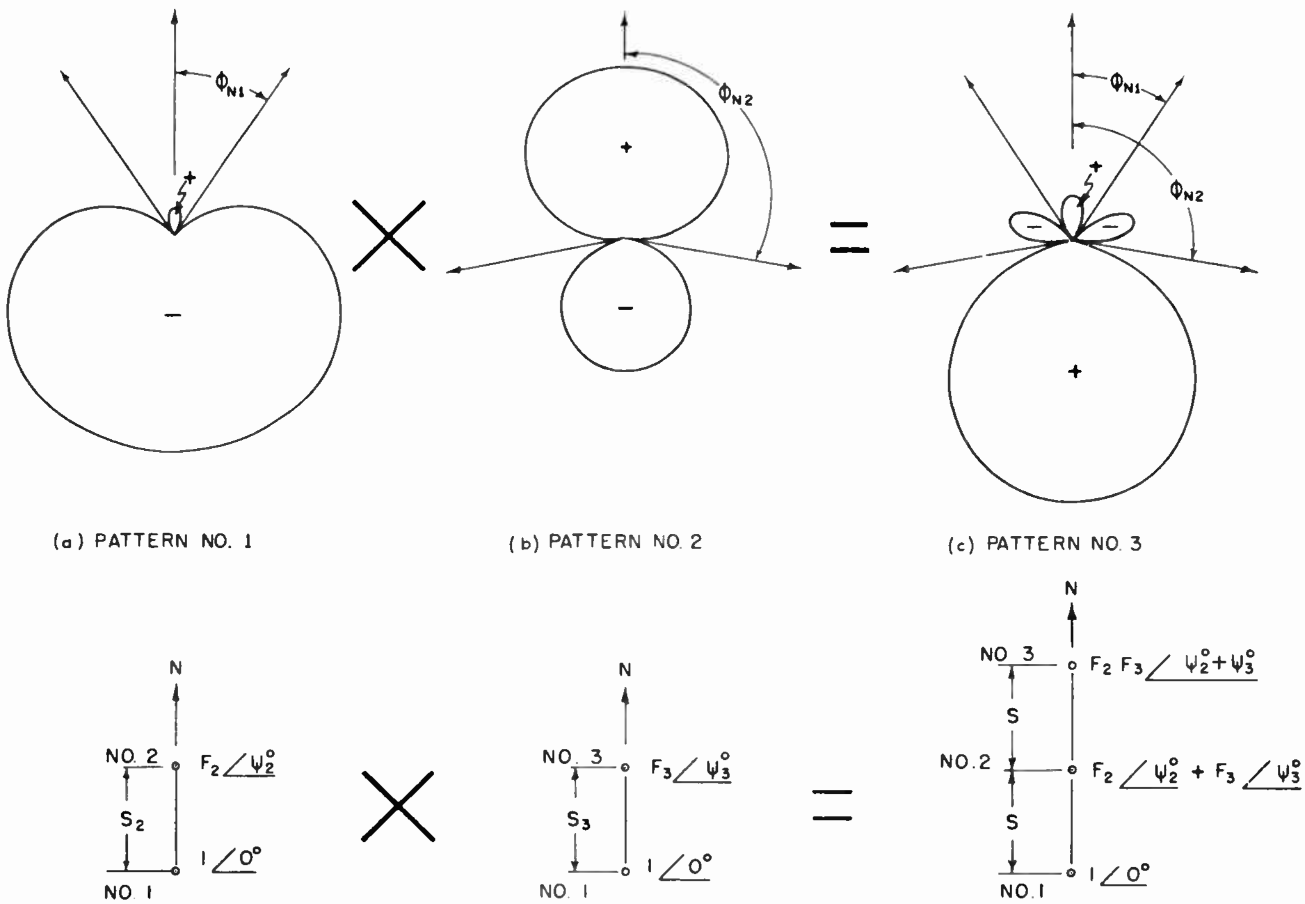

Figure 9. Multiplications of patterns to produce a three tower in line array.

the three-tower array is the multiplication of these fields as shown in pattern No. 3 of Fig. 9.

In the event that the protection directions are not symmetrically located, the two-tower arrays can be placed on different azimuth angles (as shown in Fig. 10) to produce a four-tower parallelogram array. The nulls of the No. 1 pattern are maintained and the nulls of No. 2 pattern are maintained in the four-tower parallelogram array. Furthermore, the spacing from No. 1 tower to No. 2 and No. 3 towers does not have to be the same. By this approach of using one or more parallelograms, a wide variety of asymmetrical patterns are possible with relative simplicity of pattern calculations. However, modern computer techniques can optimize individual tower locations, currents and phases so as to produce an efficient pattern, frequently using fewer towers than required with the parallelogram approach.

Systematization of Patterns

The pattern possibilities resulting from variations in spacing and phasing have been systematized and a sample of two-tower patterns is shown in Appendix B. See Ref. 1 for three-tower patterns.

Radiation Pattern Size

The pattern size is usually determined by integrating the energy flow outward through an imaginary hemispherical surface surrounding the directional antenna array. This method does not give information regarding the distribution of power radiated from the various towers of the directional antenna array, however, it is very useful for making comparisons of pattern size. This computation method is available in digital computer programs and is used by the FCC.

There are other methods of determining pattern size; such as the *mutual resistance method* which employs Bessel functions, and the *driving point impedance method* which uses mesh circuit equations with self and mutual impedance information.

The "method of moments" is now available in large computer programs to determine current distribution on towers and top loading cables, base driving point impedances, and the vertical pattern of directional antenna arrays.

Driving Point Impedance

The input impedance of each tower in an array, called the driving point impedance, is not that of the

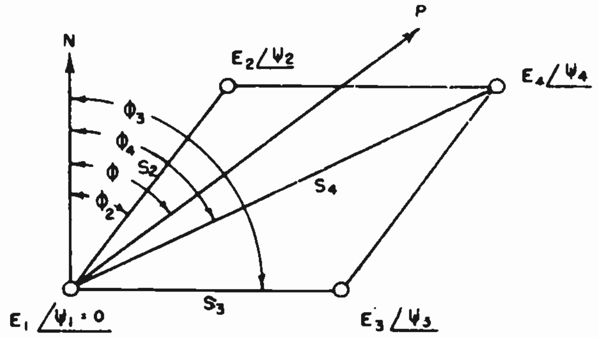

Figure 10. Multiplication of two patterns to produce a four tower parallelogram array.

nondirectional tower. The driving point impedance contains the self impedance plus the mutual impedance multiplied by the current ratios that exist in the array as driven to produce the desired pattern. The driving point impedance will modify the self impedance, depending on the array parameters, and can even make the base resistance negative so that the tower draws power from the other towers and dissipates the power into a load resistor or delivers it back to the phasing system. Because the driving point impedance is affected by the currents in the other towers, it can only be measured by an operating bridge inserted in the tower feed point, while the other towers are operating with their correct current magnitude and phase.

Base Currents Versus Radiated Fields

In a directional array, the tower base current ratios will usually depart substantially from the calculated radiated field ratios when the pattern is correctly adjusted. This is caused by the mutual coupling between towers which distorts the sinusoidal current distribution otherwise assumed for each tower. Thus, the correct pattern is initially proved by means of a series of field strength measurements in significant radial directions from the station rather than by assuming that measurement of tower currents and phases can establish the correct pattern.

Near-Field Versus Far-Field Conditions

Theoretically a directional antenna pattern is not fully formed except at an infinite distance, where the separate towers can be considered as point sources. As a practical matter, near-field effects can persist as far as 32 km (20 miles) from an antenna before far-field conditions prevail. This is especially true in the deep minimums of wide-spaced arrays; however, misleading measurement results can often occur under apparently innocent circumstances. Near-field calculations involve consideration of the actual inverse distance attenuation and the actual phase delay from each antenna element to a series of observation points along a radial.

Fig. 11 shows the results of such calculations on a minimum radial and the resulting analysis of field strength measurements. Line A is the inverse distance line for the theoretical unattenuated radiation at one kilometer. Line B is the result of the near-field calculations assuming only inverse distance attenuation, that is, no soil losses. It converges with the inverse distance line with increasing distance. Line C represents a soil conductivity of 10 mmhos/m as drawn in the conventional manner from analysis of nondirectional measurements on the radial. Line D is a composite of lines B and C. It includes the near-field calculations and is attenuated with distance in accordance with the soil conductivity previously established. This composite line converges with the near-field calculations at short distances where soil attenuation is negligible and converges with the soil conductivity line at great distances where near-field effects disappear. Since curve D accounts for both near-field effects and soil losses, it is the proper curve against which the directional field strength measurement data should be fitted. Note the good fit to the measurement data, both close to the array and at distant points even though the first 19 measurement points fall considerably above the inverse distance line A.

Pattern Size Versus Pattern Shape

The shape of a directional antenna pattern is determined by the adjustment of the phase and ratio parameters, whereas the pattern size is a measure of the power radiated and is affected by the transmitter power output and the losses within the phasing system and the ground system. Since pattern size and shape are essentially independent, it is most expeditious to adjust an array to get the correct shape before expending much concern on the size.

Field strength measurements on a previously-licensed directional antenna may appear to indicate a change in pattern shape or size when the change was in fact due to changes in soil conductivity. Such changes affect distant measurements more than close-in measurements. In some areas of the United States, the conductivity is typically higher during winter and spring months, when the soil is more moist, than in summer and fall months.

Seasonal conductivity variations are not observable in some portions of the country, yet are extreme in other areas. One well-documented case showed a seasonal doubling of signal strength at 32 km (20 miles) in the main lobe of a correctly adjusted system operating on 1380 kHz. To avoid the misleading effects of seasonal conductivity changes that might appear to distort measured directional antenna patterns in size or shape, the FCC requires that all the field strength measurements in a directional antenna proof of performance be made under "similar environmental conditions."

Standard Patterns

Theoretical (also called calculated) patterns can have nulls wherein the radiation at specific azimuths goes completely to zero. In practice, it is not possible to prove by field strength measurements that a null exists.

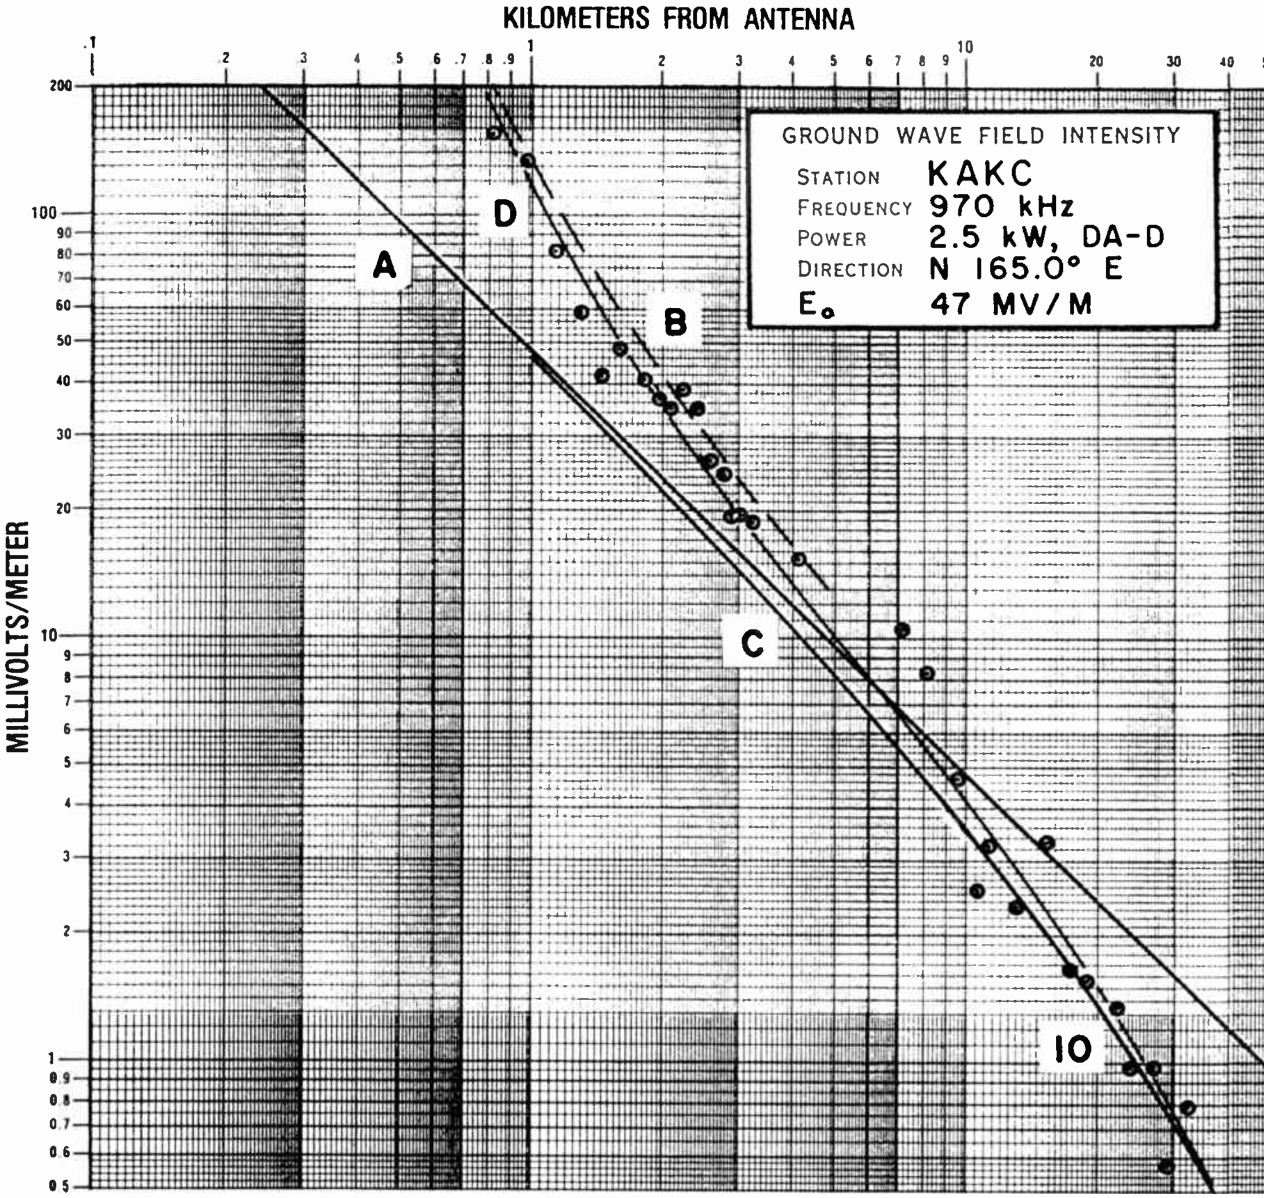

Figure 11. Near-field effects.

Reradiation and scatter from objects external to the array limit the depth to which a pattern minimum can be proven. Additionally, operational variations in phase and ratio parameters will increase radiation in any direction where the deepest possible minimum has been previously established. To accommodate these limitations, the FCC authorizes a "standard" pattern for each directional antenna station. Standard patterns exceed the theoretical pattern at all azimuths by specified and easily calculated amounts. It is required that the radiation from a directional station not exceed its standard pattern. All U.S. stations employing directional antennas have FCC specified standard patterns. These supersede all earlier patterns based on theoretical calculations or on field strength measurements. The standard pattern radiation values are now used exclusively in all calculations of coverage and interference.

Augmented Patterns

Augmentation is applied to the standard pattern when the measured field strength is exceeded in discrete directions but does not cause interference to other stations. When augmentation is desired, it is achieved by applying Eq. (C-9) in Appendix C.

APPENDIX A (CHAPTER 2.5, PART I)

DIRECTIONAL ANTENNAS FOR PATTERN SHAPE

Space Configuration

The plan configuration of the k^{th} tower in an array is shown in Fig. A-1. A space view of the k^{th} tower and observation point *P* is shown in Fig. A-2.

Vector Diagram

The field strength at the point *P* in space for the k^{th} tower is shown in Fig. A-3. The space phasing in the horizontal plane is shown in Fig. A-4 and in the elevation plane the space phasing is reduced further as shown in Fig. A-5.

Generalized Equation

The vector equation to express the vectors in Fig. A-6 is the generalized equation that can be used to express the pattern shape for a directional antenna array of n towers. The equation in condensed form is,

$$E = \sum_{k=1}^{k=n} E_k f_k(\Theta) \quad \beta_k \qquad \text{[A-1]}$$

where:

E = the total effective field strength vector at unit distance (P) for the antenna array with respect to the voltage vector reference axis. This vector makes the angle ß with respect to this axis as shown in Fig. A-6.

k = the kth tower in the directional antenna system

n = the total number of towers in the directional antenna array

E_k = the magnitude of the field strength at unit distance in the horizontal plane produced by the kth tower acting alone

$f_k(\Theta)$ = vertical radiation characteristic of the kth antenna as given in Eq. A-3

Θ = elevation angle of the observation point *P* measured up from the horizon in degrees

$$\beta_k = S_k \cos\Theta \cos(\phi_k - \phi) + \psi_k \qquad \text{[A-2]}$$

= phase relation of the field strength at the observation point *P* for the k^{th} tower taken with respect to the voltage vector reference axis.

$$S_k \cos(\phi_k - \phi) \cos\Theta$$

is the space phasing portion of β_k due to the location of the kth tower and ψ_k is the phasing portion of β_k.

S_k = electrical length of spacing of the kth tower in the horizontal plane from the space reference point

ϕ_k = true horizontal azimuth orientation of kth tower with respect to the space reference axis

ϕ = true horizontal azimuth angle of the direction to the observation point *P* (measured clockwise from true north)

ψ_k = time phasing portion of β_k due to the electrical phase angle of the voltage (or current) in the k^{th} tower taken with respect to the voltage vector reference axis

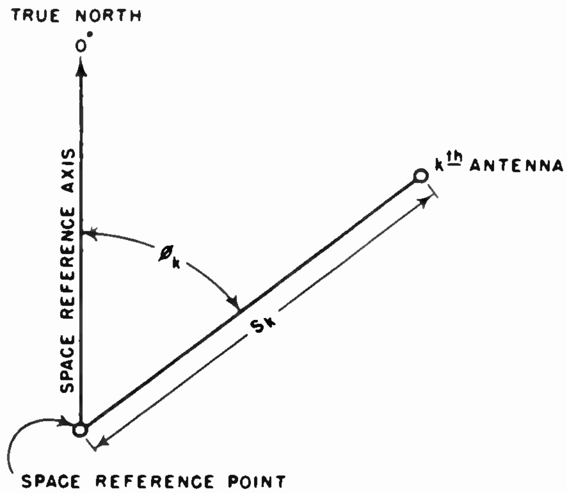

Figure A-1. Plan view of space configuration of k^{th} antenna.

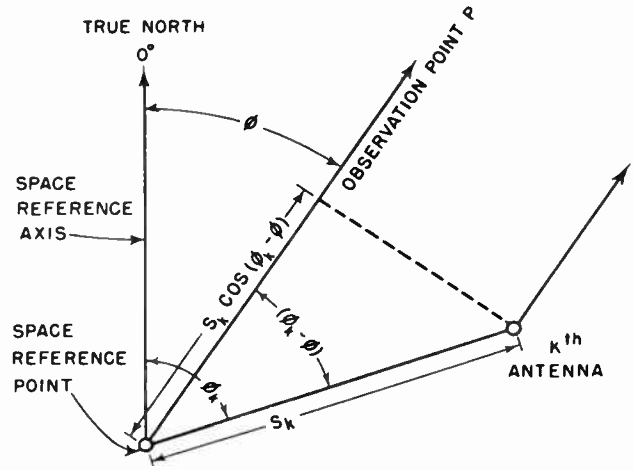

Figure A-4. Plan view of k^{th} antenna showing space phasing in the horizontal plane.

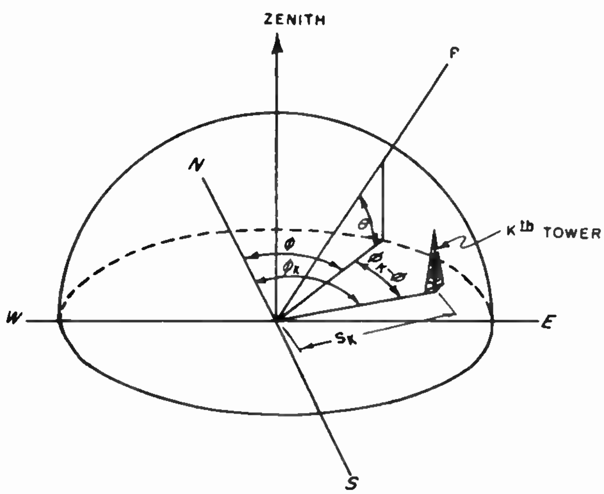

Figure A-2. Space view of observation point P and the k^{th} tower.

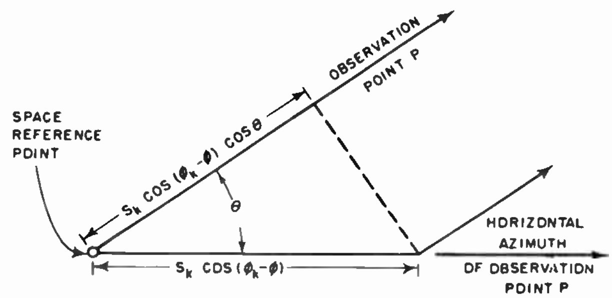

Figure A-5. Elevation angle θ shortens the spacing S_k to the value of $S_k \cos\theta$.

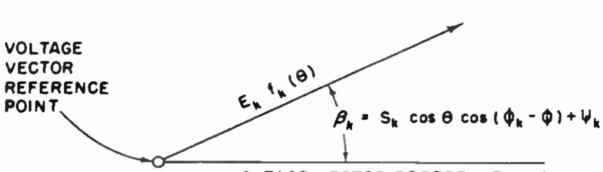

Figure A-3. Voltage vector diagram for the k^{th} antenna.

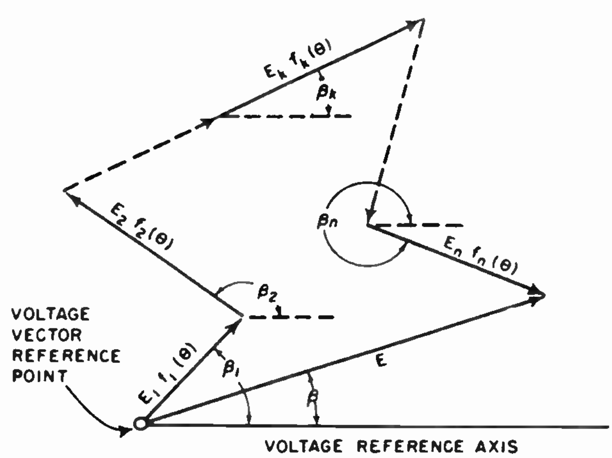

Figure A-6. Summation of field strength vectors for n antennas in the directional antenna array.

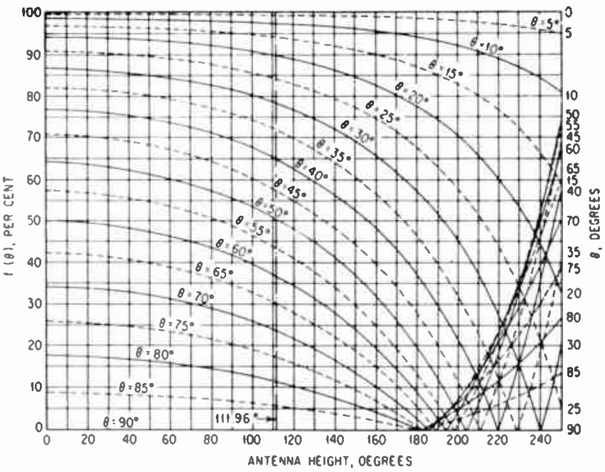

Figure A-7. Vertical-radiation characteristic as a function of electrical tower height for various values of elevation angle.

The shape of any directional antenna pattern can be computed by applying the above equations, however, many directional antenna arrays can be designed by simplified versions of this equation.

For a vertical antenna having a sinusoidal current distribution with a current node at the top, the vertical radiation characteristic takes on the form

$$f(\Theta) = \frac{\cos(G \sin \Theta) - \cos G}{(1 - \cos G)\cos \Theta} \qquad [A\text{-}3]$$

where:

$f(\Theta)$ = vertical radiation characteristic

G = electrical height of the antenna in electrical degrees

Θ = elevation angle of the observation point measured up from the horizon in degrees

The vertical radiation characteristics in Eq. A-3 are graphed in Fig. A-7.

For a top-loaded tower the formula is:

$$f(\Theta) = \frac{\cos B \cos(A \sin \Theta) - \cos G - \sin B \sin \Theta \sin(A \sin \Theta)}{\cos \Theta (\cos B - \cos G)}$$

This is the vertical radiation characteristic for a top-loaded tower of height A and top-loaded to a height of G = A + B.

For a two section top-loaded tower as shown in Fig. 5, the formula is:

$$f(\Theta) = \frac{\cos B \cos(A \sin \Theta) - \cos G + \dfrac{\sin B \cos(H - C)\cos(C \sin \Theta)}{\sin(H - A)} - \dfrac{\sin B \sin \Theta \sin (H - C \sin(C \sin \Theta))}{\sin(H - A)} - \dfrac{\sin B \cos (H - A)\cos(A - \Theta)}{\sin(H - A)}}{\cos\{\cos B - \cos G + [\sin B/\sin(H - A)](\cos \overline{H - C} \cos \overline{H - A})\}} \qquad [A\text{-}4]$$

This is the vertical radiation characteristic equation for a two-section sectionalized tower. The same procedure can be applied if more than two sections are involved. (See Fig. 6.)

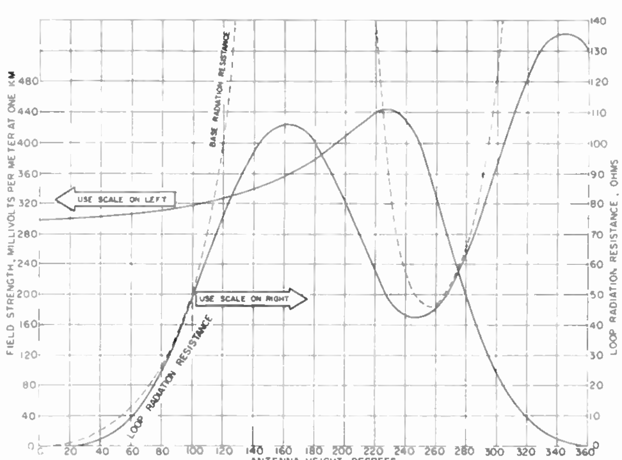

Figure A-8. Inverse field strength at 1 kilometer for 1 kw, loop and base radiation resistance as a function of tower height over a perfectly conducting earth.

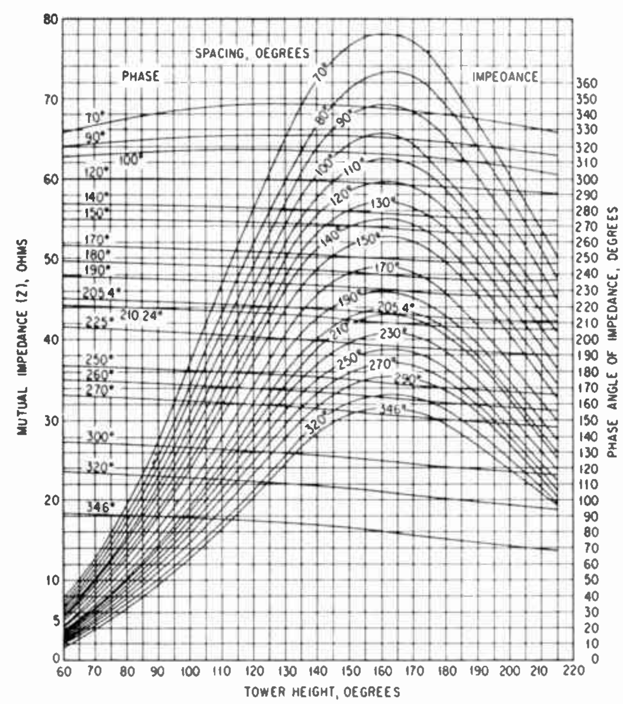

Figure A-9. Loop mutual impedance and phase angle between two towers of equal height.

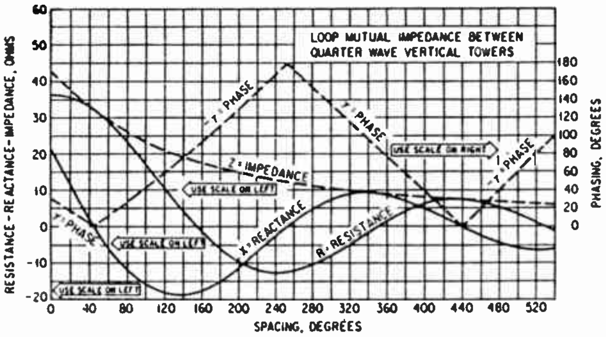

Figure A-10. Loop mutual impedance between quarter-wave vertical towers.

Theoretical Self-Loop and Base-Radiation Resistance

It is useful to know the theoretical loop and base resistance of a vertical radiator. This information is presented graphically in Fig. A-8 along with the theoretical inverse field strength at one kilometer.

Mutual Impedance Curves

The value of mutual impedance for most tower heights and spacing is given in Fig. A-9. The loop mutual impedance between quarter-wave towers is shown in Fig. A-10.

Horizontal RMS Field Strength

The field strength gain or loss of a two-tower array for various values of phasing and spacing is shown in Fig. A-11.

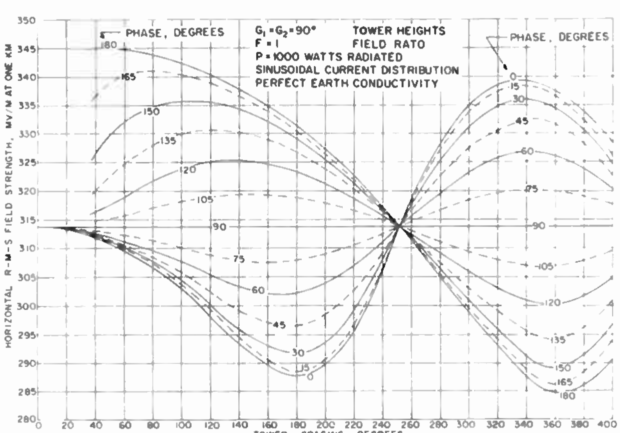

Figure A-11. Horizontal RMS field strength of two-tower directional antenna.

APPENDIX B (CHAPTER 2.5, PART I)

SYSTEMATIZATION OF TWO-TOWER PATTERNS

The pattern numbering system has been devised to furnish the antenna parameters in an orderly fashion as described at the bottom of each page. To simplify the numbering system, the spacing and phasing of each antenna is shifted in steps of 45 degrees. The spacing varies from 45 degrees on page B-1 to 1,440 degrees on page B-4 while the phasing varies from 0 degrees to 315 degrees on each page. The field strength of each antenna, E1 and E2, is expressed in percent of the maximum lobe field strength (50%) of the horizontal pattern. Finally, the last two digits specify, in percent, the RMS field strength in the horizontal plane of the two tower directional antenna array.

The detailed patterns which follow are for spacings in steps of 15 degrees up to 360 degrees. The phasings are only presented from 0 degrees to 180 degrees since the same patterns, turned 180 degrees, give the results for phasings from 180 degrees to 360 degrees.

APPENDIX C (CHAPTER 2.5, PART I)

PATTERN DEVELOPMENT OF DIRECTIONAL ANTENNAS

Theoretical Pattern Equation

The theoretical pattern equation of Appendix A can be written as follows by changing the k^{th} tower to the i^{th} tower to conform with the FCC practice, thus:

$$E(\phi, \Theta)_{th} = \left| k \sum_{i=1}^{n} F_i(\Theta) \; \underline{/ S_i \cos\Theta \cos(\phi_i - \phi) + \psi_i} \right| \qquad [C\text{-}1]$$

where:

k = multiplying constant which determines pattern size

Standard Pattern Equation

The standard pattern equation is obtained from Eq. C-1 by adding the quadrature term Q to fill minimums and increase the size by five percent, thus:

$$E(\phi, \Theta)_{std} = 1.05\sqrt{[E(\phi, \Theta)_{th}]^2 + Q^2} \qquad [C\text{-}2]$$

where Q is the greater of the quantities:

$$0.025\, g(\Theta)\, E_{rss} \qquad [C\text{-}3]$$

OR

$$10.0\, g(\Theta) \sqrt{P_{kw}} \qquad [C\text{-}4]$$

where g(Θ) is the vertical plane distribution factor, $f(\Theta)$, for the shortest element in the array (see Eq. C-2 above; also see FCC Rules Section 73.190, Figure 5).

If the shortest element has an electrical height in excess of 0.5 wavelength, g(Θ) shall be computed as follows:

$$g(\Theta) = \frac{\sqrt{\{f(\Theta)\}^2 + 0.0625}}{1.030776} \qquad [C\text{-}5]$$

$$E_{rss} = \sqrt{\sum_{i=1}^{n} E_i^2} \qquad [C\text{-}6]$$

As an example, consider a two-tower array. The theoretical pattern equation (Eq. C-1) becomes:

$$E = E_1 f_1(\Theta) \; \underline{/0^\circ} + E_2 f_2(\Theta) \; \underline{/ S_2 \cos\Theta \cos(\phi_2 - \phi) + \psi_2} \qquad [C\text{-}7]$$

Now, for 5 kilowatts, 90 degree towers, and the following parameters:

Tower No.	Height G°	Field Ratio	Spacing S°	True Bearing φ°	Phase ψ°
1	90	1.0	0	0	0
2	90	1.0	90	0	−90

E_{rss} (theoretical pattern) = 691.92 mV/m
Q (quadrature term) = 21.60 mV/m
E_{rms} (standard pattern) = 726.87 mV/m

A plot of the theoretical and standard patterns are shown in figure C-1.

The minimum horizontal field strength (at one kilometer) when the theoretical field strength goes to zero is given by Eq. C-2 for a standard pattern along the ground using Eq. C-4 with g(Θ) = 1.0. For one kilowatt and under, Q is 6 according to FCC Rules. For various FCC licensed values of power, the minimum field strength values are as follows:

P_{kW}	Q	$E_{mV/m}$
0.25	6.00	10.14
0.50	6.00	10.14
1.00	6.00	10.14
2.50	9.49	16.03
5.00	13.42	22.67
10.00	18.97	32.06
25.00	30.00	50.69
50.00	42.43	71.69

The minimum field strength (at one kilometer) for any elevation of a standard pattern, by Eq. C-5, is:

$$g(\Theta) = \frac{\sqrt{0 + 0.0625}}{1.030776} = 0.2425$$

Augmented Pattern Equation

The augmented pattern equation is obtained by adding an augmentation quadrature term to the standard pattern as given here:

$$E_{(\phi,\Theta)aug} = \sqrt{\{E_{(\phi,\Theta)std}\}^2 + A\left\{g(\Theta)\cos\left(180\frac{D_A}{S}\right)\right\}^2}$$

where: $E_{(\phi,\Theta)aug}$ = augmented pattern radiation value at azimuth, elevation

$E_{(\phi,\Theta)std}$ = standard pattern radiation value at azimuth, elevation

A = augmentation constant (insert equation C-10)

$g(\Theta) = \dfrac{\sqrt{\{f(\Theta)\}^2 + 0.0625}}{1.030776}$

S = span of augmentation in degrees

D_A = angular distance from center of span

The principle of augmentation is illustrated in the cardioid pattern of Fig. C-2.

The FCC has converted all augmented directional patterns to a table for each station as shown in the example of Fig. C-3. In this case there were six augmentations as tabulated in Fig. C-4 and shown on the polar chart of Fig. C-5.

It should be noted that where the spans overlap, Eq. C-9 is applied repeatedly, once for each augmentation, proceeding clockwise from true north.

2.5 AM Broadcast Antenna Systems

Part II: Antenna Coupling and Phasing Systems for AM Broadcasting

Edward Edison, P.E.
Hammett & Edison, Inc., San Francisco, California

AM broadcast antenna coupling and phasing systems consist principally of passive networks of inductors, capacitors, transmission lines, and auxiliary components such as lightning gaps, meters, jacks, and relays. This equipment can range from simple (such as a nondirectional station having the transmitter building located adjacent to the tower base) to complex (such as a multi-tower directional array requiring different patterns day and night). To understand antenna systems and their environment, we must consider the function of such systems and their performance objectives, as well as the characteristics of basic networks, power dividers, transmission lines, sampling systems, detuning systems, and transmitter load optimization.

It is not the intent of this chapter to make directional antenna "experts" out of its readers. However, in providing a broad perspective of the design of such systems, we hope to encourage a rational approach to the everyday problems of directional antenna operation and maintenance. The design and adjustment of the more complex directional arrays require considerable knowledge, experience, and computer power that is beyond the ken of almost all chief engineers and contract engineers. When unusual problems arise that do not yield to reasonable efforts at repair and adjustment, it is time to call in an expert; preferably the consulting engineer or firm that designed or previously adjusted the system.

THE FUNCTION OF A DIRECTIONAL ANTENNA PHASING SYSTEM

The function of a directional antenna phasing system is to distribute current to each tower with controllable phase and amplitude so as to generate the desired directional pattern. This function is accomplished typically by means of the following:

1. A network at each tower matches each tower load to its transmission line. (See Fig. 1.) This network is typically in a weatherproof box, termed an *antenna coupling unit* (ACU), or within a small building called a "doghouse."
2. The remaining equipment, usually housed in one or more indoor cabinets, is termed a *phasor*.
   A. Within the phasor cabinet (usually located in the transmitter building), networks control the phase of the current into each transmission line.
   B. Power divider circuits control the current amplitude in each transmission line.
   C. A common-point matching network adjusts the phasor input impedance to a desirable resistive value (typically 50 ohms) without disturbing the phase or amplitude of the tower currents.

Fig. 1 shows a system with only two towers. Each additional tower requires its own antenna coupling unit, transmission line, and phasing network, as well as additional components in the power divider.

PHASOR PERFORMANCE OBJECTIVES

The essential performance objective is to have both the phasor input impedance and the directional antenna radiation pattern remain essentially constant at all frequencies within ±10 kHz of the assigned channel. The performance may be disappointing if the design process proceeds by a piecemeal approach, where subsystems are independently designed for each of the functions illustrated in Fig. 1 and are then connected together. It is better to use a systems approach that considers the entire collection of components between the transmitter and the towers as a whole rather than by the "building block" approach implicit in Fig. 1. No

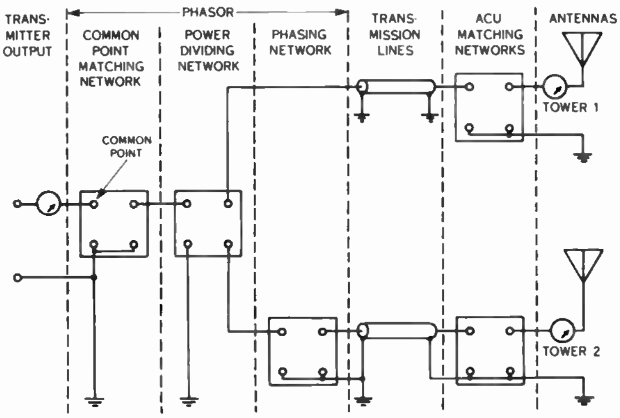

Figure 1. Block diagram of a directional antenna.

one subsystem in an array can be treated in isolation. While it is a simple matter to design a series of subsystems to provide the desired phase and amplitude parameters, these subsystems must properly complement each other if optimum bandwidth is to be achieved.

Phasor Input Impedance

An ideal phasor would present a load to the transmitter that is the same pure resistance at all sideband frequencies. However, phasors consist of coils and capacitors, whose reactance varies with frequency; therefore, this ideal cannot be achieved. The term "impedance bandwidth" is used to describe the degree of constancy of the phasor input impedance across the entire range of sideband frequencies. A useful figure-of-merit to express the impedance bandwidth as a single number is the worst-case voltage standing wave ratio (VSWR) existing at either of the two 10 kHz sideband frequencies when the system is perfectly matched at the carrier frequency. This approach yields VSWR numbers that are related to antenna performance just as television and FM transmitting antenna performance is described by VSWR limits at various sideband frequencies. The sideband VSWR can be determined by analysis of common-point impedance measurements. The resistance and reactance at each sideband frequency of interest are expressed as a percentage of the measured carrier frequency resistance and are then plotted on a Smith Chart. A Smith Chart depicts the relationship between the load impedances at sideband frequencies and the ideal matched load. The distance from the center of the chart for each sideband frequency is a measure of the VSWR at that frequency.

Bandwidth

Bandwidth requirements for each channel change greatly across the broadcast band. At 1600 kHz, a total bandwidth of 20 kHz corresponds to about one percent of the center frequency whereas, at 540 kHz, 20 kHz corresponds to nearly four percent of the center frequency. Comparatively, an AM station at the lower frequencies has a more stringent bandwidth requirement than is needed for acceptable visual transmitter performance on VHF TV channels 7 through 13 or on any of the UHF channels.

The common-point VSWR at 10 kHz above and below carrier often is better than 1.1:1 in good phasor designs. Poor designs can be worse than 3:1. Poor phasor designs manifest themselves by poor audio performance. In the main lobe of a pattern, poor bandwidth will limit frequency response; in the null sectors of a pattern, distortion may be exacerbated by limited bandwidth which causes the carrier frequency to be suppressed more than the sideband frequencies. The audible effect of the resulting distortion is similar to over-modulation.

Radiation Pattern

An ideal phasor would produce an antenna radiation pattern that remains unchanged across the channel. Variations in the phase and ratio of tower currents at the sideband frequencies can result in changes in the location and depth of the intended pattern minimums. The frequencies for which the pattern remains useful describe the *pattern bandwidth*. Pattern bandwidth cannot be quantified by simple numbers, but the concept is useful in comparing alternative designs.

The example of poor pattern bandwidth shown in Fig. 2 is for the three-tower daytime pattern of an actual station at its carrier frequency and at the 10 kHz sideband frequencies. The sideband patterns were calculated from the actual measured ratios and phases of tower currents at both sideband frequencies. This directional antenna system did not adequately protect an adjacent channel station, even though conventional field strength measurements indicated proper operation. A spectrum analyzer displaying the received signal confirmed the extreme sideband asymmetry in critical directions.

X_3 MUST HAVE SIGN OPPOSITE TO X_1

Figure 5. "L" network formulas.

BASIC NETWORKS

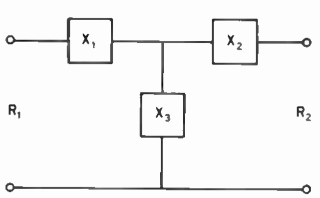
The networks used for matching impedances or for shifting phase are typically "T" or "L" configurations. "Pi" networks having shunt elements at the input and output and a central series element can be made electrically identical to any T network, but T networks are easier to adjust.

The networks at the left in Fig. 3 offer large phase shifts, while the configurations on the right offer small phase shifts. Intermediate between these two conditions are L networks which can be considered as T networks with one zero-reactance arm. L networks do not permit independent adjustment of impedance match and phase shift; however, the resulting phase delay or advance can be calculated easily, with the result often being a value that is compatible with the overall phasor design. The formulas for these networks are all based on matching into resistive loads.

The loads presented by antenna towers usually have a reactive component; therefore, the output arm of the matching network is modified to cancel the tower reactance. When this modification is made, the output arm will occasionally assume the opposite reactance sign, as shown in the parentheses in Fig. 3.

T Networks

The reactances of the input, output, and shunt arms of a T network can be calculated quickly, once the desired input and output resistances and the phase shift (b) are specified, by using the formulas shown in Fig. 4. The formulas are equally applicable for leading (+b) and lagging (−b) networks.



$$X_3 = \frac{\sqrt{R_1R_2}}{\sin\beta}$$

$$X_2 = \frac{R_2}{\tan\beta} - X_3$$

$$X_1 = \frac{R_1}{\tan\beta} - X_3$$

R_1 = INPUT RESISTANCE

R_2 = OUTPUT (LOAD) RESISTANCE

β = PHASE SHIFT (OUTPUT-INPUT)

Figure 4. "T" network formulas.

L Networks

Conventional L networks can provide a match between any two resistance values. The formula for such networks is shown in Fig. 5, which presumes a nonreactive load. If an L network is used to match a tower to a transmission line, the reactive component of the tower impedance must be considered. If the tower resistance is lower than the line impedance, the series arm of the L network is connected to the tower. This arm can then be modified from the value calculated by the formula so as to also cancel the tower reactance.

An L network can also be used to match a tower having a resistance higher than the transmission line impedance, but in this case the formula in Fig. 5 does not apply unless the tower impedance contains no reactance. In the usual case, where the tower impedance is reactive, an L network cannot be so easily calculated. The shunt arm (which is in parallel with the reactive tower load) must be one which makes the resistive component of the parallel combination equal to the transmission line impedance. Then the resulting reactance of the parallel combination is cancelled by the series input arm of the L network. Such networks are easy to adjust; the shunt arm of the L network is adjusted to make the input resistance match the transmission line characteristic impedance, and the series arm is then adjusted to cancel the resulting reactive component. The two adjustments are substantially independent of each other. If the tower is one element of a directional array, an operating impedance bridge (hot bridge) at the network input must be used and the phase and ratio parameters must be approximately correct in order for the tower operating impedance to be that which will exist when the directional antenna array is operating normally.

When the tower resistance is higher than the line impedance, there are two different values of shunt arm reactance (one capacitive and one inductive) that can satisfy the conditions necessary for a match with an L network. If the shunt arm is of the same sign as the tower reactance, the required series arm will be of opposite sign and the phase shift will be small. If the shunt arm is opposite in sign to the tower reactance, the required reactance in the series arm will have the same sign as the tower reactance and the phase shift will be large.

An alternative way to design such L networks (rather than by calculating the shunt arm reactance necessary to produce the desired resistive component for the parallel combination) is to think of them as T networks in which the output arm is represented by the reactive component of the tower load. As such, these networks can be described as *Phantom T Networks*.

Phantom T Networks

A phantom T network uses the tower reactance itself as the output arm (X_2) of the network. It is electrically equivalent to a conventional T network but requires one less circuit element. Because it has only two adjustable elements, the phase shift of a phantom T cannot be independently selected but two choices are possible, corresponding to T networks with small and large phase shifts. When the input resistance and reactance are properly adjusted, the resultant phase shift is then defined. Phantom T networks can be calculated quickly by the T network formulas while using cut-and-try variations of the phase shift until X_2 exactly equals the tower reactance. Phantom T networks with small phase shifts exhibit excellent bandwidth. Those with large phase shifts are somewhat poorer.

POWER DIVIDERS

In most phasors, separate components are used to accomplish the power division function; but the same networks that control phase shift can also control the division of power, if desired. It is important to remember, when comparing different towers in an array, that the power delivered to a tower is not in proportion to the base current; a low base resistance

Given: Total power is 1000 watts with base current ratios and resistances as shown. I = Current in Tower 3.

Tower No.	Base Current Ratio	Base Resistance	Power
1	0.20	25 ohms	$(0.20\,I)^2 \times (25) = 1.0\,I^2$
2	0.70	130	$(0.70\,I)^2 \times (130) = 63.7\,I^2$
3	1.00	40	$(1.00\,I)^2 \times (40) = 40.0\,I^2$
4	0.50	10	$(0.50\,I)^2 \times (10) = 2.5\,I^2$

$107.2\,I^2 = 1000$ watts;
$I = 3.054$ amps

Tower No.	Base Current	Base Power
1	0.20 x 3.054 = 0.611 amps	$(0.611)^2 \times (25) = 9.3$ watts
2	0.70 x 3.054 = 2.138	$(2.138)^2 \times (130) = 594.2$
3	1.00 x 3.054 = 3.054	$(3.054)^2 \times (40) = 373.1$
4	0.50 x 3.054 = 1.527	$(1.527)^2 \times (10) = 23.4$
		1000.0 watts

Figure 6. Example of power division calculations.

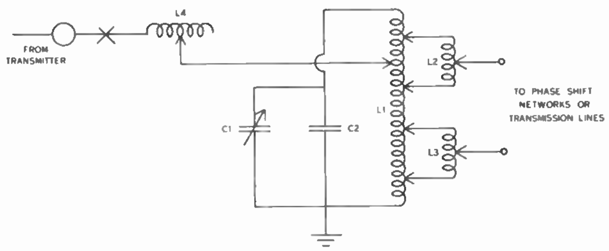


Figure 7. Typical tank-type power divider.

tower may consume very little power (I^2R) even if the current is relatively high. The actual power division is defined by the required base current ratios and the base resistances. An example of power division calculations is shown in Fig. 6.

Tank-Type Divider

In a tank-type power divider, as shown in Fig. 7, roller coils L2 and L3 (termed "jeep" coils in this configuration) adjust the power; the combination of L1, L2, and L3 is tuned close to resonance by capacitors C1 and C2. The input tap on L1 adjusts the common-point resistance; L4 adjusts the common-point reactance. This system is no longer popular because it is difficult to adjust and because bandwidth is limited by the excessive stored energy.

Shunt-Type Divider

A common type of divider is the "shunt" design shown in Fig. 8, which uses several adjustable coils in parallel, each of which controls the current to an individual tower. The reactance of the L1, L2, L3 combination is then tuned to resonance with C1. Component values are selected so that the impedance at point A is on the order of 400 ohms. A conventional T network then matches this load to the desired common-point impedance. This design is easy to adjust; however, the rollers on the variable coils may tend to bind and develop intermittent contacts after several years of use.

T-Network Power Division

A phasor can be designed to exploit the input impedance of conventional T networks to achieve control of both power division and phase, as shown in Fig. 9. In such a system, each T network presents a load at its input which is appropriate to divert the required power to its corresponding tower.

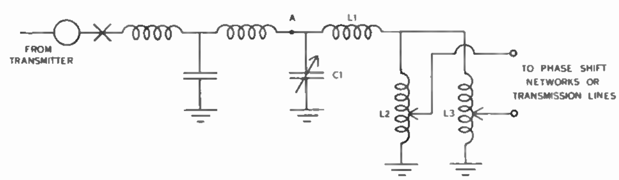

Figure 8. Typical shunt power divider.

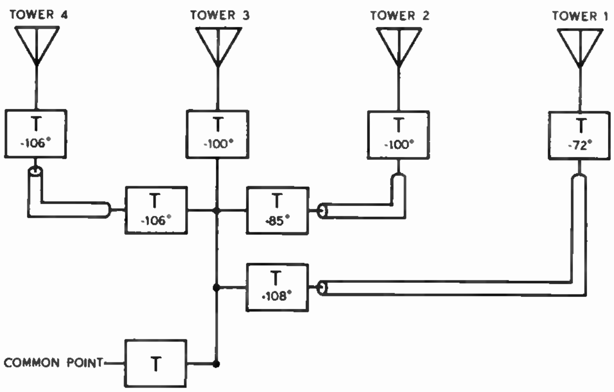

Figure 9. Typical phasor with "T" net power division.

Once such a phasor is properly adjusted, the small changes in phase and ratio that may later be required to maintain an array within tolerances are easily accomplished with very small adjustments in only the shunt and input or output arms of each individual tower network in the phasor. Although the phase and ratio adjustments interact (as with all phasors, due to the mutual coupling between towers), the shunt arms tend mostly to control power division, whereas the series input arms tend mostly to control phase. By noting which parameters are farthest out of tolerance, it is a simple matter to make small adjustments in the networks, observe the results of each change, and expeditiously restore such a phasor to the desired parameters.

Simplified Power Division

For two-tower directional systems, some very simple configurations can permit adjustment of both power division and phase shift with very few circuit elements. One such simplified system is a so-called "back-to-back" phasor; an example is shown in Fig. 10.

Components "C" and "L" are connected "back-to-back" at the output of the common-point matching network. In this example (which assumes matched

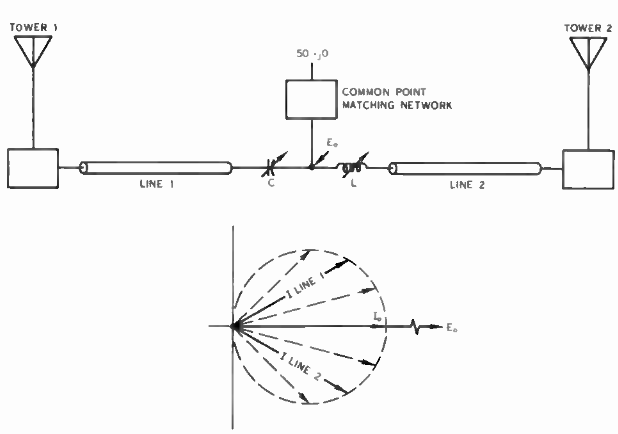

Figure 10. Example of a back-to-back phasor.

transmission lines with resistive inputs), reducing L to zero would yield a current into transmission Line 2 that is in phase with the applied voltage, E_0. As L is increased, the current into Line 2 diminishes and lags the applied voltage. As L is varied from zero to infinity, the locus of all possible Line 2 currents is the semi-circle on the lower half of the diagram. Similarly, as C is reduced, the amplitude of the current in Line 1 is reduced and its phase is advanced relative to the applied voltage. The locus of all the possible currents into Line 1, as C is varied from infinity to zero, is the upper semi-circle of the vector diagram. The ranges of adjustment of C and L need only be sufficient to reach the desired phase and ratio parameters, not the entire semi-circular gamut.

Independence of adjustment of phase and ratio is completely lacking in a back-to-back design; yet the phasor is easy to adjust. If one wants to change the ratio, an arbitrary change is first made in either component, phase is restored to the initial value by adjustment of the opposite component, and then the direction of ratio change is noted. It becomes a very simple cut-and-try process, not unlike that required to maximize transmitter efficiency by adjusting transmitter tuning and loading.

It is not always necessary to employ a coil and a capacitor in a back-to-back phasor. Often, the phase shift in the transmission lines and ACU networks can be tailored to provide the desired parameters with a series capacitor on the input to each line, rather than one capacitor and one coil. This arrangement permits a two-tower phasor in which both power division and phase adjustment are accomplished by only a pair of variable vacuum capacitors, offering excellent stability and resetability. This arrangement also provides excellent impedance bandwidth.

TRANSMISSION LINES

Many of the requirements for AM broadcast transmission lines differ from those used in FM and TV installations; the similarities and differences are discussed below.

Line Losses

The losses in transmission lines at AM broadcast frequencies are largely in the copper, not in the dielectric. For this reason, and for mechanical convenience, semi-flexible foam-filled lines are the most popular. Air dielectric lines are needed only when power levels exceed the ratings of available foam-filled lines.

Jacketing

All lines should include a black polyethylene outer jacket. Unjacketed lines can result in inadvertent poor contacts to other metallic conductors, which can be a source of minute arcs that can cause spurious emissions. Jacketed lines are particularly suitable for direct burial. Burying the lines greatly reduces the daily and seasonal temperature extremes they encounter, yielding greater stability relative to above-ground installations.

Although jacketed lines have an indefinitely long life when buried, they are vulnerable to attack by rodents, which can gnaw through the vinyl jacket and have been known to consume portions of the copper outer conductor, as well. The possible need to replace buried lines in the future should be considered at the time of initial construction. Protecting the lines in PVC conduits and/or installing spare lines are desirable options. At the minimum, PVC sweep elbows should be in place before concrete floors or foundations are poured for buried transmission lines and sampling lines that exit the transmitter building or doghouses.

Characteristic Impedance

A characteristic impedance of 50 ohms is the industry standard for radio frequency transmission lines. Such lines can be expected to be more easily available than other impedances in future years, should a replacement line be needed. The velocity of propagation in transmission lines is less than the velocity in air. Therefore, the electrical length of any line is somewhat greater than its physical length. This increase must be considered in any phasor design. Typical values of transmission line velocity constants are listed below:

Obsolete solid-dielectric flexible lines	68%
Original foam-filled lines	79%
Low-density foam (LDF) lines	88%
Semi-flexible air dielectric lines	90–93%
Modern rigid copper lines	99.8%

Phase-Stabilized Line

In its first year, a new directional array will usually experience small drifts in indicated phase and ratio parameters that will not be repeated seasonally thereafter. This initial drift is caused by the minor mechanical stresses remaining in the feed lines and sampling lines following manufacture and installation; these stresses are slowly relieved with temperature cycling. The result is a small initial change in characteristics following installation that will not be repeated. "Phase-stabilized" lines, which will reduce the initial drift, are available. Such lines have been temperature-cycled in an oven to relieve residual mechanical stresses. Within about a year following installation, no observable differences in stability exist between regular lines and those that were initially phase-stabilized.

Transmission Line Fittings

All modern transmission lines can be equipped with EIA-standard flanged fittings to mate with connecting equipment. Although the impedance continuity provided by such fittings is essential at FM and TV frequencies, such fittings are unnecessary for foam line antenna feeds at AM broadcast frequencies. However, adequate electrical bonds are essential between the transmission line conductors and the adjoining equipment. The dielectric in foam-filled lines is a better insulator than air. However, catalogs show such lines as having the same voltage breakdown rating as air-dielectric lines because of the limited air gap within the end fittings. For AM broadcast use, the power rating of foam lines can be increased by avoiding the use of end fittings and stripping back the outer conductor (while leaving the foam) to increase the air gap on both ends of each line.

Line Mismatch

At AM broadcast frequencies, the effects of a transmission line mismatch are quite different from the electrically-long transmission lines used for FM and television antennas, where mismatches can cause reflections back into a transmitter and result in crosstalk or ghosts. At AM broadcast frequencies, transmission lines are rarely longer than a wavelength. A mismatched transmission line yields an input impedance that is dependent on both the load impedance and the length of the line. Thus a transmission line can act as a simple impedance transformer and can be designed to exhibit a desired input impedance through proper choice of load impedance. This characteristic is occasionally exploited in designing phasing systems.

Perfect transmission line matches are not critical to overall system bandwidth. Although most phasing and coupling systems are designed with the intent that the transmission lines to the towers be matched, the consequences of substantially mismatched lines are usually trivial. Improving the match on any transmission line between the phasor and tower may improve or impair the bandwidth. Because the lines are electrically short, their behavior is more akin to that of a simple network than to the transmission lines in FM and television systems, which are often hundreds or thousands of wavelengths long. As a general rule, if lines to towers that handle 25% or more of the transmitter power are matched to a VSWR of 1.5:1 or better (at the carrier frequency) and any remaining lines are matched within 2:1, further efforts at improving matches may give only trivial reductions in line losses and trivial changes (for better or worse) in the bandwidth. Even though a line may be perfectly matched at the carrier frequency, it will never be perfectly matched at the sideband frequencies because no antenna load is absolutely constant over the desired bandwidth of ±10 kHz. The effects of the less-than-perfect sideband matches can be minimized by proper proportioning of the phase shifts between the phasor networks and the ACU networks. It is important to avoid confusion between transmission line VSWR at the carrier frequency and common-point VSWR at sideband frequencies.

Voltage and Power Ratings

With 100% modulation, the voltage on a matched lossless transmission line varies from zero on a modulation trough to twice the unmodulated value on modulation crests. This is quite unlike the situation in FM where every radio frequency cycle has the same amplitude. In FM and TV systems, the dielectric losses (because of the higher frequencies) cause the power rating to be limited by the heat generated within the dielectric as well as by the copper losses; power ratings are accordingly based on the ability of the transmission line to dissipate the heat resulting from the losses. At AM frequencies the dielectric losses are minor while the instantaneous voltages during modulation peaks can be very high. As a result, the power handling ability of AM transmission lines is usually limited by the voltage breakdown rating of the line. With 125% positive modulation, the maximum instantaneous peak voltage becomes more than three times the unmodulated RMS voltage and the instantaneous peak power becomes more than ten times the unmodulated power. An additional allowance must also be made to accommodate the increased voltage maximum along each line due to standing waves caused by any less-than-perfect transmission line match.

Under transient conditions (such as can be caused by lightning strikes or sudden component failures) the VSWR overload protection designed within all modern transmitters may not trip, and the power distribution among the towers may be drastically altered in unpredictable ways. This can lead to voltage breakdowns within buried transmission lines which are difficult locate and repair. For this reason it is good engineering practice to employ equal-size transmission lines to all towers that are capable of handling the full modulated output of the transmitter even though the power delivered to particular towers may be only a few percent of the total power during normal operation. This design factor will also be greatly appreciated in the event of an emergency requiring nondirectional operation on one of the low-power towers.

ANTENNA MONITOR AND SAMPLING SYSTEM

A directional antenna sampling system consists of current sampling transformers or sampling loops on each tower to provide a sample of the tower current, transmission lines which return the samples, and an antenna monitor which measures the amplitude and phase of each sample relative to that of the reference tower.

Sampling Loops

A sampling loop consists of a rigid single-turn coil permanently attached to each tower. Because sampling system stability is essential, the loops are typically made of galvanized or stainless angle iron or rigid copper water pipe. The loops must be at least ten feet above ground and may be insulated from the tower and kept at ground potential. However, it is more common practice to use loops at tower potential and return the sample to ground potential through an isolation coil (isocoil) formed by coiling up the sampling coax so as to form a high impedance across the tower base insulator while not disturbing the current sample carried within the coax.

Sampling Transformers

An alternative method of obtaining tower current samples is to use shielded current sampling transformers in the feeds to each tower. These have much to recommend them if the tower heights do not exceed approximately 130 degrees. Although a transformer will sample both the current going up the tower and a lesser component that flows to ground through the base insulator capacitance, the sampling error is usually inconsequential. The advantages to using sampling transformers are stability, a sampling device that is protected inside the ACU instead of being exposed to the weather, and elimination of the isocoils that are otherwise usually required at each tower.

Stability and Accuracy

Sampling system stability is vital, but accuracy is not critical because the proper phases and currents to generate a directional antenna pattern are determined by means of field strength measurements. The sampling system is required to detect changes from the original adjustments of indicated phase and ratio. The accuracy of a sampling system in measuring the absolute amplitude of radiation from each tower is inherently poor. Even though the sampling loops may be carefully adjusted so that each has exactly the same area in its single-turn coil and all are mounted at the same height, the samples will not be a measure of the relative radiation from each tower. The mutual impedances between towers seriously distort the sinusoidal current distribution which would otherwise exist throughout the height of each tower. Thus the indicated antenna monitor ratios are not an absolute measure of the relative radiation from each tower. The monitor ratios may also differ substantially from the base current ratios, particularly when the loops are a considerable distance above ground level or towers of unequal height are employed. The indications of phase from a good monitoring system are considerably more accurate than the ratio indications. Arrays with unequal-height towers usually require sampling loops that are all located approximately a quarter-wavelength below each tower top if the indications of phase and ratio are to be the best approximation of the actual radiation from each tower.

DETUNING AND DECOUPLING SYSTEMS

Detuning (Floating) Unused Towers

The most common occasion for detuning towers arises within directional arrays themselves wherein unused towers must be placed in a non-radiating condition. This is necessary in all arrays when nondirectional proof-of-performance field strength measurements must be made, where nondirectional daytime operation is permitted, or where one or more towers are not used for daytime or nighttime modes when two patterns are authorized. In more critical situations or with taller towers, more effective detuning is required than simply disconnecting the unused towers to reduce

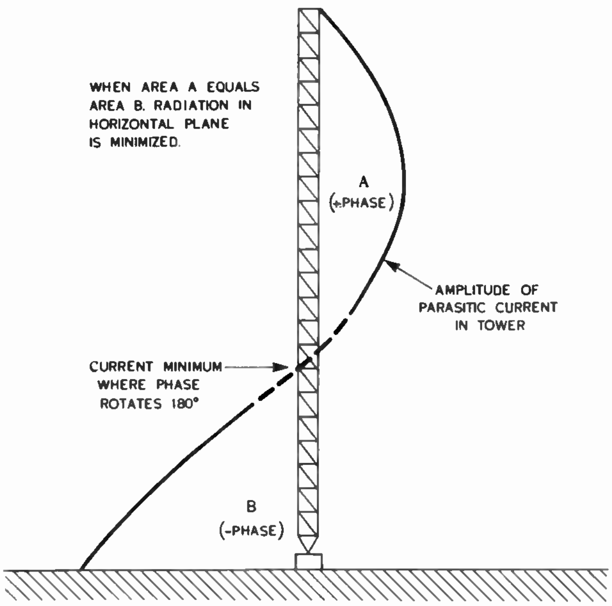

Figure 11. Current distribution on detuned tower.

the radiation (reradiation) caused by parasitic currents that flow in them due to the mutual coupling to adjacent driven towers. Disconnecting a tower will not eliminate the component of induced tower current flowing to ground through the capacitance of the tower base and base insulator. An inductive reactance of the proper value (often formed in part by the isocoil if sampling loops are employed) can be added across the base to resonate the base capacitance and effectively eliminate all current flowing to ground.

The optimum detuning (even for short towers, as well as for towers up to a wavelength tall) results when an inductive reactance across the base insulator produces a tower current distribution as shown in Fig. 11. Because there is a phase reversal at the elevation of minimum current, it is simply necessary to position

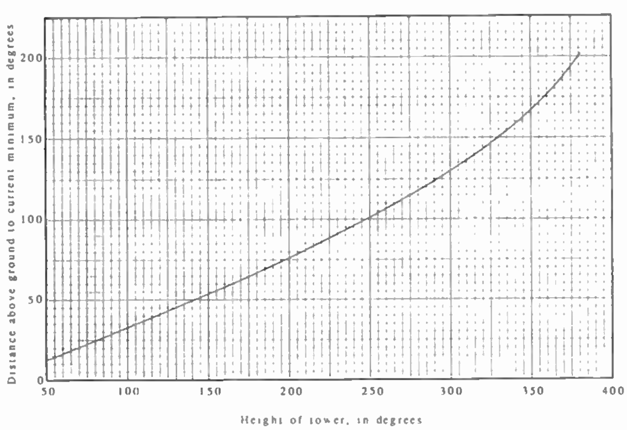

Figure 12. Approximate height of required current minimum to detune guyed towers.

a current minimum on the tower so that area A equals area B. In the horizontal plane, the radiation from the portion of the tower above the minimum will then cancel that from the portion below the minimum. The proper height for the tower current minimum (typically about one-third the tower height) is as shown on Fig. 12. The minimum can be achieved easily by climbing the tower with a field strength meter (or other current sampler and detector) and adjusting the reactance shunting the base insulator until a current null is obtained. Although the shunt reactance necessary to detune a tower is always inductive, the reactance may be so high as to not be within range of a coil of reasonable size. A vacuum variable capacitor in parallel with the coil then provides a convenient and precise way of adjusting the shunt reactance so as to float the tower.

Tower Sectionalization

Occasionally, when it is necessary to use a tower that is too tall, sectionalization of the tower is required. For example, it may be desired to share an FM tower with an AM station. If the overall tower height were to exceed about 225 degrees at the AM frequency, the tower would be a poor radiator, putting more AM signal up into the sky than along the ground. The preferred solution for such a tall tower is to include insulators in the tower legs (and an isocoupler in the FM feedline at the same height) so as to open-circuit the tower at the height needed to make it a good AM radiator. A parallel resonant circuit (an impedance pole) across the insulators can then resonate the insulator and stray capacitances to effectively decouple the upper portion of the tower. In cases where structural considerations prevent the sectionalizing of a tower by means of insulators, a workable solution can be to use detuning "skirts" to decouple the top portion of the tower. Examples of how skirts were used to sectionalize a tower at 1360 kHz and to detune it for protection of a nearby station on 600 kHz are shown in Fig. 13.

A tower skirt is an insulated wire cage constructed outside of a tower. The skirt is formed of wires that surround the tower and are spaced a foot or two away. All skirt wires are bonded to the tower at one end and can be connected in parallel at the other end so as to be tuned with a single capacitor. Electrically, the skirt can be considered as forming a shorted quarter-wave coaxial transmission line which is slightly foreshortened and loaded with a variable capacitor at its open end for easy adjustment. The tower forms the center conductor of the coax and the skirt wires approximate an outer conductor. Adjustment of the skirt tuning places a high impedance at the capacitor end of the skirt with a result that the tower is effectively open-circuited at that elevation. The effectiveness of such a tower skirt is determined by the characteristic impedance and losses in the transmission line section formed by the tower and the skirt. The most effective skirt will necessarily have a high Q, which is realized by using reasonably heavy skirt wires spaced as far as

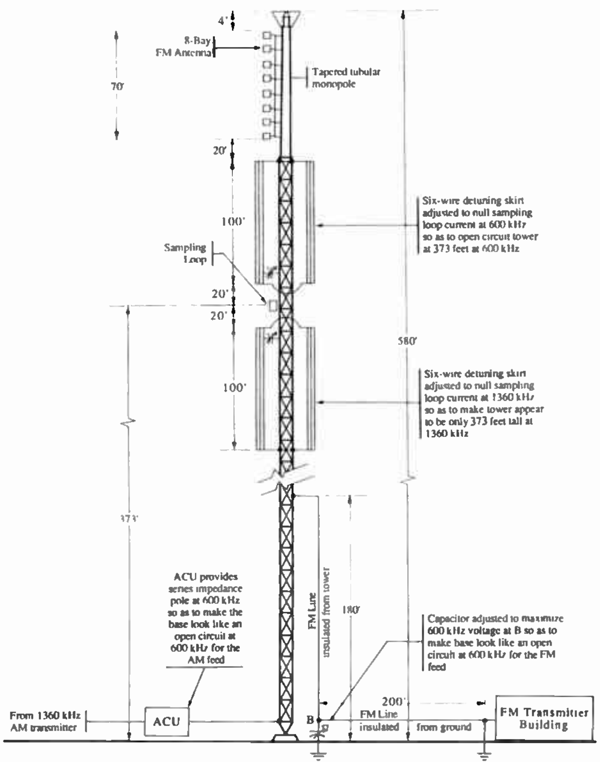

Figure 13. FM tower sectionalized to make an efficient 1360 kHz radiator simultaneously detuned at 600 kHz.

mechanically feasible away from the tower. For guyed triangular towers of uniform cross-section, combinations of three or six skirt wires are common. Inasmuch as the most effective skirt will necessarily have a high Q, it will best decouple the portion of the tower above its open end only at the frequency to which it is tuned. As a result, the tower base may exhibit a steep impedance versus frequency characteristic which can impair bandwidth. Another way of visualizing the operation of a skirt is to think of the tower and skirt wires as forming an inductive loop which is tuned to resonance so that the current flowing up the tower is effectively cancelled by a substantially equal and opposite current flowing down the skirt wires.

Detuning Power Lines

The detuning techniques described above can be applied to steel power line towers or to other tall metallic structures in order to reduce the radio-frequency currents in them, currents that would otherwise cause reradiation and distort the desired directional antenna pattern of a nearby radio station. Fig. 14 shows such an arrangement with each skirt wire on each tower leg separately tuned. Again, the effectiveness of the skirt depends on the length of the skirt section and the number, diameter, and spacing of the skirt wires.

Filter Systems

If it is necessary to control the current distribution on a tower at a different frequency in order to avoid disturbing the pattern of a nearby directional station, a filter system is needed to permit control of the impedance shunting the tower base at the other station's frequency. The control should be independent of routine phasor adjustments. Such an arrangement is shown in Fig. 15 for each tower of a station operating on 630 kHz. The 630 kHz station must control tower current distribution at 950 kHz in order to protect the directional antenna operation of the nearby station on that frequency.

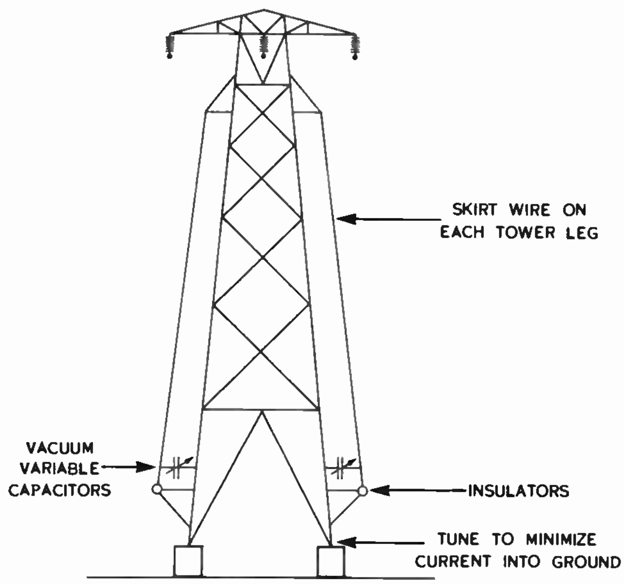

Figure 14. Skirts used to detune power-line towers.

For filters in series with antenna feeds (such as the C3/L7, C4/L8 combination), it is desirable to provide an impedance zero at the pass frequency as well as the impedance pole at the reject frequency. Even when the pass and reject frequencies are widely separated, failure to provide the impedance zero with a reasonably low L/C ratio can result in excessive losses.

Intermodulation

Filters to control spurious emissions resulting from intermodulation products generated within the final stage of a transmitter can have the same configuration

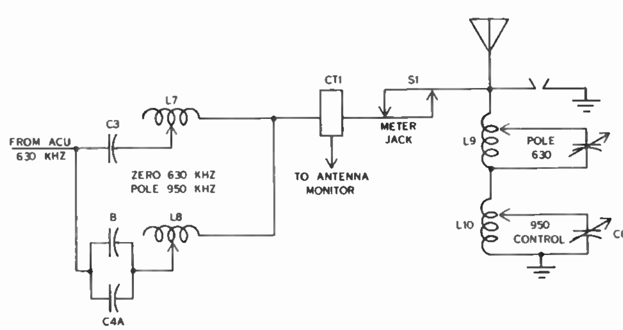

Figure 15. Independent control of tower current distribution at a second frequency.

as filters used to control tower-current distribution for a nearby station. Before such filters are designed, a knowledge of the frequencies that generate the intermod is essential. The second, third, and higher harmonic frequencies are strong components in a transmitter output stage and can generate intermod products there even though these harmonics are suppressed to acceptably low levels when measured at the transmitter output. In the general case, an unwanted incoming signal from some other station can be coupled into the final amplifier through the antenna system to mix with the fundamental or any harmonic to produce a spurious output frequency.

Effective filters can take the form of either traps to prevent an unwanted signal from getting into the transmitter or traps to prevent the resulting spurious emission from getting out (or both). Filters can be series-resonant shunt elements that short the unwanted incoming signal (or the spurious emission) to ground, or they can be parallel-resonant elements in series with the transmitter output to present a high impedance to either the unwanted incoming signal or the spurious emission.

One clever and expeditious arrangement, when a single spurious frequency must be eliminated, may be to modify the shunt arm of the common-point matching network to consist of a series-resonant L/C circuit that simultaneously has a very low impedance at the undesired frequency and the proper reactance at the station carrier frequency.

Many modern transmitters have exceedingly broadband output coupling networks which, together with improved antenna bandwidths, permit unwanted signals from other radio stations to get back into the final stage of the transmitter to produce spurious intermod products. Signals thus entering the transmitter need not be particularly strong. Many cases are known where the offending input that caused an objectionable spur originated from a radio station 20, 30, or even 40 miles away. The 500 kHz radio channel is an international distress frequency, so this frequency and channels adjacent to it should be checked for spurs whenever measurements of spurious radiation are undertaken on an AM broadcast transmitter.

Broadbanding

The term "broadbanding" can be quite confusing. Frequently it is applied to any circuit modifications that are intended to improve the impedance bandwidth of an antenna system. A "broadbander" is a circuit that in and of itself improves the impedance bandwidth, thus reducing the VSWR at the sidebands. A broadbander typically consists of the series combination of a coil and a capacitor which is inserted in series with the load to be improved (usually immediately before or after the common-point) and is adjusted to series resonance at the carrier frequency. Such a circuit is capacitive below the carrier frequency and inductive above the carrier frequency. Before a broadbander can function as intended, the load it sees must be inductive at the lower sideband frequencies and capacitive at the upper sideband frequencies. This condition is achieved by altering the phase shift in the common-point matching network (or inserting an additional phase-shifting network) so that the Smith Chart plot is "horns up", as is shown in Curve A, Fig. 16. Then the uncorrected load reactance (which is inductive for the lower sideband) can be canceled by the capacitive reactance of the broadbander and the capacitive reactance of the upper sideband load can be cancelled by the inductive reactance of the broadbander. The result is that the load reactance can be effectively canceled at any pair of sideband frequencies as determined by L/C ratio of the broadbander. For such a broadbander to function as intended, it is essential that it be effectively shielded so that there is no stray coupling between it and the other components in the phasor. When properly designed and adjusted, it can "wrap up" the common-point impedance, as shown in Curve B, Fig. 16.

Such a broadbanding circuit should not viewed as a cure-all, but it can provide a useful reduction in sideband VSWR once all other reasonable efforts at improvement have been applied.

TRANSMITTER LOAD OPTIMIZATION

A transmitter can deliver equal power to both sidebands when the upper and lower sideband load resistances are equal and the upper and lower sideband load reactances are equal. If the transmitter load VSWR at ±10 kHz from carrier is rather good (perhaps 1.2:1 or better), further adjustments to improve load symmetry may not be warranted. However, if the ±10 kHz sideband loads are rather poor (e.g., 1.5:1 or greater), sideband load symmetry can become an important matter. Symmetry is achieved by adjusting the phase shift in the common-point matching network so that the load resistances at the ±10 kHz sideband frequencies are essentially equal and the reactances are equal but opposite in sign as measured at the anode (or collectors) of the transmitter output stage.

Because different manufacturers use different output circuitry with different phase shifts, and because some have not published information as to optimum load orientation at the transmitter output terminal, the necessary measurements usually must be made on the load seen by the final amplifier stage anode or collector. Fig. 16 shows the Smith Chart orientation for the two conditions that satisfy symmetrical loading requirements. For tube-type transmitters (whose output stage functions substantially like a constant current generator), Curve C, which shows equal sideband resistances higher than at carrier, tends to emphasize the high frequency response. Curve A also shows equal sideband resistances, but lower than at carrier; this orientation tends to show reduced 10 kHz distortion. Either of the two conditions is preferable to intermediate conditions that yield asymmetrical load resistances at the two 10 kHz sideband frequencies.

Transmitter manufacturers are now more sensitive to the fact that all antenna systems provide less-than-

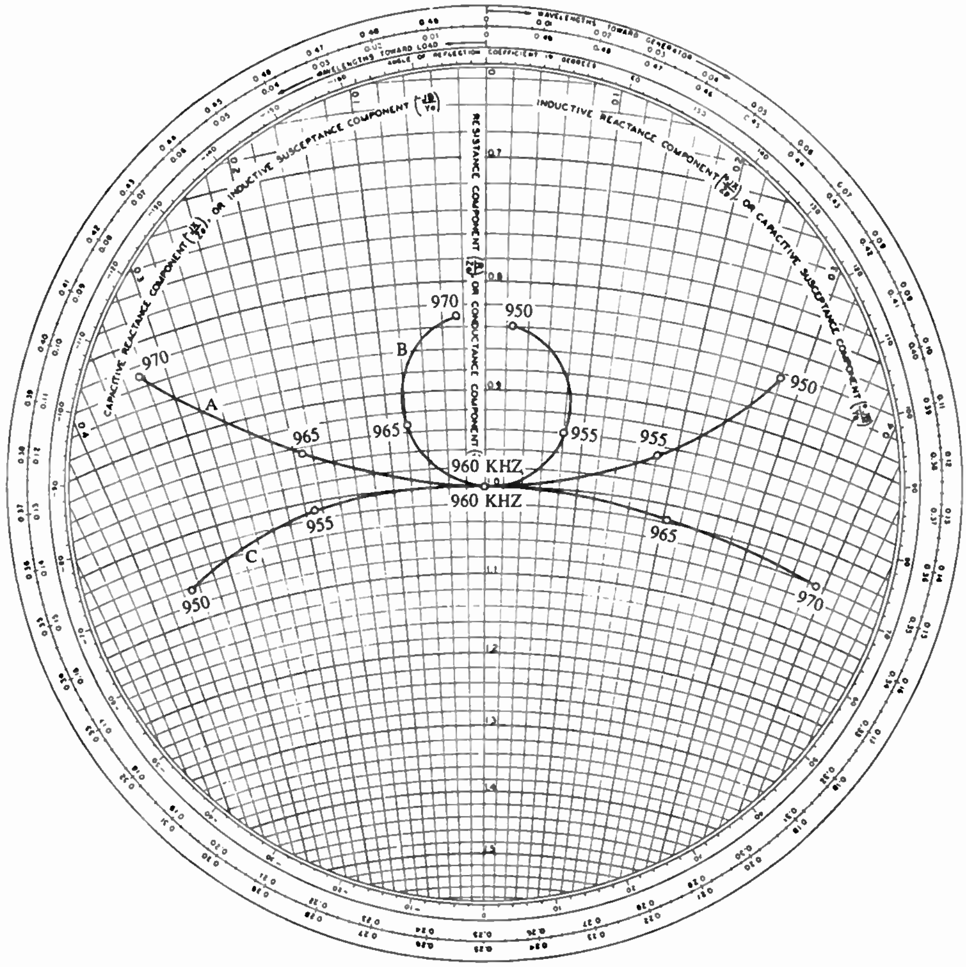

Figure 16. Proper load impedance at final amplifier plate or collector.

perfect loads at the sideband frequencies and that load orientation (as displayed on a Smith Chart) can be critical to overall system performance. Most manufactures can now supply information as to optimum load orientation (referred to the transmitter output terminals) for each specific transmitter. Experience has also shown that audio intermodulation distortion varies with load orientation, so intermod should be measured and minimized.

DIPLEXERS AND MULTIPLEXERS

Two, three, or more AM stations can be combined on a single tower, provided that sufficient frequency separation exists between the channels and the electrical height of the tower is not unreasonably short or tall at any of the channels. Depending upon the transmitter characteristics, only 35 dB or less of RF isolation is typically required between the transmitters to avoid generation of spurious emissions and to permit completely independent operation. Diplexer adequacy is assured when each station:

1. Has no objectionable spurious emissions.
2. Can conduct an acceptable audio proof, including distortion and noise measurements, while the other station is in operation.
3. Has no observable change in its indicated antenna current when the other station's transmitter is turned on and off.

The losses in diplexing and multiplexing filters can become crucial to a successful design. Since the tower impedance and required tower current at each frequency are known, the losses can be calculated with good accuracy. Capacitor losses are negligible. Coil losses can be calculated using an assumed coil Q of 300, which is a conservative approximation for typical silver-plated RF inductors in shielded enclosures. Diplexer losses can be minimized if the reactive component of base impedance can be eliminated by means of networks at the tower base. Then the shunt elements in the diplexing filters operate at lower voltage levels.

Two stations having directional antenna patterns can be diplexed on common towers provided the tower spacing and orientation permit acceptable directional patterns for both stations and the compatibility requirements previously mentioned for combining nondirectional stations are met.

Ground Systems

This material duplicates in part the information on ground systems in the previous chapters, information that is so important it bears repeating.

The current that flows into a tower does not simply disappear: it all flows back to ground through the capacitance that exists between each incremental length of the tower and the ground. (This makes the tower and ground system an integral part of the coupling and phasing system.) When this current reaches the ground, it must be collected and returned to the ground side of the ACU network to complete the circuit. The ground currents are usually strongest close to the base of the tower where the capacitance between the tower and incremental ground segments is greatest. If the ground resistance is substantial, the ground current (equal to the antenna current) will simply heat the ground and represents a power loss. To return the antenna current from the ground surrounding the tower to the ground terminal of the ACU network, a system of radial ground wires is employed. For nondirectional towers, a series of early-day experiments established that 120 radial ground wires uniformly distributed at three-degree intervals and extending a quarter-wavelength (90 electrical degrees) from the tower base was a reasonable limit beyond which the reduced losses to be realized from incremental increases in the number or length of the radials did not warrant the incremental increases in cost required for a more extensive ground system. As a result, ground systems consisting of 120 radials extending a quarter-wavelength from each tower (or foreshortened and bonded to a transverse copper strap where radials from adjacent towers overlap) have become the *de facto* industry standard, even though it is recognized that in directional arrays the ground currents do not always flow along radial lines, due to the effects of adjacent towers.

Near the base of each radio tower, there are both electromagnetic and electrostatic fields. With reasonably low base impedances (such as a quarter-wave tower), the electromagnetic field predominates. Near towers with a high base impedance (such as a half-wave tower), the electrostatic field predominates. The radial wire ground system minimizes the I^2R losses but not the E^2/R electrostatic losses which can occur in all materials near the tower base with less-than-perfect dielectric constants. The electrostatic losses are usually inconsequential in a nondirectional operation, but can become critical in a directional array. Dielectric materials in the vicinity of the tower base can include wooden fences, wooden or cement block tuning houses, and the earth that is on top of a buried ground system. The changing dielectric constant in these materials between wet and dry conditions can make enough difference in base impedance to cause substantial changes in base current ratios and phases. For these reasons the ground wires should be kept on top of the soil in the immediate vicinity of each tower base or covered with only a thin layer of gravel or paving. Beyond about 20 feet from each tower base the fields are less intense and the remaining portions of each ground radial are usually buried six to eight inches for mechanical protection. Deeper burial is called for only if the land is to be cultivated or is so soft that farm animals or machinery can sink into the soil and break the ground wires. Metal fences surrounding each tower base are quite superior to wooden fences, whose dielectric constant can change greatly when wet. If nonmetallic doghouses are employed in critical arrays, it may be necessary to provide an electrostatic shield of expanded copper mesh or Copperweld wire mesh up the side of the dog house adjacent to the tower and across its roof. The ultimate electrostatic shield takes the form of an elevated radial ground system which typically extends to a radius of 10 to 30 feet at a height of six feet or more above ground and effectively shields everything beneath it.

Number 10 AWG soft-drawn copper wire is the most common material for ground radials. Copperweld mesh ground screens, such as are employed for lighting protection under electric power substations, are suitable for the area immediately surrounding each tower, and the radial wires can be connected to the edge of such a screen. Frequently an additional 120 radials, each 50 feet long, are interspersed between the longer radials where a ground screen is not used. All connections within a ground system must be silver-soldered or brazed, as soft tin/lead solder deteriorates rapidly when buried.

OVERALL SYSTEM PERFORMANCE

Directional antenna pattern design and phasor design go hand-in-hand. Given a poor pattern design, no amount of clever circuit design in the phasor can provide an excellent system. Following are some considerations that can lead to an excellent antenna system.

In the Pattern Design

1. Avoid closely spaced towers; 90 electrical degrees or more should be the objective.
2. Avoid broadside minimums without ample spacing between towers; otherwise the driving point resistances can become very low.
3. Check to see that the individual tower radiation vectors add in-phase (or very nearly in-phase) in the pattern maximum; otherwise excessive circulating currents, poor bandwidth, and pattern instability can result.
4. Unless other considerations dictate, choose tower heights in the range of 100 to 130 degrees. Shorter towers exhibit lower driving point resistances and poorer bandwidth. Taller towers may require excessively large impedance transformations in the

ACU networks; this condition can add another bandwidth limitation.

In the Phasor Design

1. Minimize reactive power (I^2X) in the phasor components. This will avoid high Q circuits.
2. Avoid excessive use of series (trim) coils to adjust the reactance of fixed capacitors. Such coil/capacitor combinations necessarily have a steeper impedance versus frequency characteristic than a capacitor alone having the proper reactance.
3. Consider alternative phasor designs. The design with the fewest parts usually has the best bandwidth unless specific broadbanding circuits are incorporated.
4. Derate coil current ratings by 40% and mica capacitor current and voltage ratings by 50%. Remember that RF currents under heavy asymmetrical modulation can exceed 125% of the unmodulated current and that peak voltages can exceed 300% of the unmodulated RMS voltages.

A SIMPLE BANDWIDTH TEST

A simple test can evaluate the performance of the individual towers in an existing directional antenna system. The object is to determine the amplitude of each 10 kHz sideband component as radiated by each tower. This test is possible with any common field strength meter because the selectivity of such meters is just sufficient to resolve sideband components that are 10 kHz removed from the carrier. The procedure is as follows:

1. Keep the sampling lines terminated into the antenna monitor, but add "T" connectors to bridge off samples into a field strength meter operating as a linear tuned voltmeter. Be certain the samples do not exceed the safe voltage input for the field strength meter.
2. Modulate the transmitter 50% with 10 kHz sinewaves.
3. For each tower sample, first adjust the field strength meter gain so as to set the carrier level full scale (100%). Then tune in each sideband in turn and log each sideband amplitude as a percent of full scale. In a perfect system, this would result in sideband amplitudes equal to 25% of the carrier level in each tower.
4. Repeat the process for each tower.

In the best antenna systems, all 10 kHz sideband components will range between 23% and 27% with 50% modulation at 10 kHz. Poor systems have been observed to have individual tower sideband components as low as 5% or as high as 40% in this test.

In the main lobe of a directional antenna pattern, deficient 10 kHz sideband amplitudes do not usually result in measurable distortion because the radiation components from the individual towers add approximately in phase and the sideband deficiencies of any one tower are masked by the total radiation from all of the other towers. This test is useful in pinpointing limitations in existing systems.

SAMPLING SOURCE TO FEED A MODULATION MONITOR

The indications of a modulation monitor may be inaccurate at high modulation frequencies if the modulation sample is taken from a less-than-perfect antenna system. In an antenna system with a high VSWR at the 10 kHz sidebands, the voltage sampled for the modulation monitor may be higher or lower at the 10 kHz sidebands than at low modulating frequencies. The best measure of 100% modulation is at a remote point in the main lobe of the antenna pattern. Various sampling points within the transmitter or phasor can be tried until a sample source is found that matches the percentage modulation at high modulating frequencies observed in the far field of the main lobe.

CONCLUSION

When the complexities in the design of directional antenna patterns and circuitry are considered together, the need for specialists in this field is evident. However, these chapters should have increased the reader's understanding of the complexities and thus assisted in the maintenance and improvement of AM directional antenna systems.

2.5 AM Broadcast Antenna Systems

Part III: Maintenance

Edward Edison, P.E.
Hammett & Edison, Inc., San Francisco, California

Many stable directional arrays, being electrically passive devices, operate for ten or more years without any readjustment. However, maintenance attention will be needed to overcome the normal effects of age and deterioration (routine maintenance), to restore proper operation after catastrophic failures (such as caused by lightning), and to cope with new sources of reradiation that may develop within the environment in which the antenna system operates. Infrequently, readjustment and relicensing with new pattern parameters may be required.

ROUTINE MAINTENANCE

Routine mechanical and electrical maintenance is required to offset the effects of age and deterioration. Mechanical maintenance includes the attention necessary to keep the moving parts functioning and the tower painted and in good repair. Electrical maintenance may involve replacement or recalibration of base current meters; checks on the continuing proper performance of the phasor components, transmission lines, and ground system; and infrequent readjustment of the antenna phase and ratio parameters as necessary to ensure operation within licensed limits with the proper directional antenna pattern.

Mechanical Maintenance

The moving components within an antenna system may include RF relays, meter switches, dial drives, and the rollers on variable coils.

The contacts on RF relays that carry substantial currents may eventually wear out and require replacement. It is vital that such relays be interlocked so they cannot be switched while transmitter power is applied. Relay maintenance problems are reduced when vacuum relays are employed.

Meter switches, that disconnect thermocouple-type ammeters from the circuit when not being read, are subject to considerable mechanical wear and tear. Occasional lubrication and tightening of the components are necessary if the parts are to function properly. Replacement of thermocouple ammeters with modern transformer-type meters eliminates the need for RF meter switches and their associated maintenance requirements.

Dial drives on variable coils and capacitors, once properly adjusted, require little attention except infrequent lubrication. The thrust bearings on vacuum variable capacitors are factory lubricated and should not require maintenance attention. However, the rollers on variable coils are often a source of mechanical difficulties (particularly in older coils) and periodic maintenance is required if they are to operate smoothly and without excessive arcing. Networks that are designed to utilize variable vacuum capacitors instead of variable coils are superior in this regard.

Electrical Maintenance

Thermocouple RF ammeters that measure base currents and common-point currents are a frequent problem due to failure or changes in calibration. If such meters cannot be replaced with modern transformer-type units, an intermediate improvement can be effected by substituting make-before-break meter jacks at the base of each tower (in lieu of the original permanent thermocouple meters and associated protective switches). The meters can then be stored in a dry environment and taken to the towers only when base current readings are required. The effects of calibration errors are reduced if the same meter is used to measure all base currents (provided all currents fall within an acceptable range on the meter scale).

Thermocouple ammeters can be calibrated with 60 Hz current. A useful procedure is to remove all such meters from the system and to connect them in series for testing. A high-quality dynamometer or soft-iron-type meter should also be included as a calibration standard. A filament transformer having adequate secondary current rating can be used to drive current through all of the meters connected in series. Current amplitude is easily controlled by supplying the filament transformer from an adjustable AC supply such as a Variac.

Modern current-transformer RF ammeters cannot be calibrated with 60 Hz and, if defective, must be returned to the manufacturer for repair and recalibration. The transformer, meter, and interconnecting cable are calibrated as a unit. The cable length should not be changed without recalibration by the manufacturer.

Occasionally loose connections or deteriorating phasor components will produce abnormal heating. Failures from these causes can be anticipated by simply feeling all RF connections and components for warmth immediately after sign-off.

Transmission Lines

Air or foam dielectric lines in continuous lengths rarely develop troubles, but pressure should be maintained on air dielectric lines in order to prevent the accumulation of moisture. Breaks in the outer conductor of foam-filled lines that are buried may cause obscure symptoms and prove difficult to locate. In extreme situations, a time-domain reflectometer is the best tool to pinpoint the problem.

Ground System

Significant deterioration of a ground system can manifest itself in two ways. The first indications may be unusual changes in the phase and ratio parameters between wet and dry conditions. These changes depend upon the nature of the directional array and the character of the ground. When ground systems are installed in shallow tidewater or saltwater marshes, the inherent ground conductivity is so good that even drastic changes of the ground system may produce negligible effects.

A second, more obvious symptom of a deteriorating ground system is a reduction in antenna radiation and a reduction in base currents. It is not uncommon in older arrays to find that the absolute value of each base current has fallen off since the time of the initial installation, even though the base current ratios remain correct. With the available common-point power remaining constant, any increase in ground system losses must necessarily reduce the base currents.

It is essential that all joints in a ground system be made by brazing or silver soldering. Soft solder consisting only of lead and tin deteriorates quickly when buried.

The existence and continuity of buried ground radials is best checked by using an underground cable locator of the type used by utility companies to locate buried cables and pipes. These devices consist of a transmitter, which can be located at the tower base to place a modulated low-frequency signal on all connected ground wires and a receiver that detects the unique modulation. While in use, the receiver can be carried in a circle with a radius of 100 feet or more about each tower, so that the radial wires that are intact can easily be detected and counted.

Alternatively, if a cable locator is not available, a shielded pick-up loop held near the ground and connected to the external input of a field strength meter may suffice to detect the current in individual radial ground wires. Even when a radial is broken, the current beyond the break tends to concentrate in the wire instead of the adjacent earth. A most definitive check is to uncover the distant ends of adjacent radials and check for continuity between them with a DC ohmmeter.

Towers

Towers require occasional attention to ensure their structural integrity. Periodic inspections by an experienced tower contractor are desirable. Guyed towers should be checked to confirm that they are straight and plumb and that the guy tension is correct. Towers with tubular legs can rust from the inside out; a close inspection is necessary to detect this condition while repairs are still feasible. Towers with solid legs avoid the hazards of internal rust. Galvanized towers must be painted only if required for aeronautical safety. Nongalvanized towers should be avoided, not only because rusting makes the maintenance problem more severe but also because of their inferior electrical conductivity.

Lightning strikes and target shooters may destroy guy-wire insulators. Such failures can usually be discovered with the aid of field glasses or a telescope. The electrical field gradient can be very high adjacent to a tower, particularly near the top. Arc-overs and corona can be avoided by cascading guy-wire insulators (johnny balls) immediately adjacent to the tower. Under severe conditions, fiberglass rod insulators or dielectric guy cables are a preferred solution. In an existing system with marginal insulation, any dirt or salt deposits on the insulators may cause corona and arc-overs. Washing the insulators and coating them with silicone grease may provide a temporary remedy.

SUDDEN COMPONENT FAILURES

Lightning strikes are the most common cause of component failure in a well-designed antenna system. Lightning which strikes a tower should be conducted directly to ground through the ball gap that is typically part of each tower installation. Detailed information on lightning protection is provided in Chapter 2.2, "Lightning Protection for Broadcast Facilities," of this *Handbook*. However, lightning has been known to destroy components in what appear to be well-protected systems.

Damaged components can most usually be located by a careful visual inspection. Lightning currents flowing through adjacent coil turns tend to collapse them; therefore, coils should be inspected to confirm that all turns are in their original uniform alignment. The forces generated by lightning traveling through the coil strap and clip on a ribbon coil may dislodge the clip and leave the strap hanging in nearly its original position. Careful visual inspection is needed to locate dislodged coil clips.

Although vacuum capacitors are usually self-healing if subjected to minor over-voltages that cause internal arcing, the extremely high currents from a lightning strike can melt the plates together and short the capacitor, necessitating replacement.

If lightning damage is a recurring problem that warrants additional protection, the following steps are suggested:

1. Check the ball gap at the tower base. The balls should be arranged side-by-side so that dirt and water will not bridge the gap with the first rain of the season. The balls should be on the same radial line through the tower axis because towers tend to twist in high winds; this twisting could otherwise change the gap between the balls. The gap should be as narrow as possible.
2. Provide a two-or-three turn choke coil in the RF feed from the antenna coupling unit (ACU) to the tower if one is not already installed. The coil can be from 5 to 10 inches in diameter depending on the station power level and the feedline size. Its function is to present a high impedance to lightning strikes so they will jump the ball gap rather than enter the ACU. Readjustment of the output arm of the matching network will be required to offset the added inductance of the lightning choke.
3. Provide a horn-type lightning gap within the ACU similar to the design shown in Fig. 1. The relatively clean, dry, and insect-free environment inside the ACU permits a tighter gap setting and increased lightning protection than can be accomplished with an exterior gap. The path for lightning currents from the tower to the gap within the ACU should be very direct with minimum inductance and no sharp bends. Similar lightning gaps also can be installed at both ends of all transmission lines to help prevent lightning currents from getting into the phasor.
4. Adjust each gap individually by reducing the spacing until it arcs on the heaviest modulation peaks. The spacing should then be doubled for the permanent adjustment. This will be a much smaller gap spacing than is usually encountered on external gaps at the tower base.
5. Check to see that there is a DC path from each tower to ground, either through a phase sampling isolation coil, a separate static drain coil or resistor,

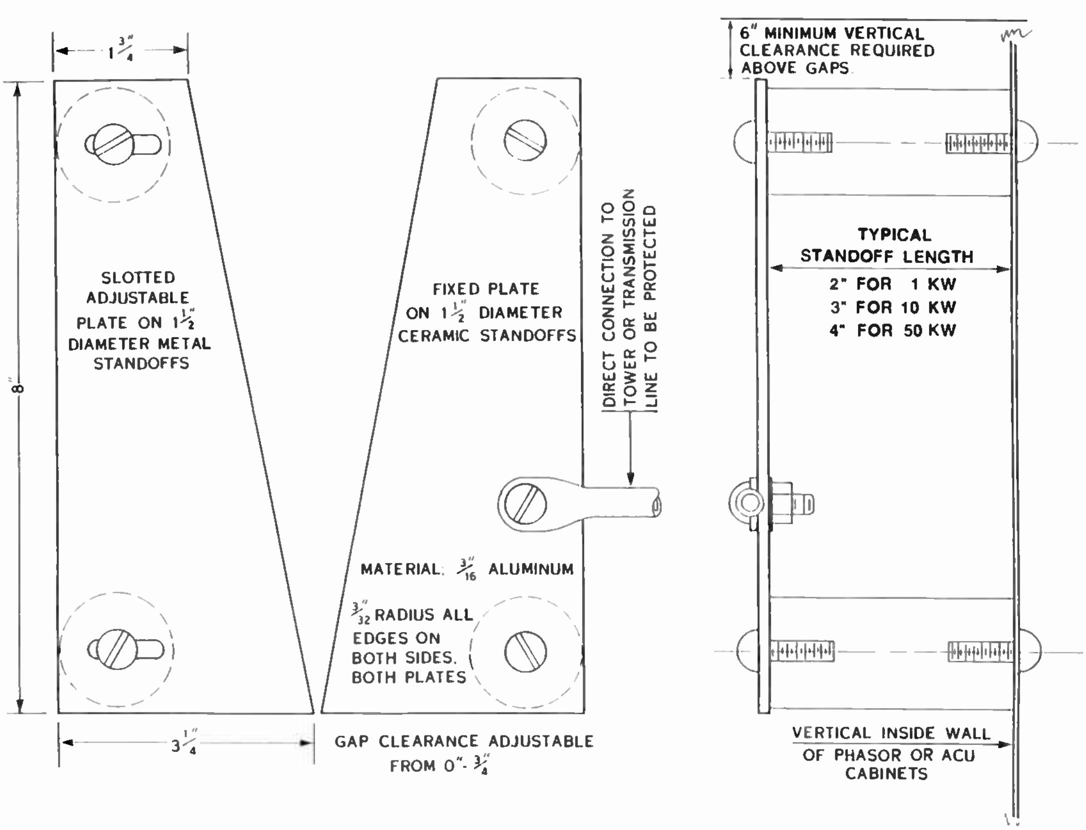

Figure 1. Suggested lightning gap design.

a spare winding on a tower lightning choke, or the network circuitry within the ACU itself. Without a static drain, static charges may build up on a tower and then discharge with a small arc that may be sufficient to trip protective circuits and take the transmitter off the air.

ENVIRONMENTAL CHANGES

The ideal environment for a directional antenna system is a flat plane of high conductivity with no tall structures in the general vicinity, such as buildings, power line towers, water tanks, or oil wells. Such structures (or any metallic objects of substantial vertical dimension) will have currents induced in them. These currents are dependent upon the size and shape of the structure, the frequency, and the ambient field strength with which they are illuminated. The currents in such objects make them parasitic antennas. The resulting reradiation can severely distort the pattern of a directional antenna array.

Reradiating objects located in the main lobe of an antenna pattern are of greater consequence than those located in or near pattern minimums where their illumination is substantially less. The reradiation from reasonably slim and electrically short objects (where the overall height is substantially less than a quarter wavelength) can be calculated with useful accuracy by means of the approximate formula shown in Fig. 2.

If feasible, a more accurate assessment of the reradiation can be obtained by measuring the RF current flowing in the reradiating object. If the object is reasonably thin (such as a guyed communications tower, a cable television headend tower, or the four individual legs of self-supporting power line towers) measurement of the current flowing from the tower to ground is not difficult. For this measurement, a toroidal pickup coil formed by the spiral steel wire in a length of clothes-dryer exhaust hose (or even better, some types of vacuum-cleaner hose) is useful. The hose section should be long enough to encircle the tower or current-carrying conductor to be measured and to have its ends attached to a field strength meter operating as

$$\left|E_r\right| = \frac{\left|E_i\right| \left[\dfrac{\cos(1.2\,hf) - 1}{\cos(1.2\,hf)}\right] h}{2000\left[\left(\ln \dfrac{2h}{a}\right) - 1\right]}$$

Where: E_r = Reradiated field in mV/m at 1 km
E_i = Incident field in mV/m at location of reradiator
h = height of reradiator in meters
a = effective radius of reradiator in meters
f = frequency in MHz
ln = natural logarithm
cos = cosine of angle in degrees

Figure 2. Formula for estimating reradiation from electrically short reradiators.

a linear voltmeter. Such a pickup coil can be calibrated by encircling a conductor carrying a known current, such as the feed, to the base of a radio tower.

It is not necessary to measure the current distribution throughout the height of electrically short objects. The current distribution can be assumed to be triangular, decreasing to zero at the top of the tower if it is freestanding; or the current can be assumed to be uniform throughout the entire height of the tower as a worst-case assumption where powerline towers exhibit heavy toploading due to the capacitance to ground of the conductors they support. Once the current is measured, the reradiation can be calculated by relating the "ampere-feet" of current in the reradiator to that in a quarter-wave tower at the same frequency. For example, a quarter-wave tower at 1000 kHz is 246 feet high, has a base resistance of approximately 50 ohms, and a base current of about 4.5 amperes for one kilowatt. With sinusoidal current distribution on the tower, the average current throughout its height would be 64% of the base current or about 2.9 amperes. Thus, at 1000 kHz about 700 ampere-feet of current would produce about 190 millivolts per meter of radiation at one mile or 300 millivolts per meter at one kilometer. This corresponds to radiation (or reradiation) in the order of 0.5 millivolt per meter at one kilometer for each ampere-foot of current in the reradiator. This rule-of-thumb as to the resulting reradiation from short towers is proportional to frequency when applied to channels removed from 1000 kHz.

The techniques for detuning reradiating objects are the same as those described in the previous chapter for detuning unused towers within a two-pattern directional array.

RADIATION HAZARDS

In 1986 the FCC promulgated rules limiting human exposure to radio frequency fields at all AM, FM, and TV broadcast sites. This subject is covered in detail in Chapter 2.9 of this volume. At AM broadcast frequencies, the potential for human exposure in excess of the radiation limits exists only in the immediate vicinity of radio tower bases and in the vicinity of phasors and antenna coupling units that are not in fully-enclosed cabinets. Phasors and ACUs employing open panel construction can exceed exposure limits at distances up to about five feet depending upon the station power level. Metallic fences surrounding each tower base form excellent shields at AM broadcast frequencies and greatly reduce the area exceeding exposure limits when compared to unprotected towers or towers within wooden fences. One neat arrangement, when weatherproof ACUs are employed, is to mount them so that their locked front door is in the plane of the fence surrounding the tower and is accessible without entering the fenced enclosure.

Compliance with radiation hazard limits effectively prevents maintenance or painting of a tower while it is in use. Therefore it is now highly desirable to provide for nondirectional operation on either of two towers so that every tower can be de-energized in turn when required for maintenance without taking the station completely off the air.

READJUSTING AN ARRAY

Any readjustment of a directional antenna array should be undertaken only by personnel who have a basic understanding of directional antenna theory and practice. At the minimum, the material in the preceding two chapters should be read and understood. Before any array adjustments are attempted, considerable information needs to be collected and analyzed.

Four conditions for proper array performance are explained below. All of these conditions should be met simultaneously in normal operation.

1. The antenna monitor indications should agree with the station license within the FCC tolerances of five percent for tower current ratios and three degrees for phase. A special case is a "critical" array which has been assigned tighter tolerances by the FCC.
2. Changes in base current ratios should be consistent with changes in antenna monitor ratios. Although the base current ratios and antenna monitor ratios are rarely in exact agreement (and will differ greatly in arrays with unequal height towers), these ratios should change by essentially the same percentage for small changes in the actual base current ratios. In other words, when the monitor indications match those shown in the license or the most recent proof, the base current ratios should also match what is shown in the same license or proof. Discrepancies are an indication of changes in the sampling system or in the base current metering and should be investigated.
3. The reradiation environment must be essentially unchanged from that in which the array was last in proper adjustment. Any substantial structures such as powerline towers or steel-frame buildings constructed recently in the vicinity of the array, particularly in the main lobe of the pattern, can cause trouble. Grounded structures approaching a quarter-wave high can distort critical antenna patterns even if located one or two miles away in the main lobe of radiation.
4. The monitoring points should be within the limits shown on the station license. A high monitoring point may result from a changed environment due to the construction of buildings or powerlines near the monitoring point. If a high monitoring point does not correlate with observed changes in antenna monitor parameters, the point is suspect and should be checked by measuring and analyzing ten or more of the other points on the same radial that had been measured and recorded in the most recent proof or partial proof. Readjustment to reduce excessive radiation is indicated only if the analysis of ten or more points confirms that the radiation in that direction is in fact in excess of the standard pattern limit.

Soil Conductivity

The analysis of a radial may be misleading due to changes in soil conductivity. Increased soil conductivity during wet seasons may cause substantial increases in signal strength at distant measuring points when compared to the same measurements during dry seasons. This phenomenon varies with distance, with season, and with differing geographical regions. These effects may not exist in some regions, but in extreme cases may show 2:1 changes in field strength at a distance of 20 miles. When analyzing field measurements, soil conductivity variations can be eliminated by comparing the present ratio of directional to nondirectional field strength at each measurement point to the same ratio in previous complete or partial proofs.

Because new nondirectional measurements may be needed at a future date, it is important to incorporate in the phasing system a switching capability to permit reversion to nondirectional operation at those stations which do not normally have a licensed nondirectional mode.

READJUSTMENT DATA AND ANALYSIS

Directional antenna arrays vary so much in pattern shape, suppression requirements, and phasor circuitry that precise readjustment instructions cannot be described. If possible, the consulting engineer who adjusted the array before its last proof of performance should be consulted on the problem. The following guidelines should prove helpful:

1. Carefully log all dial settings and all coil tap locations before making any changes.
2. Keep in mind what parameter you are trying to change before twisting any knobs or changing any coil taps.
3. Make changes only in small increments, typically never more than about one degree or one percent in phase or ratio.
4. Keep a step-by-step record of each change as it is made so that the array can be restored to intermediate or initial conditions, if necessary.
5. Remember that even small adjustments of phase or ratio can have a measurable effect on the common-point resistance. The power fed to the antenna system is only correct if the common-point resistance and current are essentially correct. A permanently installed common-point operating impedance bridge is a convenience not only for keeping track of the common-point impedance during adjustments but also for continuing confirmation of the licensed common-point value in day-to-day operation.
6. Construct vector diagrams for each important direction. Samples of such diagrams are shown in Fig. 3. The phase relationships must include both the electrical phase of the currents fed to the

towers and the space phase component for each tower relative to the reference tower as viewed from each direction. Such diagrams will assist in visualizing what effect any contemplated changes in phase or ratio for any tower will have on the resultant field in each direction. The vector diagram amplitudes may be in terms of the individual tower field ratios (such as in Fig. 3) or in terms of the theoretical unattenuated radiation. The theoretical unattenuated radiation from each tower (expressed in millivolts-per-meter at one kilometer or one mile) is obtained by multiplying the theoretical pattern field ratio for each tower by the pattern constant K, which is also usually shown in each theoretical pattern.

7. If the pattern includes essentially zero minimums (which need to be as deep as possible), make talkdown adjustments at a series of the most distant points on the null radial from which adequate two-way communications can be obtained. At each talkdown location, adjust the phasor for any combination of tower currents and phases that gives the deepest possible minimum. (A deep minimum can usually be confirmed by rotating the field strength meter 90% on a vertical axis and noting that the signal received from scattered reradiators is stronger than that received from the station when the meter is in its normal measurement orientation.)

Construct the vector resultant for each talkdown on a vector diagram similar to that shown in Fig. 3, but use the antenna monitor indications of phase and ratio instead of the theoretical parameters. The vector resultant will probably not be zero because of errors in the antenna monitoring system, nonsinusoidal current distribution on the towers, and reradiation from objects external to the array. However, the resultants so plotted from a series of talkdowns along a radial will enclose an area in which the optimum adjustment has its vector resultant at its center. Knowing the desired resultant for each critical radial direction, one may then be able to infer a set of phase and ratio parameters to satisfy conditions in all directions simultaneously.

For simple arrays, a pragmatic approach that often yields effective results, is to station observers with field strength meters at each of the several monitoring points or in other critical directions. By using a two-way radio to learn the effect on field strength, cut-and-try adjustments of the phasor can yield a set of phase and ratio parameters that satisfy all conditions simultaneously.

Following readjustment, if any of the new phase and ratio parameters exceed the three degree phase and five percent ratio tolerances permitted by the FCC when applied to the parameters shown on the current station license, a partial proof-of-performance will be required before the FCC will license the new parameters. If the new parameters are within tolerance of the licensed values, a partial proof and application for changed parameters may still be desirable in order to avoid long-term operation uncomfortably close to the tolerance limits.

2.6 Antennas For FM Broadcasting

Peter K. Onnigian, P.E.
Consulting Antenna Engineer, Sacramento, California

Additional material provided by:
Eric Dye
Jampro Antennas, Sacramento, California

INTRODUCTION

This chapter is dedicated to broadcast engineers, technicians, and station managers who must make important decisions regarding FM transmitting antennas. To insure the best possible signal strength in the station's service areas, the site location, antenna height, antenna type, and propagation conditions must all be considered.

FM broadcasting was first authorized in the United States in 1940 by the Federal Communications Commission (FCC). The first FM station began operation in 1941. In 1945 the FM service was assigned to the 88 to 108 MHz band and divided into 100 channels, each 200 kHz wide. In 1991 there were over 5,400 commercial and 1,700 educational FM stations.

Most FM antennas are nonsymmetrical, that is they are mounted on one side of a steel supporting tower or pole. FM antennas outside the western hemisphere on the other hand are usually symmetrical, that is installed on all faces of a tower. However, both methods are capable of providing excellent omnidirectional azimuth patterns.

Antennas for FM broadcasting use horizontal polarization (H-pol), vertical polarization (V-pol), or circular polarization (CP).[1] Cross polarization is used as a means to prevent co-channel interference in some European countries but not in the western hemisphere. CP, together with its special form, elliptical polarization (E-pol), was introduced in the United States in the early 1960s as a means to provide greater signal penetration into the many different forms of FM receiving antennas, which are now found in the service area. H-pol is the standard in the United States. CP or E-pol may be used if desired. V-pol only is permitted for noncommercial FM stations seeking to limit interference to TV channel 6.

In the 10 year period between 1980 and 1990 there were over 300 million radios sold in the United States, of which over 140 million were automobile AM/FM radios.[2] FM radio receivers use a variety of antennas including extendable monopoles (whips), dipoles, and capacitive coupling to power lines and headphone leads.

Antennas for FM broadcasting must be chosen carefully in order to cover the service areas properly with adequate level and quality signals. For economic and technical reasons, the desired effective radiated power (ERP) should be produced with a balance between antenna gain and transmitter power. It is the purpose of this chapter to provide sufficient technical information for the broadcaster to achieve this.

The height of the antenna over the service area, distances to areas of population, the ERP, and the economics are items that must be considered.

Antennas currently available in the United States differ considerably from those to be found in Europe. The various American types are discussed so that the engineer will be informed on the subject. Considerable advances have been made in recent years in the design and fabrication of FM antennas. These improvements provide greater penetration of signals into automobile FM radios as well as popular small FM transistor radios of all kinds.[3] The newer FM broadcasting antennas must meet the more stringent requirements for FM stereo and subcarrier broadcasting. Most FM stations in the United States are using CP antennas.

PROPAGATION

FM broadcasting has some distinct advantages over AM (medium wave) broadcast service. These advantages stem from the propagation characteristics of FM frequencies as well as the modulation system.

There is essentially no difference between day and night FM propagation conditions. FM stations have relatively uniform day and night service areas. FM propagation loss includes everything that can happen to the energy radiated from the transmitting antenna during its journey to the receiving antennas. It includes the free space path attenuation of the wave and such factors as refraction, reflection, depolarization, diffraction, absorption, scattering, Fresnel zone clearances, grazing, and Brewster angle problems.

Propagation is dependent upon all these properties out to approximately 40 miles (65 km). Some additional factors enter the picture at greater distances. Radio wave propagation is further complicated because some of these propagation variables are functions of frequency, polarization, or both, and many have location and time variations.

The technical intent of the broadcaster is to put a signal into FM receivers of sufficient strength to overcome noise and to provide at least 20 dB carrier-to-noise ratio, which will provide at least 30 dB of stereo separation. The required RF signal level varies from about 2 μV/m (microvolt per meter) for high sensitivity FM stereo tuners in the suburbs to about 500 μV/m for less sensitive transistorized portables. Automobile receivers have wide ranged sensitivity values.

FM antenna manufacturers do not guarantee coverage. They supply antennas which meet certain radiation pattern requirements and gain. Many of the antennas assume an omnidirectional pattern. Although reasonable in free space, it is never fully achieved in practice due to sources of distortion (support structure, feed lines, etc.)

Some manufacturers in the United States provide azimuth pattern adjustment service to insure a horizontal plane pattern circularity of ± 3 dB when mounted on the side of a specific tower or pole. It must be pointed out that this radiation pattern and gain are for free-space conditions and may not relate directly to signal strengths measured at or near ground level, well away from the antenna.

Radiation pattern and propagation are two distinctly separate conditions. The pattern is the radiation which is transmitted by a given antenna in any given direction, without any propagation limitations, as measured on a good antenna test range. Propagation depends on path and environmental conditions existing between the transmitting antenna and the receivers.

The actual service area signal strength contours are based upon two probability factors. Contours are not solid signal areas. For example, the FCC signal coverage charts referred to as the F(50/50) curves, are based upon a probability of occurrence of certain voltage levels at 50% of the locations, 50% of the time. This means that at any given location, 30 ft above ground, the signal has a 50% chance to measure up to the predicted contour level. Furthermore, half the time at that location, it may reach or exceed the level predicted while at other times it may be lower in strength.

These FCC charts (FCC Rules, Section 73.333) are based upon the assumption that average propagation conditions exist. One or more of the conditions mentioned in the second paragraph under this heading may reduce the measured signal strength from the predicted values substantially.

Propagation Loss

The power radiated from a FM transmitting station is spread over a relatively large area, somewhat like an outdoor, bare light bulb on top of a tall pole. The power reaching the receiving antenna is a very small percentage of the total radiated power.

At 100 MHz and a distance of 30 miles (48 km) the figures indicate the free-space path loss to be 106 dB.[4] The formula used to compute free-space loss is:

$$FSL = 36.6 + 20 \log D(\text{miles}) + 20 \log F(\text{MHz})$$

Doubling the distance increases the space loss by 6 dB. The path loss does not attenuate the signal with distance as much as some other factors. Path loss between an earth station and a satellite is a classic text book example of a 6 dB loss every time the distance is doubled. But a typical FM station signal travels through a nearly perfect dielectric (air) and over the imperfect earth's surface (ground). Herein lies the FM radio propagation loss problem.

Refraction, diffraction, and reflection from scores of objects such as hills and buildings may occur in the propagation path between the transmitting and the receiving antennas. These, along with absorption, scattering, lack of Fresnel zone clearances, and other factors, all reduce the signal strengths.

Signal loss due to foliage has been well known to UHF TV broadcasters for many years.[5] This same condition exists to a lesser degree for FM broadcasting. Trees, shrubs, and other foliage on hills or smooth terrain affect the reflected as well as the lateral signal loss with distance. With average values of permittivity and conductivity in both foliage and ground, a loss of about 2.5 dB was found to exist in a ten-mile path, at FM frequencies.[6] The height gain factor is increased with heights above the foliage.

Considerable depolarization takes place because the transmission through or reflections from ground foliage is a diffracted field contribution.

Multipath Problems

The ideal reception condition is a strong direct single source signal. When energy from two or more paths reaches the receiver, (due to reflections) a condition called multipath reception occurs. Poor reception is experienced when there is insufficient strength difference between the direct and the reflected signals, because they can cancel each other where the geometry places them out of phase.

Nothing is more important in the way of broadcasting facilities than the location of the transmitting antenna. Great care must be exercised to find a suitable site. Poor selection of the transmitter point can result in very unfavorable signal propagation and negate the entire project. One very serious result of poor site selection is multipath propagation in some directions.

As an example, the transmitter should not be located so that strong reflections take place from nearby hills or mountains. This can happen when the transmitter is placed on one side of a large city and the other side of the city has a high mountain range. Radiation into the city directly from the transmitting antenna, as well as reflections from the nearby hills and mountains will create two or more signal paths to many receivers. These reflections can be so strong that only a 10 dB difference may exist between the direct and the reflected condition which causes severe multipath problems.

A TV station at this same location would experience unusable signals due to heavy ghosting, even with directional receiving antennas, which exhibit moderate signal pickup from their back. This is illustrated in Fig. 1 where a mountain range causes reflections back into a large city.

The multipath example shown in the sketch was an actual case. The site was chosen by the FM broadcaster, without proper engineering guidance, simply because the hill had a tower, building, power, and a road was in place. Later, the broadcaster learned why the original owner, a television station, had abandoned the site: the TV station had failed in part due to extremely heavy ghosting into the principal city.

A much better FM transmitting site was located on the hills between the high mountain range and the city. Using a directional transmitting antenna with very little radiation towards the high mountains, reflections were satisfactorily reduced, and the FM station is now operating successfully.

Multipath reflections are very easy to identify. On an automobile radio, the signal will drop out, sometimes abruptly, as the car moves. This effect may be rhythmic with distance while traveling slowly. It is sometimes called picketing as it acts like a picket fence alternately blocking and letting the signal pass. A field strength meter will usually reveal great variations of signal when moving, say, 100 ft (30 m) in a line with the transmitter. Cyclic variations over quite uniformly spaced intervals on the ground as great as 40 dB have been observed by the author.

This variation in signal levels is caused by the reflections adding and subtracting from direct and reflected signals caused by propagation problems existing in the path between transmitter and receiver. It usually has nothing to do with the qualities of the transmitting antenna. It is a function of site selection. This should not be confused with a similar effect observed near the base of the tower supporting a high-gain antenna. Nulls produced by stacking bays for gain are found near the antenna and may be filled-in if needed. (See Beam Tilt and Null Fill in this chapter.)

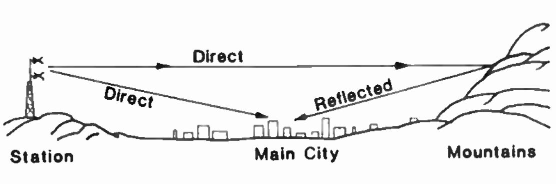

Figure 1. Example of poor station location causing severe multipath conditions due to delayed reflections from mountains on the right. Not to any scale.

Ground Reflections

In the elevation plane between transmitter and receiver, nearly all FM signal coverage lies between the horizon and 10° below. Called the *grazing angle*, it lies between the horizontal plane and the earth's surface. Generally the higher the transmitting antenna above the service area, the greater this angle will be.

The angle of incidence and reflection are not the same, as shown in Fig. 2. The depression angle and the grazing angle are not equal as would be the case for a flat earth. Reflections from these angles play an important part in the strength and the quality of the signal in FM broadcasting with circular polarization.

The ground which causes reflections at these grazing angles does not treat H-pol and V-pol in the same manner. The V-pol is attenuated considerably more than the H-pol as shown in Fig. 3. The phase of the V-pol changes substantially with angle, while H-pol remains nearly the same. At these useful low propagation angles, there is considerably less V-pol signal reflected than H-pol, when grazing takes place. Field measurements confirm this fact.[7] For this reason, it is impossible to measure accurately axial ratios in the service area. To be meaningful, the H-pol and V-pol ratios must be measured on a good antenna test range.

It is quite difficult to predict accurately the reflection coefficient (efficiency), which varies considerably as a function of polarization, frequency, grazing angle, surface roughness, soil type, moisture content, vegetation growth, weather and the season. There are complex formulas for predicting the ground conductivity at the frequency of interest. For 100 MHz, a value of 10 millimhos per meter ground conductivity is often used, with a permittivity of 25, as being about the average for the continental United States.[6]

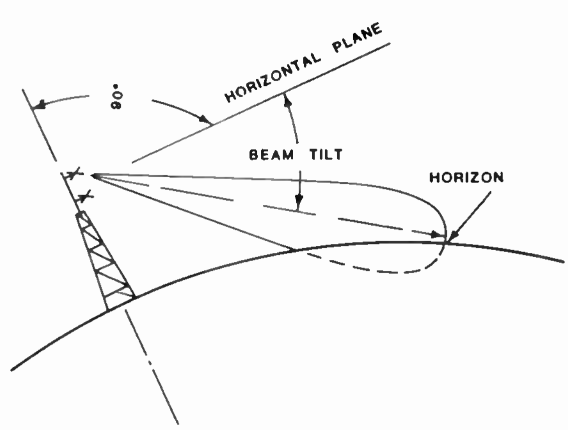

Figure 2. Beam tilt to radiate maximum ERP at the horizon. Not to any scale and exaggerated for illustration.

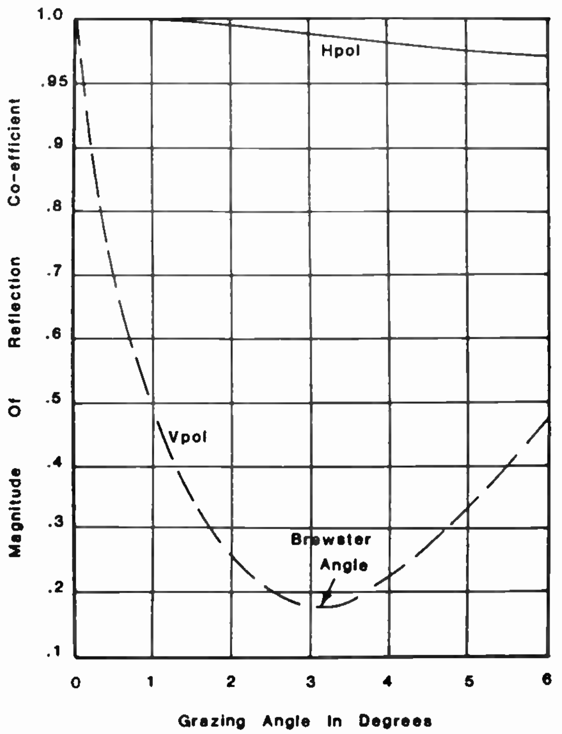

Figure 3. Magnitude of reflection coefficients showing differences for Hpol and Vpol, and the Brewster angle.

Brewster Angle

For polarization with the electric field normal to the plane of incidence, there is no angle that will yield an equality of impedances for earth materials with different dielectric constants but like permeabilities. An incident wave with both polarizations present will have some of the one polarization component but little of the other reflected. The reflected wave at this angle is thus plane polarized with the electric field normal to the plane of incidence, and the angle is the polarizing angle.

Notice that in Fig. 3 the minimum reflection coefficient occurs at a grazing angle of about 2°. Below this angle, the reflection coefficient rapidly increases to unity. The angle at which the minimum reflection coefficient occurs is called the Brewster or polarizing angle, after the Englishman who first discovered this phenomenon.

For ground reflections occurring near the Brewster angle, the reflection coefficient is much smaller for V-pol than the H-pol. Therefore, the reflected V-pol signal component of CP are attenuated considerably. The greatest attenuation for V-pol from ground reflection occurs at this angle.

Field measurement of V-pol signals will usually show a significant variability of H-pol to V-pol ratios due to this Brewster angle phenomenon. The Brewster angle is a function of soil conductivity and may change from place to place, as well as from season to season.[8]

It is important, then, that the antenna height above the service area results in grazing angles which are less than the Brewster angle. Otherwise the V-pol will be reduced and the radiation will be much more elliptical than circular in polarization.

Fresnel Zone Clearance

A much neglected consideration in FM transmitting antenna location and height is Fresnel zone radius clearance in the path to the service area. Microwave engineers always make certain that their signal paths have this important clearance.

The effect of clearance above ground or other obstacles was studied by August Jean Fresnel, a French scientist who first discovered this phenomenon in optics. Fresnel zones are circular areas surrounding the direct line-of-sight path of a radius such that the difference between the direct and the indirect path length to the zone perimeter is a multiple of half-wavelength longer than the direct path. This is illustrated in Fig. 4. The zone diameter varies with frequency and path length. The greater the path length, the larger the required mid-path clearance required for full signal.

Fresnel also discovered that the entire first zone radius is not required for full signal strength. Six-tenths of the first zone would suffice, which is fortunate since the radius is quite large at the FM frequencies. The equation for determining the first Fresnel zone radius for 4/3rd earth curvature is:

$$R = 1140\sqrt{d/f}$$

where d is the path length in miles, f is in MHz and R is in feet for the first radius.

In Table 1 the required 0.6 first Fresnel zone radii clearances at the middle of the path are shown for 98 MHz and service areas up to 52 miles (92 km) from the transmitter. The idea is to raise the height of the transmitting antenna so that the mid-path height is as high as or higher than shown in the table. Due to the geometry of the Fresnel zone, if the terrain is relatively flat, the mid-path radius will control and be larger than that required elsewhere along the path. If the mid-path clearance is less than the values shown, the FM signal will be attenuated in accordance with the curve shown in Fig. 5, presuming ideal reflection off the ground or obstructions.

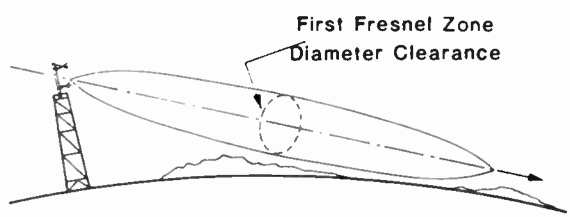

Figure 4. First Fresnel zone clearance occurs as shown above, but only six-tenths is required for full free space signal level. Not to any scale.

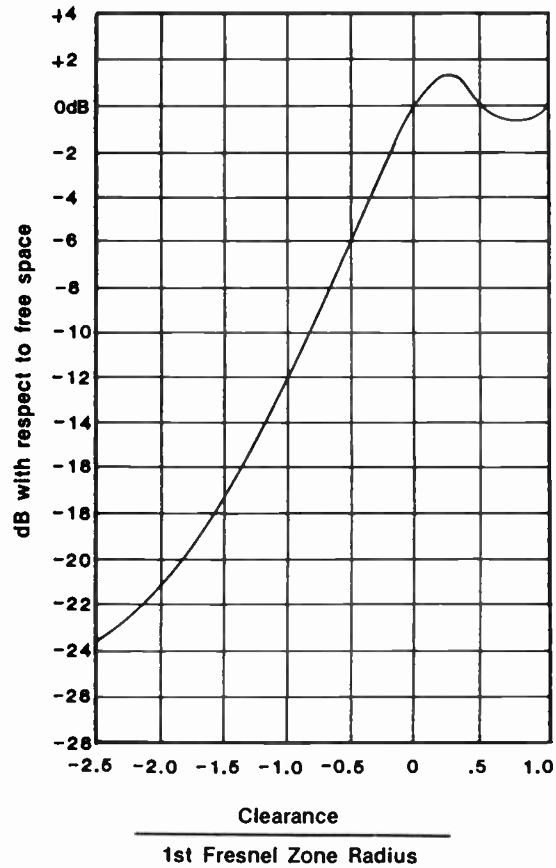

Figure 5. Attenuation of FM propagation when the path between transmitter and receiver lacks Fresnel zone clearance in the ratios shown.

The center-of-radiation heights of the antennas in Table 1 are actual and not height above average terrain (HAAT). Some of these recommended heights will reduce the allowable effective radiated power (ERP) in accordance with FCC 73.211 (b), depending on the class of station and the zone. However, it is better to have the Fresnel clearance than the maximum low height ERP values, as the higher heights will produce stronger signals.

It is a well known propagation axiom that greater heights are more useful in producing higher signal strengths far from the antenna than ERP levels, everything else being equal.

Without the first Fresnel clearance of 60% the signal level at the distant point may suffer. This reduction will follow the curve shown in Fig. 5 for different values of clearance and worst case reflection conditions.

In order for the FCC prediction curves to be valid, the recommended minimum antenna heights should be achieved. These heights not only provide line-of-sight conditions to the service limits but also proper Fresnel clearances. Both conditions are required for the FCC F(50,50) curves to be valid.

The values in Table 1 are for relatively flat terrain, but take into consideration the FCC suggested roughness factor of up to ±150 ft (50 m). Where the tower height is limited by HAAT values or other limitations, the signal strength will suffer due to those factors.

Soil Conductivity

The conductivity and permittivity of the soil, together with the vegetation on it, play a small part in the attenuation of FM signal strength. Average soil has a dielectric constant of about 15 millisiemens per meter at 100 MHz.[9]

TABLE 1

Recommended minimum antenna heights (for flat terrain and 98 MHz).

Service Area Radius Required		Fresnel Zone Six-tenths Clearance		Recommended Min. Antenna Height		Probable FCC 80-90 Class
Miles	Km	Feet	Meters	Feet	Meters	
5	8	155	47	310	95	A
7½	12	189	58	378	115	A
10	16	218	66	426	130	A
15	24	267	81	534	167	A,B,C-2
20	32	309	94	618	188	B-1,C-2
25	40	346	105	700	213	B-1
30	48	378	115	756	230	B
35	56	409	125	818	250	B
40	64	437	133	875	267	C-1
45	72	463	141	925	282	C-1
50	80	488	149	975	297	C-1
57	92	522	159	1,043	318	C,C-1

Linear Height Gain Effect

By raising the receiving antenna above the immediate effects of the soil, the signal level will be increased. Actual field measurements have proven a 9 dB increase in signal when the dipole was raised from 3.28 ft (1 m) to a level of 30 ft (9.1 m). This is due to reflection phenomena in the foreground of the receiver, not ground conductivity.

FCC Service Contours

From the FCC coverage prediction charts, it is possible to draw contours of the various grades of service for a given ERP and antenna height above average terrain. These predictions, at 50% of the locations, 50% of the time, constitute the basis for the service contours. The city grade contour is 70 dBμ (3.16 millivolts per meter) and primary service contour is 60 dBμ (1.0 millivolts per meter).

The FCC Rules, Section 73.333 charts for these predictions have a built-in terrain roughness factor, as explained above.

GENERAL COVERAGE STANDARDS

There are certain height and power levels fixed by the FCC for various classes of stations. The United States has been divided into three different geographical areas based on population density as well as propagation refractive index levels. These ERP and height values have been set to prevent co-channel and adjacent channel interference.

Zone I, generally speaking, is the northeastern part of the United States. Zone I-A includes Puerto Rico, Virgin Islands, and that portion of California lying below the 40th parallel. Zone II includes Alaska, Hawaii, and the remainder of the United States not in the above two zones. This is more fully described in FCC Rules Section 73.205.

Under Rules which resulted from Docket 80–90: "Modification of FM Broadcast Station Rules to Increase the Availability of Commercial FM Broadcast Assignments," in 1983, new ERP levels and additional classes of stations were created. The distance to the 60 dBu (1 mV/m) signal contour is the controlling factor so that the ERP based on the HAAT is adjusted to produce that level and no more at a specific distance for a particular class station.

Table 2 shows for each FM class station, the zone, the maximum ERP, the maximum HAAT, and the distance to the 60 dBu contour calculated by using the maximum ERP and HAAT, and then rounding to the nearest kilometer and mile. The FCC issued these in that docket and they are currently the standards.

Under the Rules, Class C stations are required to have at least 100 kW ERP and an antenna height of more than 984 ft (300 m) above average terrain. Class C-1 stations are now permitted a maximum of 100 kW ERP with an antenna maximum HAAT of 984 (300 m), while C-2 stations may go to 50 kW at a maximum HAAT of 492 ft (150 m). Higher HAAT may be used with reduced ERP values, in accordance with equivalent 60 dBu coverage. Class C and C-1 stations may thus share the same antenna and tower.

Stations may be upgraded using the easiest method, which is to increase existing location tower height. Such factors as local zoning laws and aircraft flight patterns may preclude this approach, however.

FM Signal Measurements

The signal strength received at 5 ft (1.5 m) above ground, which is about average for auto whip antennas, is several times lower in level than at the standard FCC measurement height of 30 ft (9.1 m). This fact should be taken into consideration when comparing low height measurements with the FCC Rules Section 73.333 prediction charts, which are based on a 30 ft receiving height, where signals are considerably stronger.[10]

Signal levels inside houses, apartments, offices, and other structures vary greatly. Levels depend on the type of building construction, but in nearly all cases will be lower than those outdoors. Reflections inside the building reduce stereo separation, and cause cross-talk problems with SCA channels. Outside FM receiving antennas generally provide good reception.

Field strength measurements should not be used to determine the transmitting antenna radiation pattern or efficiency except under carefully controlled conditions.

TABLE 2

Docket 80-90 FM station classes, zones, and ERP.

FM CLASS	ZONE	MAX. ERP In kW	MAXIMUM HAAT Feet	Meters	DISTANCE TO 60 dBu Miles	km
A	I, I-A	3	328	100	15	24
B	I, I-A	50	492	150	32	52
B-1	I, I-A	25	328	100	24	39
C	II	100	1,969	600	57	92
C-1	II	100	984	300	45	72
C-2	II	50	492	150	32	52

The propagation factors discussed previously camouflage the true antenna performance. The only technically acceptable way to determine the antenna's characteristics is on an antenna test range.

Elsewhere in the *Handbook* is an entire chapter dealing with the recommended methods and equipment to make FM and TV field strength measurements. This information may be used to determine the actual quality of service and the areas where useable signal levels in fact exist. Predicted contours may be considerably different from actual measured values.

Required Signal Strength

What is the minimum satisfactory signal strength? What is the maximum above which it is wasteful? The history of FCC proceedings provides some of the following levels:

34 dBu = 0.05 mV/m For rural areas
60 dBu = 1.00 mV/m Suburban areas
70 dBu = 3.16 mV/m Principal community
82 dBu = 12.64 mV/m Highest useful level

The first three levels were set by the FCC in the early 1950s when tube receivers and H-pol antennas were popular. Modern day transistor radios have much greater sensitivity. CP has added greater signal penetrating power than H-pol when the levels were first established.

The FCC defines two grades of signal contours on its applications. The first is based on the 70 dBu contour (3.16 mV/m) required to cover the principal community of license. The second is the 60 dBu contour (1 mV/m) which defines the primary service area.

The FCC also stated that, in rural areas, levels as low as 50 microvolts-per-meter were useful. Indeed current home stereo tuners and FM auto radios operate very well with only 25 microvolts-per-meter. In practice, 50 microvolts-per-meter (0.05 mV/m) provides good quieting in nearly all automobile and transistor radios receiving a stereo signal from a CP station antenna. Therefore 50 microvolts-per-meter should be considered the minimum useful signal level.

If the highest level of 3.16 mV/m is quadrupled, it will be 12.64 mV/m. This is a 12 dB increase, equal to increasing the FCC power level by more than 15 times. It can be safely said that this level of 12.64 mV/m is considerably more signal than necessary by any present day working FM radio. Any signal level higher than this at the receiving antenna has not proven to be of significant value.

Blanketing

Excessive RF signals can overload the front end of receivers and make satisfactory reception impossible. The FCC in Section 73.318 defines the 115 dBu (562 mV/m) level as the "blanketing contour," and adopted the free-space prediction method to predict how far this contour extends.

New or modified FM stations have the responsibility to satisfy all complaints at no cost to the complainant, of blanketing-related interference inside this contour within one year of commencement of operations.

The distance to the 115 dBu contour is determined using the following equation:

$$d \text{ (in kilometers)} = 0.394\sqrt{P}$$
$$D \text{ (in miles)} = 0.245\sqrt{P}$$

where P is the maximum effective radiated power (ERP), measured in kilowatts of the maximum radiated lobe, irrespective of vertical directivity. For directional antennas, the horizontal directivity shall be used.

ANTENNA CHARACTERISTICS

Antenna Gain

Gain can be increased by adding additional radiating elements (bays) to the antenna at the cost of narrowing the radiated beam. High-gain antennas concentrate the energy into such a narrow beam that often null fill must be employed to achieve the desired signal strength within the first few miles to the tower.

Directional antennas achieve increased gain over nondirectional antennas by limiting the radiated energy in various directions. Directional antennas are useful when the tower is located near a large body of water, mountain range, or other areas where energy radiated in those directions is otherwise wasted. They are also employed to avoid interference where stations are insufficient distances apart.

Antenna gain is expressed in power ratio or in dB. For example, an antenna with a power gain of 2 is also said to have a gain of 3.0 dB.

FCC Rules, Section 73.310(a) defines antenna gain as the inverse of the square of the root mean square value of the free-space field strength produced at one mile in the horizontal plane, in millivolts per meter for 1 kW antenna input power to 137.6 mV/m. (In metric units, 1 km and 221.4 mV/m).

Notice that this gain is in reference to a horizontally polarized half-wave dipole. For a CP antenna, the gain is half for the same input power.

A two-bay H-pol antenna has a power gain of approximately two. But a two-bay CP antenna in FCC terminology has a gain of about one because the other half of the power is V-pol and is not considered in the gain calculations. Only the horizontal polarization mode is used by the Commission. The vertically polarized energy must not exceed the H-pol (except for noncommercial, educational FM facilities attempting to minimize interference to TV channel 6 reception).

The power gain of an antenna is used with the transmitter gain and transmission line loss when determining the Effective Radiated Power (ERP). Consider for example a 10 kW transmitter and an antenna power gain of 5. Neglecting transmission line loss, the ERP is 10 kW × 5 = 50 kW ERP. If the antenna gain were 10 and the transmitter power was 5 kW, we would have the same ERP of 50 kW. (5 kW × 10 = 50 kW ERP)

Effective Radiated Power (ERP)

The FCC defines the term *effective radiated power* to mean the product of the antenna input power (transmitter output power less transmission line loss) times the antenna power gain. Where circular polarization is used, the term ERP is applied separately to the H-pol and V-pol of radiation. For allocation purposes, the ERP is the H-pol component of radiation only. The V-pol component power normally must not exceed the H-pol power.

Beam Tilt

FM broadcasting antennas are normally mounted on towers which are plumb, so the peak power beam in the elevation pattern is perpendicular to the tower axis. A standard FM antenna without any beam tilt radiates more than one half of the total radiated power above the horizon. All this power is lost.

The higher the antenna is above its average terrain, the larger the predicted coverage area. Since the earth is curved, the service horizon is bent lower than a perpendicular angle from the earth's surface. Thus the strongest portion of the signal is aimed above the horizon. It also follows that the higher the antenna above the terrain, the greater is the elevation angle down to the earth's horizon.

In order to strike the farthest service area from a high HAAT, the beam may need to be tilted down towards the earth. Electrical beam tilt lowers the beam angle equally in all azimuth headings and is chosen more frequently than mechanical tilting, which exhibits different effects in different directions. Choose enough tilt to position the center of the main beam on the furthest edge of the desired coverage area or just below the horizon, whichever is closer.

For low gain antennas (two to four bays), the main beam is very broad, and if the antenna height above average terrain (HAAT) is less than 500 ft there is little to be gained with beam tilt. On the other hand, beam tilt makes a large difference on high-gain antennas mounted on towers with a large HAAT.

Fig. 6 shows the comparison between elevation angle path and coverage distance. It incorporates the curvature of the earth. This chart can be used to determine the optimum beam tilt. Follow the curve which is closest to actual HAAT, and mark the point where it intersects the horizon or crosses the distance of furthest desired coverage area (vertical axis). Read the beam tilt on the horizontal axis. Round this value up to the nearest ¼°.

Consulting engineers, familiar with this problem, can easily work out the required amount of beam tilt, if it is necessary. Typical values are one-half to one degree of tilt, depending on the antenna height, distance to the far service area, and the antenna elevation pattern.

Beam tilt is usually accomplished electrically, by delaying the currents to the lower bays, and advancing the phase of the upper bay currents during the design and construction of the antenna at the factory.

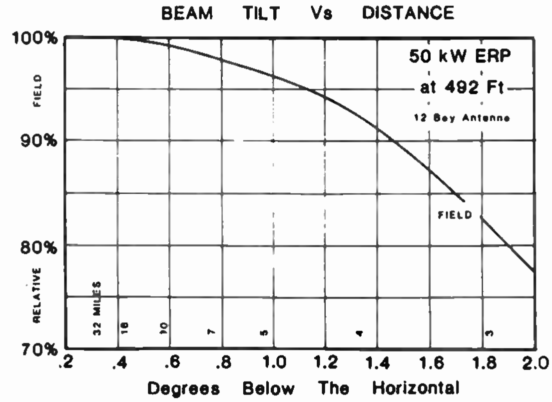

Figure 6. Twelve bay Cpol antenna with 0.3° beam tilt showing ERP distribution with coverage from 492 foot (150 m) tower over flat land. Degrees below the horizon are based on 4/3rd earths curvature. Horizon is −0.341° at 32 miles (52 km).

Null Fill

While the beam tilt puts more signal into the far reaches of the service area, it does not solve the problem sometimes caused by high-gain antennas within several miles of the transmitter. Elevation angle nulls common to all antennas with two or more bays appear farther and farther away from the antenna as its gain is increased with more bays.

When multiple bay arrays are employed, lobes and nulls occur in the elevation pattern. As the number of bays increases, the main beam narrows and the first null radius increases. The advantage of beam tilt and null fill varies depending on factors such as tower height, site elevation, number of bays, and relative locations of communities to be served.

A simple rule-of-thumb is that null fill is beneficial when there is desired service area within the radius of the first null. The equation below gives the approximate radius of the first null for multiple bay antennas.

$$\text{Null Radius (miles)} \cong \frac{H_{(ft)}}{\text{Number of Bays}/5280\ \text{ft/mi}}$$

where H is the height (ft) of antenna above radius ring.

In most FM applications, the null is very close to the antenna, thus a small amount of null fill (5–10%) takes care of the problem. Larger amounts of null fill are unnecessary and reduce the gain of the antenna. Note that null fill has no effect on distant coverage.

Refer to the "TV Antennas" Chapter 2.7 for information on null fill and beam tilt. The matter is essentially the same for FM and TV antenna systems.

VSWR Bandwidth

According to theory, the bandwidth of an FM signal is infinite if all the sidebands are taken into account. Also, at certain modulation indices, the carrier amplitude goes to zero and all the transmitted power is on frequencies (sidebands) other than the carrier frequency. Practical considerations in the transmitter and receiver circuitry make it necessary to restrict the RF bandwidth to less than infinity.

Prior to 1984 the maximum deviation for FM stations was 75 kHz, representing 100% modulation. In that year the FCC changed the maximum deviation to 82.5 kHz (110%) for those stations with 10% injection of subcarrier channels. This additional deviation requires greater antenna system bandwidth than previously needed.

System bandwidth is measured at the point in the antenna system where the transmitter is connected. This usually includes the harmonic filter, the main coaxial transmission line, and the antenna.

The significant sidebands are usually considered to be those whose amplitude exceeds one percent of the unmodulated carrier. With 110% modulation (82.5 kHz deviation) these side bands produce a bandwidth of 260 kHz.[11,12]

The VSWR bandwidth is the range over which the system under consideration has a reflection coefficient of less than five percent; a VSWR of 1.1:1.

Checking System VSWR

From time to time, the VSWR of the narrow-band antenna system should be checked and adjusted. If the exciter has thumb wheel exciter frequency adjustability in 10 kHz or 50 kHz steps, it can be used to change the frequency to check VSWR on different frequencies (with the transmitter operating at low power during the overnight experimental period). The reflectometer may be used as the indicator.

Alternately one of several methods for checking VSWR in coaxial line systems using test equipment may be used. These include a signal generator test setup, an impedance test set, or a network analyzer.

The VSWR should be measured to ensure that the reflection response is balanced to 130 kHz on each side of the carrier frequency. With transmission lines longer than 300 ft (100 m) it is suggested that the VSWR bandwidth be under 1.08:1 all the way out to ±130 kHz. The additional delay due to increasing line length becomes more of a problem, so the amplitude of the reflection must be reduced, for best operational results.

Importance of Low VSWR

The VSWR shown by the transmitter reflectometer does not increase or decrease the range of the signal. It has nothing to do with coverage. But VSWR values above 1.1:1 may decrease the final amplifier efficiency. Other definite negative effects of VSWR are increased intermodulation products and AM synchronous noise. Stereo separation is also degraded with increased VSWR.[13]

Intermodulation and SAM Distortion

Intermodulation distortion and synchronous AM (SAM) noise can be caused by narrow VSWR bandwidth in the antenna system, as well as by final amplifier circuitry all the way to and including the antenna.[14]

Synchronous AM (SAM) is extremely important in FM transmitter facilities employing subcarriers. SAM is AM modulation of the carrier caused by frequency modulation of the carrier frequency in the VSWR notch. At the notch the reflected energy is the lowest. As the deviation takes place, the greater the frequency swing, the greater will be the reflections, due to the VSWR notch. With a flat VSWR curve, SAM does not take place. If the VSWR curve is skewed, SAM will occur and intermod and stereo crosstalk will increase.

Directional Antennas

The FCC sometimes requires that the azimuth radiation pattern be directionalized to reduce normally allocated ERP towards a given short-spaced station, or for other reasons. See the FCC Rules Section 73.213, 215, and 316(b) and (c). To conform to these specifications, most broadcasters order antennas which are pattern adjusted, measured, and certified to the Commission's requirements.

Directional antennas are licensed for peak ERP values based on the azimuth pattern. The V-pol gain may not exceed the H-pol gain in a CP directional array nor may V-pol exceed the H-pol in the protection direction (except in the case of FM protection to TV Channel 6, mentioned elsewhere). The amplitude away from the null cannot climb more than 2 dB per 10° of azimuth.

Directional antennas are usually mounted on poles although some have been tower mounted. Since the support affects the pattern, they are specified and measured with the pole or tower on which they are mounted. Most firms will make the antenna meet the specific pattern requirements.

Directionalizing is a combination of the natural pattern resulting from sidemounting and the use of parasitic elements. Using the two factors, virtually any directional pattern can be produced.

Antenna gain is calculated differently for directional antennas. The azimuth directivity increases the gain value to correspond to the pattern. If all elements/bays are the same (the typical case), pattern multiplication can be used to determine gain. For linearly polarized antennas, the gain is simply the product of the azimuth directivity, the array factor, and the efficiency factor. The array factor is referenced to an ideal dipole. For directional CP antennas, the power distribution between polarizations must be taken into account.

$$\text{Antenna Gain (H-pol)} = g_H \times \text{array factor} \times \text{efficiency}$$

$$\text{V-pol} = g_V \times \text{array factor} \times \text{efficiency}$$

$$\text{where: } g_H = \frac{D_H \times D_V \times GA}{D_H + D_V \times GA}$$

$$g_V = g_H / GA$$

D_H and D_V are the directivities of the H-pol and V-pol azimuth patterns, while GA is the gain if the H-pol over the V-pol pattern.

Due to the gain of its azimuth patterns, directional antennas have gains which are typically 2 dB to 6 dB higher than their nondirectional counterparts of equal number of bays.

ANTENNA POLARIZATION

Horizontal and Vertical Polarization

Radio waves are composed of electric and magnetic fields at right angles to each other and to the direction of propagation. When the electric component (*E*) is horizontal, the wave is said to be horizontally polarized, as shown in Figs. 7B and 7D. Such a wave is radiated from a horizontal dipole. References are with respect to the earth plane. If the desired electric component is vertical as in Figs. 7A and 7E, a vertical dipole could be used to produce the vertically polarized wave.

Circular Polarization

When the two plane waves are equal in magnitude, and if one plane wave lags or leads the other by 90 electrical degrees, the field will rotate as shown in Fig. 7, at the speed of the carrier frequency and will be polarized circularly.

Only in the special case where the horizontal and vertical components are equal in strength with a 90° phase difference is the radiation said to be CP.

The direction of rotation shown by the vector arrows in Fig. 7 depends on the relative phase of the two components. Thus the polarization of the wave will appear to have either clockwise or counter-clockwise rotation, as shown. The FCC has set clockwise rotation as the technical standard, in order that similar sense of rotation antennas may be used for reception in the future.

Notice that in Fig. 7 the polarization rotates as the field propagates in time and space. Importantly, vertical and horizontal components are in quadrature phase. It is this rotation which enhances the signal penetrating qualities of CP, so useful in FM broadcasting.

The axial ratio as shown in Fig. 8 is that between the maximum and minimum voltage component at any orientation of the reference measuring test dipole which is placed perpendicular to the direction of propagation. An axial ratio of 1:1 (0 dB) is perfect. In

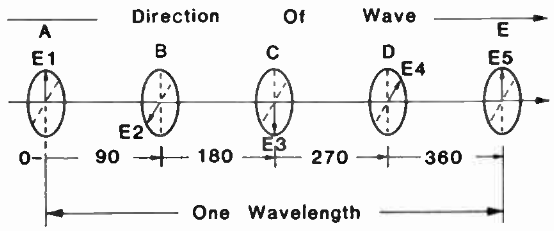

Figure 7. Circularly polarized wave propagation in one wavelength of travel, showing right hand rotation. Note vector rotation with wave travel.

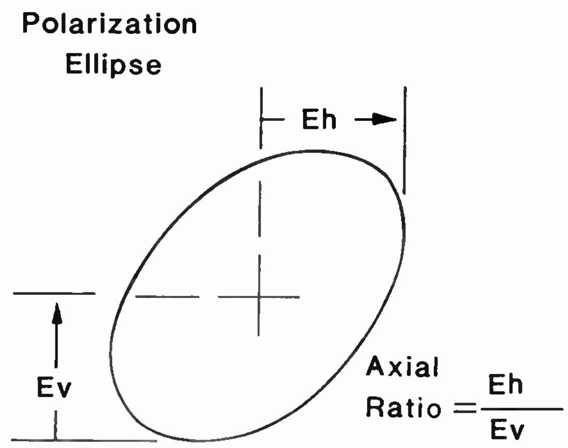

Figure 8. Axial ratio expressed in dB is the ratio of the larger polarized component divided by the smaller at any reference dipole orientation, where the maximum ratio occurs.

practice, axial ratios of 2 dB or better are considered to be excellent and commercially available. Axial ratios over 4.9 dB (1.75 to 1 voltage ratio) are considered to be elliptically polarized, a hybrid form and not as good in signal penetrating qualities as CP.

Since receiving antennas are linearly polarized, the introduction of CP does not increase the net power received since the vertical and horizontal components never occur during the same instant. Thus, CP does not necessarily mean an increase in coverage. However, the introduction of CP eliminates the requirement of the receiving antenna to have a specific polarization. Thus, CP allows more consistent coverage within the contour. Its rotating vector can penetrate areas where linear polarization is stopped, shadowed, or canceled due to out-of-phase reflections.

Summary

1. CP radiation does not increase the distance to the FCC contours.
2. Interference and allocation contours are not changed when switching from H-pol to CP.
3. The service contours are predictions based on the horizontal component of the CP radiation only.
4. The ERP from a CP station reaches it maximum H-pol power 90° *after* it reaches its V-pol peak.
5. H-pol and V-pol components do not add since they do not occur at the same instant, as shown in Fig. 7.

MATCHING COVERAGE AND ANTENNAS

Typical Class A Station Coverage

Table 3 shows the FCC predicted signal strengths for a typical Class A facility on a relatively flat plane, with the antenna center 328 ft (100 m) above average terrain (HAAT). A power of 3 kW is used. The first

24	38.6	.27	.55	.55
26	41.8	.27	.40	.40

two columns show the distances, with the farthest being the horizon from this height. The third column indicates the true earth angle from the antenna to the distances shown. From the elevation information, the ERP from each antenna was determined at each vertical angle. This ERP value was used to find the signal strength from the FCC F(50,50) FM prediction chart, FCC Rules Section 73.333, Fig. 1.

Under the signal level in millivolts-per-meter (mV/m) column, the predicted field strengths shown in this Table are based on the above procedure. From 5 miles (8 km) to the horizon, the signal strengths are identical. This is due to the shape of the antenna elevation pattern near the maximum.

Departure occurs as the depression angle to the receiver becomes larger. Beyond 4 miles (6.4 km), the one-bay antenna and the six-bay antenna produce nearly the same signal level.

Going towards the transmitter from 4 miles (6.4 km), the field increases in favor of the one-bay antenna. In this example, the table clearly indicates that the high-power transmitter low-gain antenna does not improve the signal strength available to the receivers beyond about 4.5 miles (7.25 km). The signal level starts to increase between 4 miles and 5 miles (6.4 and 8 km). Any increase above this level is useless because full limiting has certainly taken place in even the poorest FM receiver. (See Required Signal Strength in this chapter)

In Table 3 the same signal strength of (16 mV/m) at 5 miles (8 km) comes from either transmitter-antenna combination. This is due to the fact that the ERP power at the vertical angle of −0.74° is about the same from both antennas. The ERP at 0.0° elevation pattern will of course be exactly the same for both combinations. The field does not change measurably until observation is made beyond 1.5° from the peak 100% value in a six-bay antenna.

The signal strengths in this table were based on relatively flat terrain for an antenna 328 ft (100 m) HAAT. The true earth curvature distance to the horizon is 25.56 miles (41.23 km). Therefore the outer reaches of useful signal drop off very rapidly beyond this point in the typical Class A station.

There are no nulls in a one-bay antenna pattern. In a six-bay antenna the first null occurs at about −10°, approximately 0.37 miles (0.6 km) from the tower. Antenna arrays are never perfect so the null is never zero power. With a minimum radiation of five watts in the first null, the predicted signal would be 31 mV/m. The second null is closer to the tower and with the same five watts ERP would be even stronger in this example. So in practice there may be no need to fill in the nulls of the six-bay antenna.

Another consideration is that the nulls may fall very close to the tower and the number of people occupying the null areas may be small. Thus problems resulting from these close-in nulls would be minor.

Typical Class B and C-2 Station Coverage

The same comparisons of transmitter-antenna combinations can be made for Class B and the new Class

TABLE 4

C-2 stations, operating with a HAAT of 492 ft (150 m) with 50 kW ERP. This is shown in Table 4. A 55 kW transmitter with a two-bay CP antenna would provide the 50 kW ERP, with high efficiency coaxial lines. It is compared with a 10 kW transmitter feeding a 10-bay CP antenna. The terrain flatness is assumed not to exceed ±150 ft (50 m).

Table 4 indicates that the signal levels are the same from 4.6 miles (7.4 km) out to 35 miles (56 km) under similar columns as for the Class A station comparisons. The FCC uses a receiving height of 30 ft (10 m) so the horizon is a bit further away, at 31.3 miles (50.5 km).

From the transmitter out to about 2 miles (3.2 km), the signal rises much more rapidly in the two-bay antenna than in the ten-bay, the latter being somewhat similar to a cosecant curve. There is surplus signal close in and more than is needed or can be tolerated.

Therein lies one of several problems with high transmitter power and low-gain antennas as seen in Table 4. With the two-bay antenna there is 900 mV/m at one mile (1.6 km) and 562 mV/m as far out as 1.55 miles (2.5 km). This is above, or at, the blanketing level of 562 m/Vm. (See "Blanketing" in this chapter) The high-gain antenna does not cause this type of problem under identical conditions.

The signals from both combinations are much more than necessary for present day FM receivers out to about 10 miles (16 km). There is no practical difference technically in useable signal strengths presented to receivers in the entire market area, from either antenna. There is, however, a great deal of savings in capital costs as well as operating expenses between the two combinations.

One antenna factor is not clearly indicated in Table 4. The two antennas have elevation pattern nulls. The two-bay antenna null at −30° falls 852 ft (260 m) from the base of the tower and can be disregarded. The ten-bay antenna nulls can be filled to as little as 2½% field, which will not affect its gain. This would represent a minimum ERP at the nulls of 31 watts. Although seemingly very small, it is very effective as shown in Table 5.

It is obvious that the ten-bay antenna nulls can easily be filled to produce signal levels in excess of those required. If the transmitter is located in a populated area, these high levels prevent the loss of stereo separation and noise in the SCA (if there are reflections from high level lobes in the built up areas). This problem is common to TV transmitters which produce ghosts from high signal level lobe areas reflecting into null areas. This problem is greatly and satisfactorily reduced with null fill as shown in Table 5.

MATCHING TRANSMITTER POWER AND ANTENNAS

Several available combinations of antenna gain and transmitter power will provide the necessary ERP. But which combination is the best? The choice is further complicated by the nature of the terrain in the service

TABLE 5
2½% Null fill in — 10 bay antenna.

Null	Angle	ERP	Distance	Field
First	−5.75°	31 w	4,800 Ft	31 mV/m
Second	−11.50°	31 w	2,240 Ft	70 mV/m
Third	−17.25°	31 w	1,512 Ft	109 mV/m

area. Is it all flat, some rolling hills, mountainous or a large valley? What are the regulatory limitations on the antenna supporting tower height?

Important considerations when choosing the transmitter power and the gain combination to produce a given ERP are as follows:

- Transmitter
- Feed system
- Antenna
- Transmitter tubes
- Tower
- AC power consumption

The transmitter, antenna, tower, and coaxial feed line are one-time capital costs for the station. Tube costs and commercial power use, however, are a continuing hour-by-hour cost factor. From the above it is apparent that a low-power transmitter is much more economical than a high-power transmitter. But is there a difference in signal strength?

The ERP is the product of the antenna power gain and the antenna input power. Many different combinations of power gain and input power will yield the same ERP. The azimuth pattern will be quite similar for many different antenna power gains.

The only difference in various combinations is the elevation pattern. As discussed in the Typical Class A and Class B Coverage Sections of this chapter, there is no momentous or important difference in serving listeners from very different transmitter/antenna ratios.

The signal strength at any given location is a direct function of the ERP from the antenna elevation pattern angle to that location, the height of the antenna, and the propagation path. The ERP at the pertinent angle is the product of the elevation pattern relative amplitude at that angle squared, times the maximum ERP. In practice there is no significant difference between a 3 kW ERP Class A station using a 7.5 kW transmitter and a one-bay CP antenna, or, one using a 1 kW transmitter and a six-bay CP antenna, all other factors being equal.

Normally, all the power radiated above the antenna elevation pattern to the horizon is wasted. It is the radiated power below the angle to the horizon that strikes the earth with all its FM receivers. Therefore only the radiated power towards the earth should be considered useful.

The ideal antenna system would put the same signal level from the base of the tower all the way out to the horizon. This requires an antenna whose elevation pattern is a cosecant curve, the normalized reciprocal of sine. It would be the most efficient antenna elevation pattern. Although this curve is impossible to achieve, it is approached as the antenna gain becomes greater.

ANTENNA SITE SELECTION

The transmitter location must be carefully chosen. Site economics should be secondary to the technical advantages of a particular site. Fresnel zone clearances and other factors outlined in this chapter should be considered. A site with an operating FM or VHF TV station makes an excellent source of signals to check propagation for a new station. If the existing station is FM, make certain that its antenna pattern has been optimized to provide as much circularity as possible.

A good field strength meter should be used to measure the actual signal from the existing station. Relative readings are important, not the absolute. Check for reflections as well as level changes within a short walking area of about 100 ft (30 m). Check for stereo separation. Using this information, the operation of a new station near the one being checked can be compared before moving or submitting the FCC application. The consulting engineer may find it useful to consider this information to evaluate the suitability of the new site.

High-Gain Antenna Contradictions

The many advantages of high-gain, low-power transmitter combinations to produce the ERP have been shown. Their superiority in relatively flat land applications cannot be disputed.

There is, however, the matter of unusual height over average terrain to be considered. As examples, if the transmitter is located on Mt. Wilson, in California, on a very tall building in Chicago, or New York, the elevation pattern problem can become serious. This is true particularly when there are listeners near the sites as is the case for these three locations.

Mt. Wilson which serves the greater Los Angeles metropolitan area is more than one mile (1.6 km) above most of its listeners. In fact coverage is required from 11 miles (17.75 km) out to the horizon which is −0.57° at 105 miles (168 km). Pasadena, the nearest city, is 13° below the horizon. A high gain antenna tilted down 0.5° would serve the far reaches well, but would not lay down a moderate signal at −13°.

Section 73.211 of the FCC's Rules limits the ERP for overheight antennas such as those on Mt. Wilson with 2,900 ft (884 m) HAAT. New stations using that height must reduce ERP in accordance with the equivalence calculation, so that the predicted signal at the 1 mV/m contour does not extend beyond 32 miles (52 km) for Class B stations.

In these situations a moderate gain antenna should be considered. From Mt. Wilson several existing four and five-bay antennas now provide excellent service.

TV CHANNEL 6/FM ANTENNA PROBLEM

Television channel 6 occupies the band from 82 MHz to 88 MHz. The FM broadcast band extends from 88 MHz to 108 MHz. Noncommercial educational FM stations are assigned from 88 MHz to 92 MHz. Interference can exist between the two, with the TV station viewers receiving interference from the FM stations. The FM receiver is relatively selective with a response to about 200 kHz, but the TV receiver has a bandwidth of at least 6 MHz. However, more than TV receiver selectivity is involved in this interference problem. See FCC Rules Section 73.525.

Three principal techniques can be employed to minimize channel 6 interference from FM stations: (1) collocation, (2) where collocation is not feasible, location of the FM station in an area of low population density, and (3) antenna cross polarization.

Collocation

The purpose of collocation (that is, placing the FM transmitter at the channel 6 transmitter site) is to achieve the same propagation path for both TV and FM stations, thus maintaining a nearly constant desired-to-undesired signal ratio in the service area. If possible, both antennas should be mounted on the same tower. If not, a maximum separation of 0.25 miles (400 m) between the two is still considered as collocation.

The horizontal and vertical plane radiation patterns of both antennas should be similar because the objective is to maintain a near constant desired-to-undesired signal ratio. The HAAT should be similar, thus the desirability of collocating on the same tower. The maximum ERP of the FM stations operating on this basis is in Section 73.525(d) of the FCC Rules.

Alternate Locations

The FM station may not be intended to serve the same community as the TV station, or collation may not be possible. In this event, the FM broadcaster should locate in an area of relatively low population density by imposing a limit on the population which may be included within that area where a particular undesired-to-desired protection ratio is exceeded.

Two ratios were proposed by a committee which studied this problem in 1983.[15] Their recommendation varied according to the educational station frequency separation from the channel 6 aural frequency of 87.75 MHz. In any event, the interference area should not have more than 3,000 people living in it. See FCC Rules Section 73.525(c) and (e).

Cross Polarization

Several organizations have made discrimination tests in the United States and in Europe with cross-polarized antennas. It has thus been well established that discrimination of 16 dB is to be expected in rural areas and 10 dB in urban areas between two stations one using the V-pol and the other using H-pol, and the receiving antenna being similarly polarized. This is sufficient in most cases to resolve the FM-Channel 6 problem.

While technically, cross polarization will help solve the problem, the Commissions Rules do not require it. This is left as an option for the FM applicant to use. Most TV channel 6 receiving antennas will remain H-pol, while automobile FM antennas will stay V-pol. So if the TV station remains H-pol, this interference problem may be cleared up if the FM station will switch to V-pol. See FCC Rules Section 73.525(e)(4).

Rejection Filters

The FCC believes that rejection filters installed at the TV receiver would be helpful, while others think this is not a satisfactory solution. Unfortunately, many viewers do not sufficiently understand this problem and are thus not motivated to have the necessary filter installed.

It is further complicated by the fact that many of the existing TV receivers still have balanced antenna inputs (300 ohms) and filters designed for them that do not usually provide the necessary amount of rejection. As more TV receivers with coaxial inputs are purchased by the TV viewing public, this situation could change. Coaxial (75 ohm) filters with 20 dB of attenuation of the FM signal are readily available.

COMMERCIALLY AVAILABLE ANTENNAS

There are several basic classes of antennas available for FM broadcasting. These and variations of them are made by several manufacturers in different models, gains, and input power ratings. They may be broken down into the following classes:

- Ring stub and twisted ring
- Shunt and series fed slanted dipole
- Multi-arm short helix
- Panel with crossed dipoles

These antennas have many things in common. For example, nonsymmetrical antennas are designed for sidemounting to a steel tower or pole. Radiating elements are shunted across a common rigid coax line. This has eliminated the problems associated with the older corporate feed system using semi-flexible solid dielectric low-power cables.

Shunting elements every one wavelength across a transmission line makes impedance matching simple. Bandwidth is limited by the VSWR of the individual elements and the use of an internal transformer.

With more than about seven bays, the first three of the above antennas have a more difficult task being matched and there is undesirable beam squint, since the elevation beam angle changes with frequency deviation by the transmitter. Antennas with more than seven bays are fed from or near the center, thus dividing the phase change in one-half and effectively eliminated the beam squint. Center feeding also simplifies the VSWR matching.

A means for tuning out reactance after the antennas have been installed on the tower is also common with all the antennas. Located at the input to the antenna, the VSWR tuner consists of adjustable location dielectric or metal slugs on the inner conductor of the main coax line. Several fixed-position variable capacitors, spaced one-eighth wavelength along the main feeder near the antenna input are also used on some side-mounted antennas to adjust the VSWR to very small values.

Another variety of antenna has curved radiating elements around a circumference whose diameter is determined by the number of element arms. Each radiator consists of two, three, or four such circular arms, depending on the model. Each element is fed through a shunt arrangement, and then shunted across the vertical rigid feed coaxial line.

Wideband panel antennas are becoming popular where high buildings, favorable mountain sites or high towers are available. Several firms make wideband panel antennas. Some have very wideband VSWR features in each radiator. Others with not so broad VSWR, use phase impedance compensation similar to the European scheme, which uses 90° phase quadrature impedance compensation.

Phase quadrature compensation makes it possible to cover the entire 88 MHz to 108 MHz band with a VSWR under 1.1:1 while maintaining excellent elevation, and azimuth patterns, together with very good axial ratios. Power ratings up to several hundred kilowatts are offered so that many FM stations can be diplexed into one such antenna.

Only the wideband community FM antenna design now uses a corporate feed system, while the others are shunt fed from a common rigid coax line. This corporate feed system, using air dielectric semi-flexible line at the lower power levels, is very successful. It splits the input power to many different dipoles at the correct amplitude and phase.

These four basic antenna classes are described in greater detail on the following pages.

Standard Sidemount Antennas

Standard sidemount antennas come in a variety of shapes and forms. They are currently used in the majority of applications. Their chief advantages are low cost, easy installation, availability of high gains, and low tower constraints. They are available in linear polarized configurations (H-pol or V-pol) or circularly polarized (CP).

Most sidemounts are comprised of a series of radiating elements, or bays, which are fed via a rigid inner-bay feed line. The most typical feed lines used are 1⅝-inch O.D. for applications with less than 10 kW antenna input power, and 3⅛ inch line for up to 40 kW. Most antenna elements come in high and low power versions. These antennas are mounted directly to the side of a tower or pole. Leg and face mounts are typical on tower structures.

Some manufacturers with test ranges offer sidemount antennas with custom directional patterns. The pattern shaping is accomplished by optimizing its mounting and adding parasitic reflectors which are on the order of one-half wavelength. Repeated range tests have shown that the sidemount antennas have largely distorted patterns due to feed lines, mounting structures, and other conductive media in the antenna aperture.

Sidemount antennas are inherently narrow banded. The bandwidth of a single element rarely exceeds 1 MHz. Although diplexing two stations on a single sidemount is occasionally done, the spread between stations must be small (a few MHz), and compensation tuning (such as long stubs must be used). In addition, none of these antennas are symmetrical, and each type has uncontrolled radiation from booms and feed lines in the aperture. This distortion deteriorates the antennas axial ratio and circularity.

Series-Fed V-Dipole Antennas

This antenna has similar bandwidth to its shunt fed counterpart, but the array is typically intentionally tuned high in frequency. The combination of this tuning scheme, and the internal protection of its feed allow this antenna to be somewhat resistant to light icing.

This model is larger in size and heavier than other types of sidemount antennas. Care should be taken in determining tower constraints. The antenna is typically field tuned for an optimized match. Careful placement of ceramic slugs can produce a good VSWR over the stations useful bandwidth.

Ring Radiators

There are several antennas that are simple adaptations of ring radiators and were designed and manufactured in the 1950s and 1960s for horizontal polarization. By adding vertical stubs to the ends of the radiator or twisting the ring, elliptical polarization (of sorts) is achieved.

Both the ring and the ring stub suffer from temperature variations which tend to change the spacing between the ring openings and thus the electrical capacitance and resonant frequency. The ring stub and the twisted ring are not really circularly polarized because the axial ratio varies considerably with azimuth. At best they may be said to be elliptically polarized.

Over the years the design has improved by adding a second horizontal ring and improving the feed. Reducing bay spacing reduces high axial side lobes. The antenna has very good circularity in free space, but like other types of sidemount antennas, it is strongly affected by its support structure and feed line.

The radiation patterns are strongly affected by the tower mounting environment. Being of relatively high Q design, they are more susceptible to detuning because of icing. Radomes and electrical deicers are available to overcome this problem. While the icing problems may be overcome, pattern optimization is not offered for these antennas.

Ring-Stub Antennas

The H-pol radiation from these antennas comes from the ring portion whose plane is parallel with the earth. There is a minor lobe from each radiator, which is strengthened with vertical stacking for additional power gain. This nadir-zenith lobe is the result of 360° stacking on the rigid coax feed line. It reduces the gain and presents a lobe at the tower base which is detrimental to low level audio equipment and personnel located in a building at the base of the tower.

In order to keep the cost down, like the twisted ring antenna, the ring-stub is manufactured in several radiator-to-radiator spacings across the FM band. This results in some minor beam tilt up or down depending on the frequency. Most higher priced slanted dipole and helix antennas are spaced exactly 360° and are usually tested to assure this spacing during production.

Shunt Fed Slanted Dipole Antennas

The slanted dipole antenna in its present configuration was developed and patented in 1970.[16] It consists of two half-wave dipoles bent 90°, slanted and fed in-phase.

The slant angle is critical as it is the factor which determines the ratio of vertically and horizontally polarized radiated power. The phase point center is at the feed insulator on the dipole support arm as shown in Fig. 9. When fed through a vertical support pole on which the antenna was mounted during initial development tests, the axial ratio varied less than 1 dB.

The commercial adaption uses a horizontal boom containing a step transformer. This boom supports two half-wave dipoles in which the included angle is 90°. The two sets of dipoles are rotated at 22.5° from the horizontal plane. Two opposite arms of the dipoles are delta matched to provide a 50 ohm impedance at the radiator input flange. All four dipole arm lengths may be adjusted to resonance by mechanical adjustment of the end fittings. Shunt feeding, when properly adjusted, provides equal currents in all four arms resulting in excellent azimuth circularity.

Figure 9. Three bay Cetec model JSCP-3 non-symmetrical FM antenna mounted on the tower leg. The guy cables are insulated fiber glass rods near the tower legs. (Photo courtesy Cetec Antennas)

Short Helix Antennas

A relatively recent asymmetrical radiator is the four-arm shunt fed helix. By using four dipoles, curved so that their circumference is about one wavelength, a CP antenna is produced.[17] Each dipole is about one-half wavelength and is shunt fed. These are supported on a four arm structure, one end of which is tied to the supporting structure. The dipoles overlap so that the current flow around the circumference is circular. The four feed arms are connected in shunt and the feed impedance is quite low, but may be brought up to useful values with an internal step transformer.

The CP quality of the four-arm side-fire short helix is good. Three and two arm models are also available, but their axial ratio is not as good as the four arm. Pattern circularity is ±1 dB for the four arm, together with an axial ratio of about 3 dB.

These radiators are stacked about one wavelength apart on a rigid coax feed line to obtain the necessary power gain. Like other asymmetrical FM antennas its patterns are strongly affected by the supporting structure. See "Pattern Optimization" in this chapter for the need and methods to circularize the azimuth pattern.

Electrical deicers using the stainless steel dipole arms as one half of the heating circuit are available. Heat is created by passing a large current at low voltage through each arm from voltage dropping transformers placed at each bay level. Plastic radomes are also available to keep snow and ice off the sensitive VSWR parts of the antenna.

Twisted Ring Antennas

This type consists of one or more rings, which have been partially twisted so that the open ends of the ring are about 10 inches (25 cm) apart. One semi-circular arm of the ring is fed with a small loop or by a direct tap on that arm. A number of these rings are fed in the same manner as the ring stubs, *and have the same zenith-nadir lobe problem.*

The mechanical twist is not the same when viewed in all the azimuth directions. Therefore the current is not the same, with the end result that in some directions there is much more elliptical radiation than in others.

These antennas are very simple and relatively inexpensive for single frequency use, but have some serious operational limitations for CP operation. They do not have the same signal penetrating effect as the slant dipole, short helix, or the flat panel antenna type of CP antennas.

Short Helix—Multi-Arm Antennas

The number of arms may be increased to four instead of the two in the slanted dipole variety. To provide CP, the arms are curved to form a one wavelength circumference. These short multi-arm helices are also stacked in the conventional manner, like the others in this series for power gains as desired. This design uses 2 gamma feed straps to feed all the elements in phase. This antenna is shunt fed, and is arrayed and mounted similarly to the slanted vee dipole antenna.

The azimuth pattern of all these non-symmetrical antennas is affected by the supporting steel structure. With pattern optimization, the pattern can be made quite omnidirectional. See "Pattern Optimization" in this chapter.

Series Fed Antennas

A similar arrangement of arms supported by a T arrangement may be series fed. That is, part of the outer end is insulated from the rest of the dipole and fed across the insulated break. To allow for adequate power handling capacity and to increase the VSWR bandwidth, three-inch (75 mm) diameter tubing is used.

The antenna has an VSWR bandwidth of about 1%, so it makes an excellent single channel FM antenna. The antennas are usually mounted on the side of a supporting tower or pole, and stacked vertically to achieve required power gain.

This antenna has greater wind loading than the shunt fed version due to its larger element diameters necessary to achieve useable VSWR bandwidth. It presents considerable large amounts of ac power for electrical deicing. Plastic radomes also present additional wind loading.

Flat Panel Antennas

Panel antennas for CP FM broadcasting are relatively new in the Western Hemisphere, although H-pol and V-pol have been used in Europe since the mid-1950s. This antenna was developed in Europe to provide a wide bandwidth for several collocated government stations without the need to change antennas when a new channel was added or the operating channels were changed from time-to-time.

Panels are from 7 ft to 8 ft (2,100 mm to 2,450 mm) square in the flat configuration. In the cavity style they are about 8 ft (2450 mm) in diameter and about 3 ft (1,000 mm) deep.

A heavy metal frame is often used over which large diameter wire mesh has been welded. The wire mesh screen openings vary from 4 to 12 inches (100 mm to 300 mm). Electrically they are considered nearly solid metal. These openings produce relatively low wind loads. The entire flat frame or cavity is strong enough to support a man on its mesh openings. Some manufacturers hot dip galvanize their steel after fabrication; others use stainless steel construction.

For FM use, two crossed dipoles are used as the illuminating source for each panel or cavity. Each dipole is fed in phase quadrature, that is one dipole receives its peak current 90° after the other, to produce CP. A typical set of electrical and mechanical specifications for a CP eight-bay cavity community antenna is shown in Table 6.

Flat panel antennas are typically sidemounted on large face size towers. The screen panels greatly reduce interaction and distortion between the antenna and tower. The panels are directional, thereby requiring 3 or 4 panels to be mounted around the tower to achieve acceptable azimuthal circularity.

These antennas are usually branch fed, and often the array's top and bottom halves are fed separately. This allows operation of either half of the antenna separately when it is necessary for maintenance or repairs. Circular polarization is achieved on each panel by feeding two perpendicular dipoles 90° out-of-phase. This phase offset helps this antenna achieve usable bandwidths on the order of 10 MHz.

By pulling the dipole back on its feed support arms, the arrowhead shaped dipoles control both V-pol and H-pol azimuth patterns. Rotating the dipoles 45° with the earth-ground reference improves the polarization ratios even further.

Round dipoles made of tubing as large as 6⅛-inches

TABLE 6

Typical measured community antenna performance.

Operational frequency range	88 to 108 MHz
Safe RMS input power rating	200 kW
Power gain ratio, each polarization	4.4 (6.43 dB)
Maximum VSWR any frequency between 88-108 MHz	1.1:1
Elevation pattern beam tilt	−0.5°
Polarization	Right hand circular
Axial ratio	Better than 2 dB
Azimuth circularity Vpol or Hpol	Better than ±2 dB
Antenna dead weight, less than	7,000 Lbs (3,183 kgs)
Active wind load, RS-222-C 50/33 PSF	8,000 Lbs (3,636 kgs)
Antenna input flanges, two, size	6-1/8 inch
Number of bays (stacks)	Eight
Radiator type	Circularly Polarized Cavity

(155 mm) in diameter are used along with a single line quadrature feed. This combined arrangement makes an excellent wideband CP panel to cover the entire FM band. Power splitters, dividers, and cables, along with a number of these panels, completes the antenna.

Even on large face towers, circularity in the H-pol can be quite good, on the order of ±2 dB. On standard configurations, the V-pol pattern is quite different. As a result, the axial ratio of this antenna ranges from good at some azimuth headings to rather poor at others. This is because the azimuth pattern of a H-pol dipole is like a figure eight, or cosine function, while the pattern for a V-pol dipole is not directional in its azimuth plane. Therefore, each polarization will react quite differently when mounted in front of a panel.

Dipoles on these panels are often mounted at 45° referenced to the ground. This has no effect on the axial ratio or pattern performance, it instead is done for tuning considerations to compensate for mutual coupling.

Variations to this design have reduced the differences between the patterns of the polarizations. These techniques are effective for applications requiring only a few MHz of bandwidth. One method optimizes the angle of the dipole bend as well as its distance to the panel. This design requires three panels to be mounted around a tower. Axial ratio and pattern circularity are improved at the cost of system bandwidth.

Another method uses four dipoles forming a square shape in front of the panel. By adjusting the spacing between the dipoles, the beamwidth of a panel can be controlled. Over a small bandwidth, the pattern performance is greatly improved. It is necessary to mount four panels around a tower for a circular pattern. A large amount of panel interaction and leakage are severe design limitations.

For projects that require wider bandwidth, skew mounting is often used. This physical configuration allows the panels to be fed in mod 1 (0°, 90°, 180°, 270° phase for 4 around) which can increase the bandwidth of the system at the input. Although skew mounting deteriorates pattern performance, the increase in bandwidth extends its applications.

Cavity Backed Panel Antennas

The use of a cavity screen instead of a flat panel has greatly improved axial ratios. The cavity acts as a resonator with little leakage towards the tower. The shape of the azimuth pattern in each plane becomes both controllable and symmetrical. System bandwidth is improved over the flat screen design. By adjusting the diameter of the cavity structure, beam widths can be altered to meet specific requirements. Mounting three cavities around a tower gives good pattern circularity. Axial ratios usually range from good to excellent.

The cavity antenna uses the reflective properties of the flat screen panel. In the cavity however, the illuminating dipoles are flat instead of round and all four arms are parallel to the plane of the cavity. Like the flat panel with its round dipole supporting balun, the cavity also holds its flat dipoles with a double coaxial balun.

The dipoles in the cavity get their wide VSWR bandwidth through the sleeve dipole principle.[18] Capacity is provided by a metallic ring close to all four dipole arms placed between them and the back of the cavity. Circulating surface currents flow on the dipole arms, which result in evenly radiated patterns in all polarization planes. The bandwidth of a single cavity can cover the full 20 MHz band with a VSWR better than 1.1:1. Therefore it is not necessary to skew mount these antennas for bandwidth considerations.

This antenna has the advantage over some other designs of greater VSWR bandwidth. It is considered closer to state-of-the-art due to better elevation and azimuth pattern control of both planes of polarizations by the shape of the cavity.

Cavities, and flat panels can be modeled using a computer. Factors such as tower size and orientation, as well as the phase and skew of the elements, can be modeled to determine optimum mounting and feeding. This is useful in projects which require a directional pattern. A station should take pattern constraints and desires to an antenna manufacturer to find out what is feasible.

Crossed Dipole Theory

Common to the flat panel and the cavity is the operation of the dipoles which generate CP. The dipoles are fed currents in phase quadrature, through a coaxially balanced balun, which provides equal currents to all four arms of the two dipoles. They excite the entire cavity or flat panel with a rotating RF field in a plane parallel to the dipoles. The RF field is thus CP and may be ideally represented by a rotating vector of constant magnitude revolving one revolution per wavelength of propagation distance. It is right hand polarized as the field rotation is clockwise as viewed from behind the screen, looking toward the direction of propagation, if the phasing between the two crossed dipoles is properly made.

Radiation patterns, associated beamwidth, and directivity are determined to a large extent by the size of the cavity or flat panel. The geometry of the dipole has less effect than the reflector size. The size and shape of the dipole controls the antenna impedance and the VSWR. The screen panel, be it flat or a cavity, fulfills the following five important electrical functions:

1. Isolates the radiating elements from the tower or the mounting structure, and reduces mutual coupling.
2. Provides sharper beamwidth and more gain than achievable with the dipoles alone.
3. Furnishes pattern control so that the beamwidth is nearly equal for both horizontal and vertical plane polarization.
4. With an effective balun feed system, the crossed dipole radiated pattern phase is very uniform as the amplitude changes normally with azimuth.

5. Computer aided designs are easily achieved in production for various width towers because the pattern is simply pure electrical geometry.

Antenna Element Spacing and Downward Radiation

Most FM antennas have elements that are spaced one wavelength apart (9 ft to 11 ft) for reasons such as gain considerations, mutual coupling effects and ease of feed design. There are cases, however, which require a different element spacing. High levels of downward radiation is the most common reason, although considerations such as aperture constraints and beam shaping also utilize nonwavelength spacing.

Radio frequency radiation (RFR) safety levels must be considered in nearly all site locations. Power radiated in the lowest sidelobe can cause a variety of problems, of which human exposure levels are most critical. Guidelines set by ANSI require that the level of radiation not exceed 1.0 mW/cm^2 (for FM) in areas of free human access. Depending on factors such as antenna type, height of antenna above ground level, and ERP, a station may require an antenna with short-spaced elements to meet the safety level.

$$S = \frac{(0.64)\,\mathrm{EIRP}}{\pi R^2}$$

where:

S = Power density
EIRP = Effective isotropic radiated power
R = Distance to the center of radiation

The above equation is taken from FCC OET Bulletin 65, which outlines a method of computation to predict the ground levels of RFR. Values of field strength can be obtained from the antenna manufacturer. If the calculated level points to a possible exposure problem, reduced inter-bay spacing might eliminate the problem. Realize that no equation can provide exact results. The only accepted method for correctly determining levels is by direct measurements at the site. Factors such as poor tower RF grounding and noninsulated guy wires may make actual levels substantially higher. See Chapter 2.9, "RF Radiation Hazards," for further instructions.

When antenna elements are arrayed, the resulting elevation pattern contains lobes and nulls. The furthest sidelobe from the horizon typically peaks between 70° and 90° below the horizon for full wave spacing. This lobe occurs since the physical path results in no phase cancellation in that direction, and thus each elements downward radiation is additive. Shortening the spacing changes the difference in the elements physical path length, and results in some phase cancellation.

Half wave spacing, for example, greatly suppresses the levels of the side lobes, while increasing the width of the main beam. Despite the lack of power in the side lobes, the extra width of the main beam causes the pattern to be less directive. Thus this exchange results in an overall gain reduction on the order of a third. Spacing the elements 0.8 wavelengths apart improves sidelobe suppression and the gain of the antenna is not greatly affected.

Short spaced antennas are fed either by a shunt or branch feed system. For half-wave spaced antennas, a shunt line delivers each element 180° out-of-phase with the next element. This phase distribution problem can be overcome by flipping every other element upside down, thus inducing a 180° phase shift in the feed. Other spacings, such as 0.8 wavelengths, require a branch feed, which can deliver equally phased signals to each element independent of spacing.

Problems With Sidemounted Antennas

Single station FM antennas are typically sidemounted on a pole or tower. Unlike panel antennas, the support structure greatly effects or distorts the radiation pattern. The resultant pattern may have large peaks and nulls that can result in coverage and reception problems.

In addition, the V-pol and H-pol patterns react quite differently to these distortions. Due to the geometric complexities of the CP radiating elements and tower structure, no computer model exists to accurately predict pattern effects. Therefore, the use of test ranges are required to determine how an antenna behaves when mounted on a tower section similar to the one on which the antenna will eventually be used.

For nondirectional stations, a test range can determine the proper mounting of an antenna to achieve an acceptable circularity. Depending on the tower size, the depths of nulls can be greater than 10 dB. An optimized mounting configuration can make the nulls less significant and oriented in areas where service to the primary coverage area is not hurt. Parasitic reflectors are often used to improve the circularity of nondirectional antennas.

When the top spot on a tower or structure is available, pole mounting is often preferred. A pole provides a stable and symmetrical support structure which has low interaction with the horizontally polarized component. In combination with the feed line, the pole typically induces a null in the V-pol pattern, directly opposite of the elements. Proper orientation of the element can reduce the effects of pattern distortion.

Mounting an antenna on the side of a tower can produce unpredictable results. The position of the peaks and nulls vary greatly from the orientation of the elements. As the face size of the tower increases, the distorting effects magnify. To compensate, many stations use smaller sections of tower at the top, where they plan to install the FM antenna. Eighteen-inch and smaller face towers tend to produce good results. With careful planning, the use of a 24 inch or larger face tower can also be successful.

Note that the patterns of each polarization react differently, and thus axial ratios can be quite poor. See the following section on pattern optimization.

PATTERN OPTIMIZATION

Single-station FM antennas are usually sidemounted on a pole or tower. This is economical and it frees the tower top for other possible uses. Unfortunately the pole or tower tends to distort the radiation pattern, seriously affecting station coverage in some directions.[19]

This problem can be serious if the FM antenna has been randomly attached to a support tower. FM antenna makers do not manufacture and sell towers. A few have made supporting poles on which the FM antenna has been affixed, adjusted, and pattern tested. TV antenna makers, on the other hand, always make the antenna as a complete self-supporting structure to be mounted on top of a support. They are usually not faced with this sidemounting problem. The logical but more expensive solution would be to make the FM antenna a self-supporting structure just like TV antennas.

Improper FM antenna sidemount installation on a tower can cause serious pattern problems. Measured patterns have indicated that, in some cases, the maximum radiation can actually be in the opposite direction from the desired direction.[20]

Need To Optimize

It is not wise to gamble with an FM station's antenna coverage. Nulls may be toward important service areas. Nulls as low as 1% of the RMS power have been measured with towers varying in width from 18 to 120 inches (0.5 m to 3 m).

Another problem is that with nulls come lobes. Lobes as great as 9.8 dB over RMS have been found. When used without pattern optimization, this lobe would produce an ERP in a given direction nearly ten times the FCC licensed value.

Translating this to a 50 kW ERP station there would be radiation in some directions of only 0.5 kW and others with 477 kW. This is a maximum to minimum ratio of 29.8 dB, and clearly not acceptable.

With CP came additional problems as the H-pol and the V-pol ratios are not always the same and vary moderately in any given azimuth. This ratio can be as great as 15 dB and must also be addressed in order to resolve the horizontal plane circularity problem. The axial ratio could be degraded causing the V-pol radiation in certain directions to be much stronger than the H-pol. This violates FCC's requirement that with CP, the V-pol must not be stronger than the H-pol component.

Section 73.316 of the Rules covers FM antennas but does not specifically address this problem of azimuth circularity. In fact the FCC assumes that FM nondirectional broadcast antennas have perfectly circular horizontal radiation patterns.[21] In actual practice, they seldom do.

In order to produce a horizontal plane pattern which even approaches a circle requires considerable work by the firm making the antenna. Since it is nearly impossible to produce a circular pattern with a nonsymmetrical sidemounted antenna, the term and technique, optimization (to do the best possible) is in common usage now.

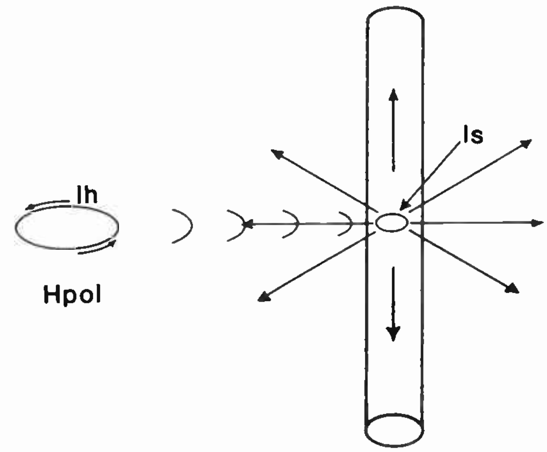

Figure 10. The effects of supporting steel towers or poles on one side of a non-symmetrical antenna are shown as horizontally polarized currents Ih flow on supporting members as Is and reradiate in all directions.

Theory of Optimization

Fig. 10 indicates how energy from the horizontal loop representing H-pol is intercepted by a pole and reradiated. Similarly, in Fig. 11 energy from the vertical dipole is intercepted and reradiated as V-pol.

In the first case, the pole diameter is small in wavelength in the direction of the electric field, thus, scattering is minimal and not much H-pol radiation can be expected. However when the V-pol dipole excites the pole, a large amount of energy is intercepted (Is) and reradiated because the large dimension of the pole

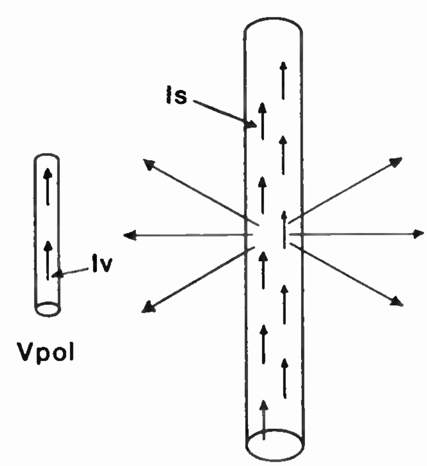

Figure 11. Vertically polarized current Iv flow over the supporting structure members as Is and reradiate in all directions.

(length) is parallel to the electric field. A similar effect is produced by the vertical transmission line which is common to the antenna itself, (IV in Fig. 11). The result is appreciable distortion of the vertically polarized azimuth pattern.

Fig. 12 shows the resulting H-pol and the V-pol patterns. The pole and/or vertical coaxial line have transformed the V-pol pattern from circular to a cardioid, while the H-pol pattern remains essentially omnidirectional. The null of the cardioid can be more than 7 dB down from the RMS value. This phenomenon is well known, and as a compromise, broadcasters generally install the antenna on the side of the tower support structure facing the main service area. There are many exceptions to this, as some measured patterns on triangular towers of standard construction have shown.

In Fig. 12 the V-pol is much stronger than the H-pol in the favored direction. In the opposite direction, there is little V-pol. The power ratio of H-pol to V-pol is 16 times. This makes for a very poor CP antenna in some directions.

Tower and poles under about 2 ft (0.6 m) in cross section will exhibit the same effects on the antenna patterns, as in Fig. 12. Towers greater than this size obviously will increase the complexity of scattering effects. Three or four tower legs, the horizontal and diagonal cross members, transmission lines, ladders, tower lighting, and deicer conduits, all will be excited by the vertical and horizontal currents from the radiators. All these surfaces will reradiate and affect the horizontal plan patterns.

In contrast to the simplicity of the antenna on the side of a pole, the tower supported antenna may be mounted on the face, or on a corner, at or between horizontal cross members, or tilted at various angles compared to the tower—all multiplying the complex factors affecting the patterns.

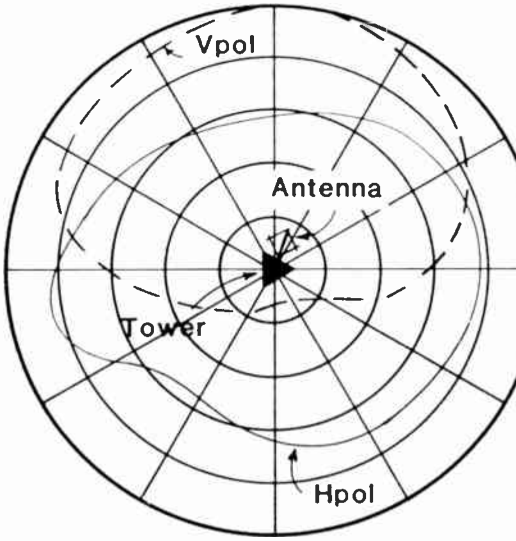

Figure 12. Combined results of Hpol and Vpol reradiation distort both patterns, producing more than 17 dB variation. This poor Cpol pattern should be pattern optimized to smooth out the azimuth pattern.

Optimization Methods

The most popular technique to achieve the desired pattern is through the use of Yagi antenna principles, wherein parasitic elements are placed in the field of the radiator to modify its radiation pattern. For example, a shortened dipole (director) placed in close proximity to a radiator reinforces radiation in the forward direction, and suppresses the signal in the opposite direction. If the parasitic element is longer than the radiator (reflector), the effect is reversed. The signal is suppressed on the side of the parasitic element and reinforced in the direction of the radiator.

Similarly, parasitic elements can be used with FM antennas mounted on the sides of towers or poles to produce pattern changes. As discussed here, both directors and reflectors may be used. Both are frequency sensitive. The effects of the supporting structure are also frequency sensitive.

Therefore, an arrangement of parasitic elements for a given FM frequency will not necessarily be the same for another, nor will the pattern be the same for a given arrangement, if it is moved up or down the tower by as much as 1.5 ft (0.5 m).

The resulting patterns cannot be predicted. There are many factors which affect the horizontal plan pattern. Only by actual antenna pattern range testing can the patterns be adjusted and properly measured. Therefore the cost for doing this is high, since it is time consuming, and requires qualified antenna technicians and the use of an antenna range. In addition, the final parasitic arrangement must be permanently fabricated and installed. However, the results are well worth it.

Pattern Service

There are two basic types of pattern service furnished by several antenna manufacturers in the United States. FM antennas may be adjusted for the best omnidirectional pattern possible or they may be adjusted to proven minimum ERP values in particular azimuth directions. The minimum required values, plotted on a polar chart by the broadcasters may be combined with the tower orientation. Using the customer's make and model tower, two or more bays of the antenna are fabricated, installed on a section of the tower, and put on the test range. Adjustments are made such as leg chosen, distance from the leg, and the orientation of the antenna with respect to that leg. Parasitic elements are then used to further improve and shape the pattern, so that the minimum ERP values will be achieved in the customers service area as given with the order on the polar plot.

For example, a Class A station may wish that a minimum of 3 kW be radiated in a pie from 90° to 120° and the remainder of the azimuth be no less than 1.5 kW. This would then require the antenna technicians

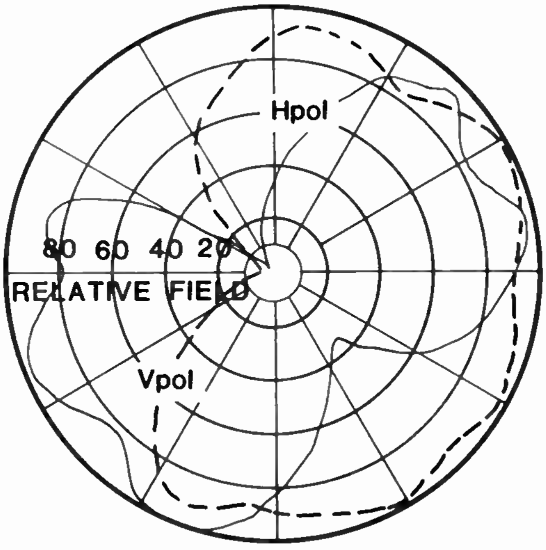

Figure 13A. Measured non-symmetrical Cpol pattern of tower side mounted antenna. Vpol variation is ±15 dB, while Hpol is ± 12 dB. The axial ratio was 24 dB. Antenna patterns are very poor.

to achieve a pattern without any field voltages less than 70% and that the vectors between 90° and 120° to be 100%. This sort of work has been done by many antenna manufacturers. See Figs. 13A and 13B for a typical before and after optimized pattern.

Various methods have been used to optimize FM antenna azimuth patterns. Some firms use models at twice the operating frequency. Others use theoretical methods, backed up by experimental proof. The final optimized antenna is match marked on the tower sections so that it will be assembled exactly as it was made and tested at the fabricator's plant, and tested on the antenna range.

A complete set of installation prints must be provided so that the antenna is assembled exactly as tested, with all the correct locations, and angles of all the parasitic elements.

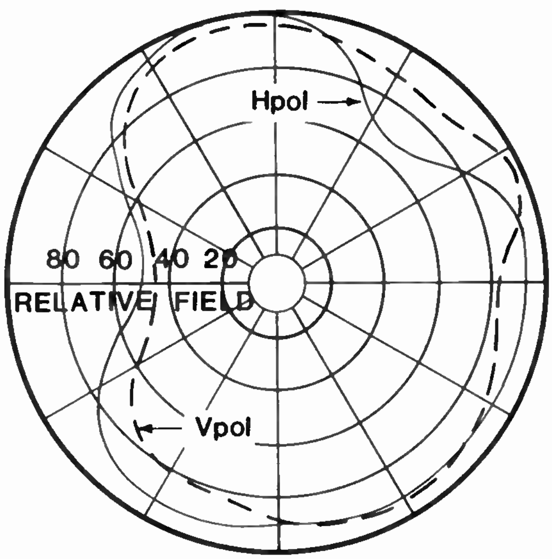

Figure 13B. Same antenna as 22A but much improved after pattern optimization. Hpol variation is ±3 dB and Vpol is ±3.4 dB. Axial ratio is quite acceptable at 2.9 dB.

WIDEBAND COMMUNITY AND MULTI-USER ANTENNAS

The most significant recent developments in FM antennas have come in broadband designs. Flat panels, cavities, helicals, and a new sidemount have given broadcasters a range of choices to fit their application. Factors such as pattern requirements, tower constraints, and system budget can narrow the options.

In order for an antenna to be useful throughout the 20 MHz FM band, its operation must be the same on any frequency. The VSWR on 89 MHz for example, must be just as good as on 108 MHz. The CP azimuth pattern should remain the same on one end of the band as the other, as must the axial ratio. This is a much more rigorous requirement than placed on the single-channel slanted dipole or the ring stub.

In the wideband antennas, several factors go together in order to meet these severe requirements:

- Basic wideband dipole radiators
- Screen-panel pattern control
- Quadrature phase distribution

By using these three principle parameters in a wideband antenna the radiation pattern, VSWR, and the gain can be nearly the same on any channel within the FM band.

Several methods are used to make the VSWR of the crossed dipoles as good as possible. The dipoles are usually fed with a folded balun or the split-tube type balun.[22] This improves the impedance match, phase as well as amplitude linearity of the resulting azimuth pattern.

The length to diameter (or width) ratio is usually about three. This not only reduces the Q but also increases the voltage flash over levels. The low Q also increases the bandwidth by decreasing the rate of reactance change with frequency.

A natural factor aiding the VSWR problem is the fact that in order to obtain CP from two crossed dipoles, there must be a phase quadrature of the two currents feeding the crossed dipole. The two reflections, as a result of VSWR, return back to the phasing device 180° out-of-phase with each other. Being the same amplitude, they cancel.

All of the above factors, plus two or three more levels of quadrature reflection cancellations, bring the overall system input at the antenna to under 1.08:1 across the band. This cancellation technique eliminates the need for electrical deicers or plastic radomes, as the VSWR is not affected by moderate ice coatings.

However radomes may be necessary with flat panels, to physically protect some radiators from falling ice.

These and other factors all contribute to make the panel-cavity antenna the best possible for either single channel or community antenna use.

Top Mount Antennas

There are a few broadband designs which require top mounting on a pole. The first design incorporates a series of dipoles which are mounted on a pole. Each dipole is branch fed individually. By rotating the mounting scheme, circular patterns can be achieved. The rather small radius between dipoles keeps nulls from crossover points to an acceptable level. Large bandwidths and good patterns have been measured on this system. The considerable amount of feed cables that run through the aperture, however, can cause problems if not properly RF grounded or shielded. Line damage, failure, and pattern distortion are possible results.

Spiral (or normal mode helical) antennas are now being used for FM applications. This traveling-wave-type antenna has bandwidth on the order of 15% to 20%. Fed from the top, a series of wires are wrapped around the conductive pole over an aperture of 2 to 3 wavelengths. The pitch angle of the wire wrap controls the pattern characteristics. Pattern circularities of ±1 over a 20 MHz band have been measured. Axial ratios better than 2 dB are considered typical. The feed system is enclosed by stainless steel feed cans which eliminates pattern distortion by the feed system, a common fault of other top mounts. In icing regions, heating elements inside the radiating wires stabilize its performance.

Multi-Channel Sidemount

The most recent design in broadband FM broadcasting antennas is the sidemount. This design incorporates dual baluns which insure a balanced and symmetric current excitation. This balance eliminates spurious radiation from currents on booms, feed lines, and other nearby conductors. The feed arms are of the skewed vee dipole configuration. Excellent circularities and axial ratios have been measured in free space. Interaction with feed lines and support structure still distort the pattern, though to a lesser extent.

A single FM element has been measured to have a bandwidth of 5.5 MHz with a VSWR of 1.1:1. This bandwidth does not limit the spread of two combined stations. By centering the band edges, the antenna can tune two stations over 8 MHz apart with a VSWR of 1.1:1 over each channel. This comes at a cost of poor performance at center frequencies, thus three stations over 8 MHz is not achievable. As a sidemount, this antenna has substantially reduced costs and tower constraints over a panel type.

Community Antenna Economics

The community antenna fits best in multiple station service. This allows sharing costs so all parties benefit from a superior antenna that each station independently could not economically justify.[23]

If enough planning is done in advance, it may be possible to install all the FM stations of one community on one tower, at considerable savings to all users. Some preclusions are lack of adequate mileage separations, the existence of excellent facilities, and FAA tower height limitations.

The break-even point appears to be with four stations. When five stations are involved, there is a 20% reduction in cost to each of them when compared to the costs of putting up their own individual single channel antenna and tower at the same height. See Table 7 for a break-out of costs for a wide-band community antenna system.

Community Antenna Examples

The costs used in Table 7 include an eight-bay CP omnidirectional community antenna with a gain of 4.40 mounted at the tower top. It also includes a dual run of 6⅛-inch (155 mm) coaxial transmission line, for upper-lower half feed system. The 1,020 ft (310 m) tower height puts the antenna center at approximately 984 ft (300 m) maximum HAAT level on flat terrain.

The guyed, lighted, and painted tower is EIA-RS-222-C rated for 85 mph (137 km) ground wind areas. The number of diplexers are equal to the number of stations so there is always one wideband port left for emergency use if one station loses its diplexer. The dual coax line permits using one-half of the antenna in the event of a problem in one line or one-half of the antenna.

The single channel comparison antenna system also has the same 984 ft (300 m) tower, but with one run of 3⅛-inch (79 mm) line. Diplexers are not used. An eight-bay single channel slanted dipole antenna with a power gain of 4.30 is sidemounted and has electrical deicers. Its pattern is optimized for a smooth circular azimuth pattern. The VSWR is field adjusted to be under 1.1:1 for ±250 kHz at the station carrier frequency.

All outdoor installation work was included in the costs shown. Both sets of costs have one antenna field technician for VSWR checking and adjusting the diplexers in the community example. Tower founda-

TABLE 7
Wide-band panel antenna costs (1985).

Number of Stations	Total Cost of System	% of Single System Cost
4	$1,410,000	Break Even
5	1,460,000	−20%
6	1,510,000	−31%
7	1,560,000	−39%
8	1,640,000	−44%
9	1,690,000	−49%
10	1,740,000	−52%

tions and buildings are not included as this is a variable cost item, and may be done by the owners.

In 1984, a group of Houston, Texas broadcasters formed the Senior Road Tower Group, and installed a 2,049 ft (625 m) tower supporting a twelve-bay community FM antenna system, with its HAAT at 2,000 ft (610 m).[24] This height permits the maximum service allowed.

Two runs of 8³⁄₁₆-inch (208 mm) diameter coaxial lines are used to feed the antenna in such a manner that power in both the lines causes right hand CP from the antenna for nine FM stations.

The nine stations use one diplexer each, all of which are housed in one 2,400 square foot (223 square meters) room. The 10 port modular diplexer has a total power handling capability of 350 kW. The insertion loss for each station is 0.80 dB (17% loss). The isolation between the various transmitters meets FCC spurious emission (intermodulation) requirements.

All the diplexers are monitored at a central operating rack which indicates each diplexer's forward, reflected, and rejected power. This permits trouble shooting in an orderly and rapid manner. Electrically operated coaxial switching permits each station to be connected to the dummy load for individual testing. Air conditioning and chilled water are used to remove heat produced during operation.

The tower also holds one UHF-TV antenna below the FM antenna, plus three levels of two-way radio communications antennas at the 800 ft, 1,200 ft, and 1,400 ft (244 m, 366 m, and 427 m) levels. In addition there are individual single-bay CP antennas for each station, fed with a 3⅛-inch (79 mm) line.

The income projected from the use of the two-way radio antenna facilities helps defray the operating costs of the entire plant including the electric power bills.

This community FM antenna project demonstrates the technical feasibility for a large system with nine FM users. It also demonstrates that the full intent of FCC Docket 80–90 can be met to the broadcasters satisfaction, as well as its wider range of listeners.

The technology is now available to combine multiple FM stations efficiently and without problems. The difficulty is in bringing broadcasters together to start, plan, fund, and complete such a large undertaking.

Technical Advantages

Besides the financial advantages cited under the economics heading, there may be the competitive advantage of protecting the channel classification and using the same height antenna as the competitor. Other advantages include its emergency upper-lower half feature for transmission line or antenna half backup. The flat VSWR curve is highly useful for SCA and stereo operation. Stations sharing this type antenna will all experience less intermodulation interference than if they had separate antennas, but closely placed.

STATION DIPLEXING

Diplexers are passive devices used to combine the power of two or more stations and feed the combined power to a common transmission line and/or a common transmitting antenna. This system of utilizing one well-sited, high-quality antenna has become popular, convenient, and economical.

Wideband panel antennas, although expensive for use by one station, are very cost-effective for two or more stations. These antennas maintain their omnidirectional horizontal plane patterns and VSWR throughout the FM broadcasting band from 88 MHz to 108 MHz. Thus, they make the ideal antenna for multi-station diplexing.

Diplexer Economics

Diplexers permit several stations to be combined into a single master antenna. New channels at any power level may be combined in any order by connecting another diplexer in tandem to the previous unit. The first channel may be fed into a wideband antenna without a diplexer. When two stations are to be combined, the first diplexer is put into service. When the third station is added to the system, a second diplexer is required and so forth. Fig. 14 shows this arrangement.

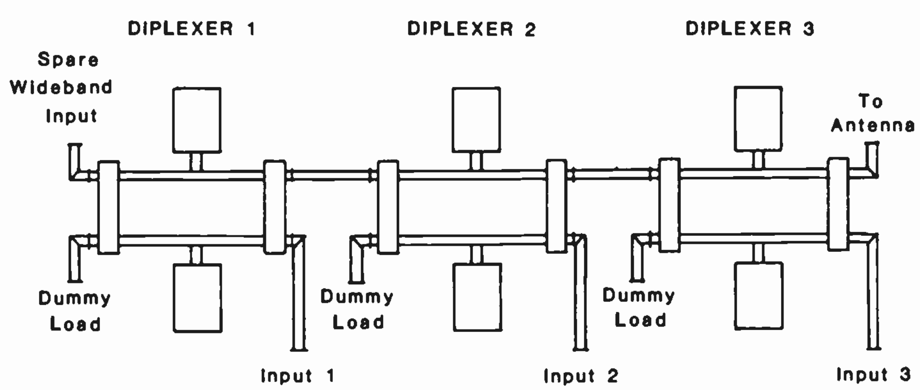

Figure 14. Three diplexers connected to provide combining facilities for three different stations for one community antenna. Note spare emergency wideband input port.

TABLE 8
Typical measured diplexer performance.
(Three Channels Into One Antenna)

Channel frequency	93.5 MHz	99.3 MHz	100.5 MHz
Input VSWR, plus minus 250 kHz	1.1:1	1.04:1	1.04:1
Isolation: From 93.5	—	− 80 dB	− 80 dB
From 99.3	− 59 dB	—	− 50 dB
From 100.5	− 80 dB	− 50 dB	—
From broad band port	− 56 dB	− 44 dB	− 39 dB
Amplitude Response:			
Carrier plus minus 250 kHz	0.15 dB	0.25 dB	0.35 dB
Group Delay, in nanoseconds:			
Carrier plus minus 250 kHz	25	27	38
Insertion Loss, carrier	0.23 dB	0.24 dB	0.23 dB

Each diplexer contains a pass through broadband input port and an injected frequency port. Nearly all uncombined diplexer power and other undesired products are absorbed by a dummy load connected to the fourth port. The third port goes to the antenna or to the next diplexer's broadband input port.

The combining of two different stations must be done without degradation to station. The important factors are amplitude, group delay, VSWR bandwidth, isolation, and insertion loss. Insertion loss is a continuing cost item as it consumes RF power that is generated by the transmitter at considerable expense. Table 8 shows the measured performance of a typical three-diplexer installation.

Diplexer specifications can be tailored to the specific requirements of the transmitters being used. Table 8 shows the measured performance of a typical three-diplexer installation.

Constant Impedance-Type Diplexers

The constant impedance-type takes its name from an operating characteristic of one of its components, the constant impedance of the broadband 3 dB hybrid. All of this type use two hybrids and cavities. Because of the use of hybrids, the constant impedance hybrid diplexer is sometimes called a *hybrid combiner*.

An efficient diplexer is not a complicated device, as it consists of two basic components, the two hybrids and two cavities. Coax is used to interconnect the components. Hybrids and cavities either have coaxial flange connections or are directly coupled. Some units are pressurized to keep moisture from tarnishing the cavities which may be silver plated or polished copper, in order to attain high Q.

A terminating load, rated at one-half the highest transmitter power being diplexed in that unit is connected to the reject port. In the event of failure of one or both cavities, half of the power will appear in this load before thermal and other sensors normally turn the affected transmitter off.

The hybrid, sometimes called a 3 dB coupler, is a four-port device. When power is fed into one port, it appears split 50% between two other ports, thus the name 3 dB coupler. Another very useful feature is that the two split powers are 90° apart in their phase relationship. The fourth port is isolated from the input port typically by 26 dB to 40 dB. If two of these hybrids are connected back to back, nearly all the power entering the first input port will appear in one of the output ports, and a second port will be isolated.

In TV use, a single hybrid is quite useful in feeding a turnstile batwing antenna, which requires split input power with a phase quadrature displacement. The old square quarter wave TV hybrid diplexers are similar in operation, but they are limited bandwidth devices and not suitable for wide-band use in FM community antenna diplexing.

FM diplexer hybrids are capable of extremely high power. They are usually made of large coaxial components with quarter wavelength coupling bars. Their large physical size and low Q greatly reduces power loss which rarely exceeds 0.05 dB (1.1%).

Many constant impedance diplexers use only reject cavities. Each diplexer contains a broadband input port and an injected frequency port. Nearly all uncombined

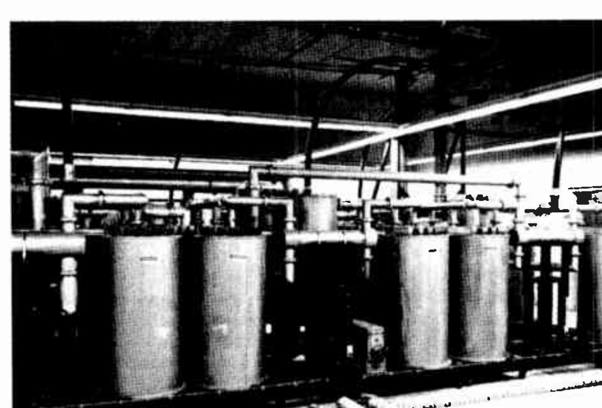

Figure 15. This Senior Road, Houston, Texas ten-port diplexing system, combines nine FM stations into one community antenna. It is capable of 350 kW total input power. (Courtesy Harris Corp.)

diplexer power and other undesired products are absorbed by a dummy load connected to the fourth port. The third port goes to the antenna or next diplexer's broadband input port.

A band reject diplexer is shown in Fig. 16. The signal from TX-1 splits equally in hybrid H-1. It passes by the cavities (C-1 and C-2) which are tuned to TX-2 frequency. The two signals of TX-1 combine in the antenna output port of hybrid H-2 since the two inputs to H-2 are equal in amplitude, but 90° out-of-phase, due to the action of hybrid H-1.

The signal from TX-2 splits equally in hybrid H-2 and are 90° out-of-phase with each other. Cavities C-1 and C-2 are tuned to the TX-2 frequency and present a short circuit to it. So the signal is nearly 100% reflected back to the inputs to H-2. These signals are 90° out-of-phase so they combine only in the antenna port of H-2 and go out to the antenna.

TX-1 frequency is not critical and can be any frequency within the FM band, as long as it is removed from the cavity frequencies by at least 1.0 MHz. However, it will work with some makes of reject diplexers when the separation is a minimum of 800 kHz.

The cavities tuned to TX-2 are not critical in their spacing from hybrid H-2. Because of the nature of the two hybrids, the VSWR remains low and is not affected by temperature variations. The isolation also remains high under these conditions.

Another advantage of the constant impedance notch diplexer is that any beat frequency or intermod product generated in the transmitter TX-2 will be absorbed in the dummy load since only TX-2 will be reflected. This is due to the frequency selectivity of C-1 and C-2.

When more than two transmitters are to be combined, the additional diplexers are merely added in series as shown in Fig. 14. Additional diplexers do not affect the performance of the rest of the system, and can be added at a later time if the need arises. Because of their simplicity, constant impedance diplexers are virtually maintenance free.

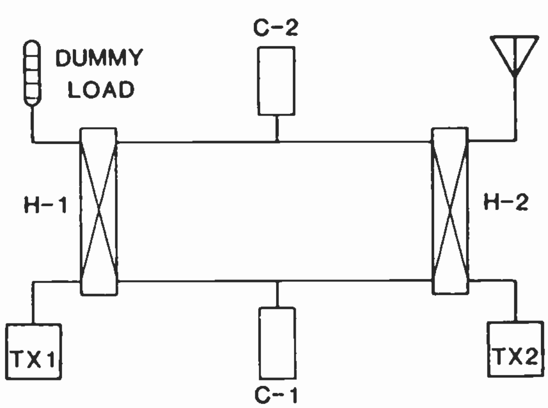

Figure 16. Basic constant impedance diplexer. See text for explanation of component functions.

Branched Starpoint Diplexers

This type does not use hybrids. Each transmitter feeds into a set of branching filters. In each set there is a bandpass cavity tuned to pass the operating frequency and at least one reject cavity tuned to the frequency of the adjacent channel to sharpen the skirt selectivity. If more than two frequencies are being combined, the middle frequencies have reject filters for both their adjacent frequencies.

All the filter sections connect to one common junction, or starpoint, which is the combiner's output. Coaxial cable lengths between each diplexer and the starpoint must be a defined electrical length for proper filtering action and low VSWR. This type of diplexer does not use an absorption load, as the small amount of rejected power is consumed by the rejected frequency transmitter and the antenna.

There is no broadband input, so adding channels requires that balanced modules be added on the output. If there is a failure of one branch, it will usually not take the others out of operation. Since there is no broadband port, the affected frequency cannot be switched as would be done with a hybrid diplexer system. However, the transmitter from the failed branch may be operated into one half of the antenna, while the output of the combiner, containing the unaffected channels feeds the other half, for an ERP reduction of 3 dB.

The principal advantages of a branched system are in space and price. There are fewer components, i.e., no dummy loads, no hybrids, and fewer cavities. They are frequently fan cooled, thus permitting the use of smaller cavities. This is all at the price of flexibility and, in some cases, performance.

Cavity Construction

In order for diplexers to work, a frequency selective electrical short circuit is required to be placed between the two hybrids. This is provided by high Q cavities.

During World War II, low-pass and high-pass filters were developed for VHF communications and radar. The need for microwave receivers with greater selectivity led to the development of magnetically coupled, quarter-wavelength long cavities. Improvements since the 1940s have made cavities with excellent loaded Qs and extremely low insertion loss.

Temperature stability improvement is the result of using invar steel, and the high Q results from silver plating and polishing the inside of the cavities. Cavity size for FM use varies due to the resonance mode selected by the design. Round cavities as small as 20 inches (508 mm) in diameter and 30 inches (760 mm) long have been used. Square types as long as 60 inches (1524 mm) using wave-guide modes have been used. Generally speaking, the larger the cavity, the smaller the RF loss through the cavity.

A very high loaded Q is necessary for a frequency spacing of 800 kHz, which is the closest frequency assignment in any specific community. Practical Q values vary from 1,000 to 12,000.

The power dissipated in heat will expand critical parts of the cavity, detuning it if the heat is not efficiently removed. Air blowers, cooling fins, or simple black paint can be used, depending on the amount of heat to be removed.

The cavities contribute most of the loss found in a diplexer. A diplexer with its two cavities tuned to the first possible channel 800 kHz away could have an efficiency of about 95% (0.25 dB loss). Efficiency goes up as the spacing between the passband and the reject frequency increases so that at 1.6 MHz it could be 96% and at 2.3 MHz, about 97%.

An extremely high Q would be excellent on the operating frequency but would not be useful on the FM sidebands. Using more cavities and stagger tuning them increases costs but does not completely solve the efficiency problem.

FM ANTENNA INSTALLATION ON AM TOWERS

The current trend is to locate FM transmitters in places where the best service may be rendered to the most listeners. This usually permits the maximum possible height to be used. Sometimes however, it may be economical and convenient to install the FM antenna on a tower used for AM broadcasting. If the steel AM tower is not base insulated but is grounded and shunt fed, the FM coaxial line may be connected to the tower, without any further problems.

Transformer Isolation

If the AM tower is insulated at the base, an isolation transformer may be used to couple the FM power across the base insulator without introducing objectionable mismatch into the FM antenna feed line. An isolation transformer is especially desirable for feeding high impedance AM radiators or AM radiators which are part of an AM directional antenna system which might be adversely affected by a quarter-wave isolation system.

These transformers have two tightly coupled RF coils which are resonant at the FM operating frequency. An air gap is provided for the AM power to pass through the two resonant loops. The capacity is quite low, resulting in a very high capacitive reactance placed across the tower base insulator.

Fig. 17 shows the internal basic construction of a typical isolation transformer. The insulation for AM under the top of the box may be high density polyethylene, teflon, or fiberglass. The metal top provides a rain shield as well as protection from dust, mud, or snow.

The use of these isolation transformers permits the AM tower to operate undisturbed by the presence of the FM antenna. It also allows the FM coaxial line to be connected in the usual manner, except for the placement of the isolation transformer. These have internal gas blocks and permit the passage of dry air pressure through the transformer via a plastic tube.

In addition to lower cost, the isolation transformer method has another advantage in directional AM tower use. It does not distort the AM radiator current distribution which may adversely affect the AM radiation pattern.

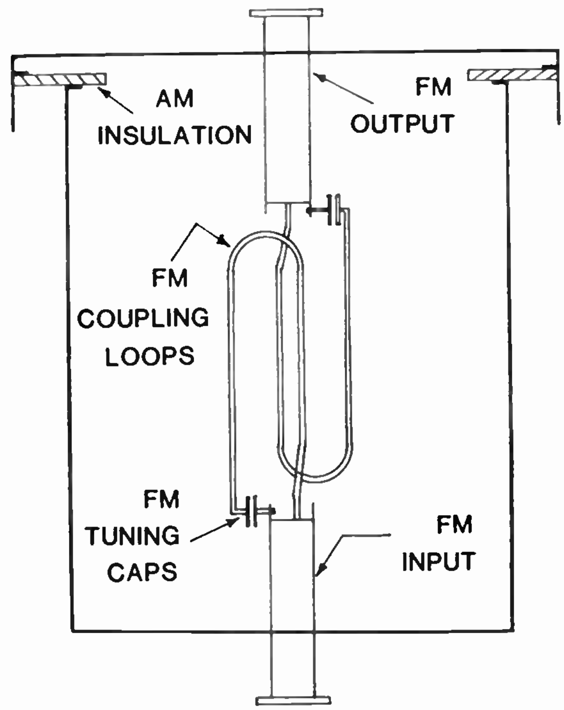

Figure 17. Typical AM-FM tower isolation transformer, used to decouple FM transmission line on a series fed AM tower.

Quarter-Wavelength Isolation

A less popular and older method is to use the technique of quarter-wavelength transmission lines. Simply stated, the opposite end of a shorted quarter-wavelength line has high impedance. This high impedance is placed across the AM tower base and may be successfully used to provide the necessary isolation. It is more difficult to physically accomplish this as the tower should be at least one quarter-wavelength high, and the FM antenna coax line must be insulated all the way down the tower. In practice the insulated part may be as short as 75° of line, as the line hangers and distributed capacity of the line tend to electrically increase the physically shorter line. For best results, the FM line should be placed within the tower body.

Guy Cable Considerations

The presence of continuous steel guy cables going through the FM antenna level on a steel supporting tower was studied by Jampro Antenna Company in 1968. It was found that guy cables had an effect of less than 0.6 dB in the azimuth pattern of a H-pol antenna. On V-pol the maximum variation was 1.8 dB on the azimuth pattern. The strongest effect is on CP where the azimuth pattern change was as great as 3.4 dB. The elevation pattern was also affected since the first and second nulls were filled as much as 4 dB.

In addition to pattern anomalies, the steel cables reradiate near the ground. This may cause RF feedback problems in some high power installations with low level audio equipment located in a building near the base of the tower.

Strong currents may be induced when the steel guys are in the immediate vicinity of the radiators. If that guy passes close to the side of the radiator, the field on that particular side of the antenna element will induce currents in the guy wire. The radiator currents can become unbalanced and the impedance of the element is disturbed, changing its VSWR and radiation pattern.

Because of these effects, it is common practice to break-up the guys using insulators, fiberglass rods, or plastic guy cable, within 10 ft (3 m) of the antenna radiators.

When a CP antenna is side-mounted on a guyed tower, the vertically polarized field will have an appreciable component parallel to the guy wire in its aperture and will induce currents in the wire. If the guys are continuous, a progressive wave traveling toward the ground will result, and will radiate most of its energy before reaching the ground. The energy will be radiated in cones concentric with the wire. A small amount of the V-pol power will thus be bled off.

Porcelain Insulators

If the FM antenna is side-mounted on an AM tower, which usually will have metal guys and porcelain break-up insulators, those insulators will probably be spaced several FM wavelengths apart. The induced currents will form standing waves on the sections between insulators and radiate multilobed patterns into space at many angles from the wire axis. If the sections between insulators happen to be of a resonant FM wavelength however, currents in the guy wires and their radiated fields will be considerable.[22] A single isolated piece of guy wire with its ends insulated can only resonate in multiples of one half wavelength, so this spacing of insulators must be avoided. In fact, with the capacitive end loading of the insulators, the resonant length of wire will be somewhat less than one half-wave, so ⅜ wavelengths should also be avoided. A quarter-wavelength is much better, but this would be quite expensive as it requires insulators every 30 inches (762 mm).

Alternatively, the guys through the FM antenna aperture on the tower could be replaced with plastic cable, which is transparent to RF energy.[25]

Nonconductive Guys

In order to eliminate FM pattern distortion, any guy cable going through the antenna level should be of nonconducting material. Plastic fiberglass (GRP) insulating rods as well as flexible plastic rope covered with a PVC plastic jacket can be used. The black jacket prevents deterioration due to ultra violet sunlight radiation, which may be injurious to the plastic strands of the rope. Plastic rope has been successfully used for more than 25 years.

Figure 18. A roll of plastic guy cable with eye and jaw end connectors in place. Diameter strength is equal to EHS steel stranded guying cable. (Courtesy Phillystran, Philadelphia Resins Corp.)

The idea is to remove metallic RF conducting steel guy cables from within the antenna aperture. The rest of the guy may be of steel construction. The length of the steel guy from its attachment point near the antenna to a point well below the antenna is simply replaced with an equal length of fiberglass rods, or plastic rope.

Plastic rope is available in continuous lengths of up to 1,000 ft (304 m) and kits are available for installing the end fittings. The cable is quite flexible as the Fig. 18 shows a 225 ft (69 m) length coiled up with its end fittings installed at the factory.

The cable may be purchased in strengths exceeding similar diameter steel guy cable. These strengths are shown in Table 9 for corresponding size of commonly used EHS (extra high strength) steel guy wire. Sizes smaller and larger than shown in the table are available.

INSTALLATION PROCEDURES

If the installation is not properly planned and carried out, there may be unwarranted delay and cost associated with putting the FM antenna on its support tower. The following suggestions are offered to avoid unnecessary delays and expenditures.

Planning The Installation

Because of the extremely high cost of rigging services, it is essential to carefully plan the installation. Make sure that all parts are on hand.

The installation of the antenna should be planned by a technically qualified person who must supply accurate tower construction information to the antenna manufacturer. If this information contains errors, these

TABLE 9
Phillystran type HPTG plastic guys.

Outside Diameter		Break Strength		Jacketed Weight		EHS
Inches	mm	Pounds	Kgs	1,000 Ft	300 m	Equivalent
0.20	5.1	4,000	1,815	18	8.2	3/16
0.29	7.4	6,700	3,039	31	14.1	1/4
0.42	10.7	11,200	5,080	55	24.9	5/16
0.46	11.7	15,400	6,975	69	31.3	3/8
0.53	13.5	20,800	9,435	93	42.2	7/16
0.58	14.7	27,000	12,247	115	52.2	1/2
0.63	16.0	35,000	15,876	142	64.4	9/16
0.68	17.3	42,400	19,235	167	75.8	5/8
0.73	18.5	58,300	26,445	195	88.5	3/4

will be carried through the design and fabrication of mounting hardware, and finally show up in the field to plague the installing crew, wasting time and money at every stage of the process.

The station should consider hiring a tower rigging firm that is financially qualified and mechanically well equipped to do the work. A written contract should exist between the station and rigging firm, with a fixed price. The rigging contractor should be licensed as a contractor in your state, and should post a completion bond. He should also supply an insurance policy holding the station harmless, and making the station and its personnel co-insured. Only in this manner will the broadcaster be protected in the event of injury or property damage.

The riggers should be knowledgeable about antennas and coax line, and should inspect the tower and check out the mounting design of the brackets before the full rigging crew arrives.

If any factors are discovered which appear to negate the installation design, contact the factory immediately. Particular attention should be paid to the following:

1. Fit of mounting brackets to tower member.
2. Freedom from interference of the mounts with gussets, leg flanges, guys, and their attachment points, tower face members, and obstruction lights.
3. Compatibility of transmission line and antenna input coax terminals.
4. Location of transmission line run relative to antenna input terminals.
5. Use of fiberglass guys on the tower in the region occupied by the FM antenna; refer to the AM Guying section in this chapter.
6. Availability of proper voltage, current, and cable size for deicers if required.
7. Adequacy of tower to carry the windload placed upon it by the antenna, particularly where radomes are used. This radome/antenna load should be checked by a competent structural engineer, as all antenna installations should be checked. This is usually required by the company carrying insurance on the tower.

Receiving And Unpacking

The boxes are usually numbered and the total number is indicated on each box; contact the shipper if not all boxes are delivered, or if equipment is received damaged. Do not store the material outdoors, boxed or otherwise.

As soon as the antenna is received, open and examine for shipping damages so that any necessary claims may be filed with the shipping company immediately. Check the material against the parts list and installation drawing.

The box with the installation drawing and instructions is usually marked. Open it first, so that the balance of the items may be easily identified and counted. Contact the factory immediately if any material appears to be missing or is damaged during transportation.

Do not call the riggers until all antenna and coaxial line at the site. Otherwise, unnecessary delays and costs may result.

Installation Tips

Broadcast antenna manufacturers furnish detailed installation procedures with their products. These instructions should be closely followed by the rigger. Together they will ensure a perfect installation saving time and money.

The following items are specifically called to the attention of the broadcast engineer (in addition to all those stated before) to permit proper installation and good performance for many years.

1. Follow manufacturer's instructions. See that the riggers also read these instructions.
2. Do not leave antenna parts where rain or moisture can enter. Store indoors and keep units capped as received.
3. Do not allow dirt or other foreign matter to enter any coaxial part.
4. Protect all antenna parts from physical damage and abuse.
5. Hoist antenna members carefully, with a tag line to prevent damage by striking against the tower.
6. Install on the tower as indicated by the manufac-

turer's instructions, remembering that bay number 1 is the uppermost top unit.

7. Riggers should lubricate "O" rings with a small amount of silicone grease before mating flanges.
8. The full complement of flange bolts must be used and they should be as tight as possible.
9. Tuners or individual element devices, if used, should be adjusted only after the entire antenna and tower installation has been completed.
10. Rigid transmission lines should be properly installed with two hangers per 20 ft (6 m) length, and with the inner conductor retaining pin on the top of each section.
11. If semi-flexible cable such as Heliax or Wellflex is used, it should be firmly tied down at least every 5 ft (1.5 m) for 3 inch (76 mm) line, and every 3 ft (1 m) for 1⅝-inch (43 mm) coax line. The line manufacturer's hangers should be used. The line should not be attached to the tower using wrap-lock straps.
12. After physical installation has been completed in accordance with the manufacturer's recommendations, the main transmission line should be pressurized with dry air through a dehydrator, air pump, or by using dry nitrogen gas. See the "Air Pressurization" section in this chapter for more information.
13. Dry air or gas pressure should be maintained at all times. Most antenna warranties are not valid unless this is done. It is the riggers responsibility to make certain that the entire coax and antenna holds air pressure.
14. The antenna system should be checked by a qualified rigger every time the obstruction lights are replaced, or if lights are not used, at least once a year. The rigger should look for vibration and storm damage, loose or broken coax hangers, and signs of arcing across exposed insulators. A dry rag soaked in 91% isopropyl or other solvent alcohol or equal should be used to wipe clean all exposed insulators in each antenna element. (DO NOT USE CARBON TETRACHLORIDE!)

STRUCTURAL CONSIDERATIONS

Most FM antennas in the western hemisphere are installed on the sides of a steel tower, between 18 and 60 inches (45 cm to 152 cm) wide. The antenna and its transmission line together with all mounting brackets introduce wind loading, in addition to their dead weight. The live wind loading is a result of the amount of physical surface presented to the wind. It is sometimes called the *wind catch area*. This consists of either flat or round antenna members, coaxial lines, mounting brackets, and hardware, all represented as surfaces which are exposed to the wind.

The dead weight of the antenna system is fixed and is always present on the tower. The live load is a variable, depending on the wind velocity, and is added to the dead load for the total amount present.

The standard wind load starts with an assumed wind velocity of 87 mph (139 m), which will produce a push of 35 pounds per square foot. (170.8 kgs/sq.m) With lesser wind speeds the wind push is less, and more with higher velocities. Various building codes determine the rated winds to be considered in the design of the tower system. While most of the United States has a 35 pound per square foot minimum rating, some parts of the country have higher requirements due to higher wind velocities. Some insurance companies may require even higher safe wind ratings.

ANTENNA POLE MOUNTING

Nonsymmetrical antennas may also be installed on a round pole, made of various diameters of steel pipe. Several antenna manufacturers supply these as a complete system and will optimize the horizontal plane pattern. The advantage of pole mounting on top of a tower or building is that the pattern may be more easily contoured. This provides more signal in the service area since the antenna orientation is not limited by a fixed triangle formed by a guyed tower.

TRANSMISSION LINE SYSTEMS

Two types of coaxial transmission lines may be used to feed FM antennas. One uses rigid coaxial line sections, each 20 ft (6.09 m) long and requires elbows, flanges, spring hangers and other devices.

The other has a semi-flexible coaxial line which is available in either air or foam dielectric, with fixed hangers. Semi-flexible cable is available on a spool whose diameter depends on the line size. EIA end flanges mate to the antenna flanges as well as other RF equipment. A typical semi-flexible coaxial transmission line layout is shown in Fig. 19.

A supply of dry air should be used with all air dielectric transmission line. Its purpose is to keep out moisture, which may find its way into the line. Dry air not only keeps the moisture from covering the internal plastic insulation, and thus arcing is greatly reduced. It also keeps the internal copper from corroding. Copper which has been exposed to moisture will turn dark brown and oxidize after time. Rigid as well as semi-flexible line in the 3 and 3⅛ EIA size which had not been pressurized have been measured with increased attenuation of nearly 4 dB per 100 ft (30.4 m) at 100 MHz. This is a power loss of 60%. See the section on "Air Pressurization" on how this may be accomplished.

Popular types and sizes of coaxial cable transmission line are shown in Table 10. The most popular are the semi-flexible air cables.

The safe power ratings shown in Table 10 are for a perfect VSWR of 1.0:1. It is considered good engineering practice to derate this by dividing the power in kilowatts by the expected VSWR. For example three inch Heliax rated at 36.8 kW at 100 MHz and divided by 1.1 derates it to 33.45 kW. Other increases

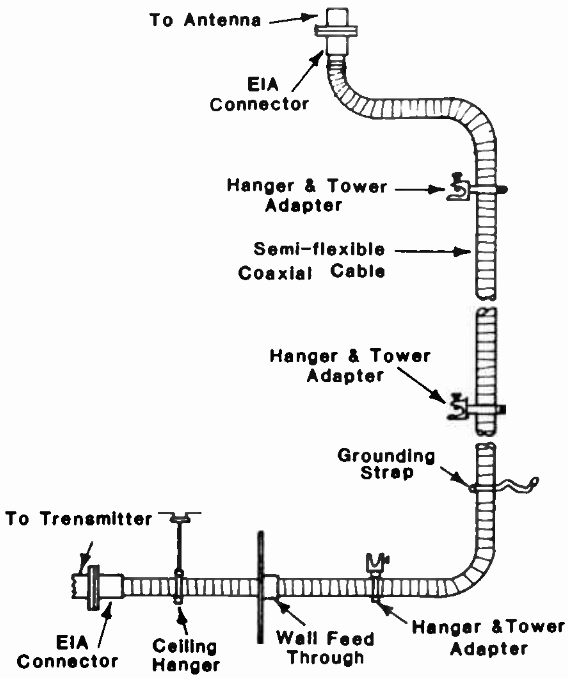

Figure 19. Typical semi-flexible coaxial cable installation on a tower. Number of various pieces of hardware depend on length and the diameter of the cable.

and decreases of coaxial cable ratings may be found in the catalogs of most manufacturers of transmission lines.

Ratings are for a VSWR of 1.0:1; ambient temperature of 75°F (24°C) with one atmosphere of dry air pressure. Rigid line is rated at 122°F (50°C). The LDF and HJ series are manufactured by Andrew Corp. of Orland Park, Illinois while the rigid line is by Shively Labs., of Howell Labs. Inc. Bridgton, Maine.

AIR PRESSURIZATION

If the antenna is operated without positive pressure of dry air or nitrogen, the manufacturer will not assume responsibility for failure under power. Moisture or even the accumulation of water within the coaxial transmission line is a very serious matter. Its presence causes the VSWR to rise. When a sufficient amount of moisture is present, arcing will take place burning the line or antenna radiating elements. High humidity or moisture will cause the inside of the coaxial transmission line to corrode over time, thereby increasing the line loss. For this and other reasons, the entire antenna system must be dry air pressurized.

After the antenna is installed and the transmission line connected, the system is purged with dry gas or dry air to remove trapped moisture before RF power is applied. A manually opened or pressure actuated purge valve is installed in nearly all FM antennas made by American firms. When the gas pressure is raised to 10 psig (0.68 atmospheres), the automatic pressure relief valve (if the antenna has one) will open up letting moist air out. The complete system purge requires a considerable volume of dry gas.

Before expending this amount, it is good practice to perform a quick check for major leaks. The system pressure is raised to a point below the relief valve setting, such as 8 psig (0.48 atmospheres) the source of supply shut off. A pressure gauge should be installed on the antenna side of the shut-off valve. The pressure, when corrected for temperature, should not fall to less than half its initial value in a 24-hour period.

If the pressure loss is more than this, the system should be checked with a leak detector, or soap suds,

TABLE 10
Coaxial transmission line.
(Characteristics At 100 MHz)

Line Type & Number	Nominal EIA Size	Attenuation In dB	100 Ft Eff. %	Safe FM Power-kW

1613-1	6-1/8	.050	98.8	161.0

to locate the leak. A pinched or missing O-ring is the most common cause for large leaks.

Once the system is known to hold pressure, it should be purged with dry air or gas. Either must be dry enough to have a dew-point well below the coldest temperature expected to be encountered. When using nitrogen, it should be of the "oil-dried" type, to remove nearly all the moisture from the gas.

Five to eight psig (0.34 to 0.48 atmospheres) should be maintained in the system at all times to ensure that no moisture will be able to enter. Very small leaks will pull in moisture, if the pressure is lower than suggested above, when the transmitter is turned off nightly. This is due to the pumping action due to expanded dry air/gas pressure cooling down, and contracting below the outside air pressure, during cold ambient temperatures.

PROTECTION FROM ICING

High Q antennas are subject to increased VSWR ratios as well as pattern distortion, with light to moderate coatings of ice. Low Q antennas such as the panel type are usually not affected in this manner. Where climatic conditions cause sufficient ice or in some cases snow to affect the antenna's performance, there are two remedies. The radiating element may be covered with a plastic cover, or, it may be electrically heated to melt or prevent the formation of ice on its sensitive surfaces.

Electrical Heaters

By far the more popular method of deicing is to order electrical heaters at the time the antenna is ordered. Electrical deicing equipment is supplied as an option and is factory installed. Kits are furnished for interbay connections, but the broadcaster must supply power from the building to the center of large arrays, or the bottom element on smaller antennas. Local electrical codes of course must be followed.

While a thermostat may be used with small total deicer wattages, a power relay operated by such a device is required and furnished with most electrical deicer kits by the antenna supplier. Due to high power costs, a sophisticated deicer control, which operates when both temperature and humidity conditions produce sleet or icing, is often required.

Most deicers use a resistance heating element which is inserted inside the antenna radiator arms. One manufacturer, however, uses a different method, dropping the 230/240 volts to a few volts with a transformer located at each bay level. The low voltage is passed through the ice sensitive arms of the radiator and connected to the far ends by a heavy teflon coated wire. The current return is by the stainless steel antenna element, whose ohmic resistance is sufficient to produce enough power heat loss to melt or keep the ice off. This method is becoming obsolete as the transformers are expensive and heating costs are rising, as hourly electrical rates go up. The voltage dropping transformers are not as efficient as direct heaters.

A word of caution when selecting a FM antenna with electrical heaters. Some deicers use 1 kW of power for each bay as described above and increase the wind loading by 225%. Others have a switchable power option feature using 125/500 watts per element, with only a 15% increase in windloading, when compared to an antenna without electrical deicers. The continuing cost of electrical deicers is a consideration of the operational cost of the station and should not be overlooked.

Automatic deicers are those with a thermostat for mounting near the antenna for accurate temperature sensing of the actual ambient temperature. The temperature zone of +20°F to +35° (−7°C to +2°C) is generally the most likely icing range, depending on humidity conditions. Deicers should be turned on at +35°F, prior to ice formation, because it is better to prevent icing than to remove it once it is formed. Power should be turned off when the temperature goes below +20°F since ice does not usually form below this temperature. Fig. 20 shows electrical deicers being wired.

Radomes

A radome is a protective dielectric housing for an antenna radiating element. Its function is to protect the antenna not only from ice, but snow and physical damage due to ice dropping from above. Radomes also protect the radiating element from environmental corrosive atmospheres.

The primary purpose of using radomes on FM antennas is to prevent the VSWR from rising with the formation of ice, if the site and height causes icing to occur during the winter months. Ice formation detunes high Q radiators, increases the VSWR, and causes vertical plane pattern changes. Fig. 21 shows a typical radome enclosing a radiator.

Ice may form on the radome but does not particularly affect the operation of the radiator if that ice is kept at least 0.05 wavelengths from the sensitive portions of the antenna element.

Radomes are particularly desirable in heavy icing environments where deicers are not adequate even with very high heat density. They are also useful in protecting antenna elements from falling ice when they are so exposed.

Radomes are cost effective with single channel high Q antennas where electrical deicer heating power costs are expensive. The deicer power cost is a continuing one, while radomes are a one time capital investment, which may be depreciated over time.

Radomes are generally composed of low-loss dielectrics with low values of dielectric constants and loss tangents. Laminated fiberglass, using glass cloth reinforcements, has a constant of about 4.1 and a loss tangent of about 0.15. Water absorption by the radome increases its dielectric constant and loss tangent. Materials which do not easily absorb water or those treated with a protective gel coat are often used to shed water and prevent the adhesion of ice.

Good radome designs take into consideration operating temperature, a relative humidity of 100%, safe wind pressures, ice, hail, snow loads, rain adhesion, wind and supporting tower vibration, fire retardant plastic, and the ability to safely withstand air contaminants over the useful life of the antenna. All these factors increase the cost, but are necessary for long, useful life. Radome shapes are dictated by the form of the radiating element in most instances.

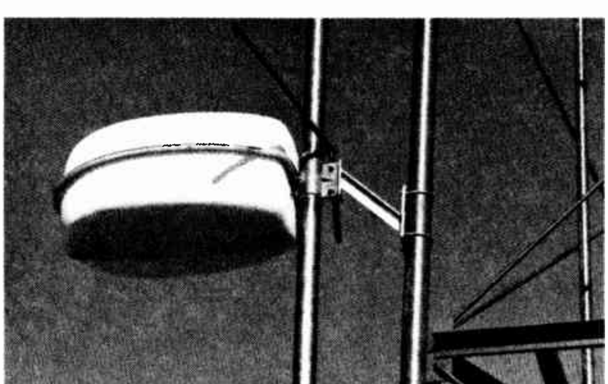

Figure 21. Radome over radiating element. Transparent to RF, it keeps ice from detuning high Q radiator. (Courtesy of Cetec Antennas)

In all cases radomes are supplied by the antenna manufacturer, and usually supplied in two pieces which are bolted together with stainless steel fasteners.

LIGHTNING

Because FM towers are usually located on high ground, hilltops, or high buildings, they require lightning protection since they are likely recipients of lightning strikes. The type of damage that can be caused by lightning to a FM tower varies. Smaller coaxial lines will usually melt; larger coax (1⅝, 3⅛) will also melt in some cases, and others will conduct the heavy current into the transmitter building to do damage there.

The FM antenna itself may heat, arc, melt, and otherwise be damaged. Holes in the outer conductor, burns, and melting at flanges are common. Teflon or polyethylene insulation will burn, depositing a film of carbon, causing further damage if RF from the transmitter continues after the strike.

Protection of the FM antenna system may be provided to some degree, by taking several precautions. The top of the tower should have a lightning rod, about one foot (0.3 m) higher than the uppermost obstruction light part. The FM antenna itself should be firmly grounded to the tower. If the coaxial cable is buried between the tower and the transmitter building, it must be at least six ft away from any tower base grounding system copper wire or strip.[26]

A ground system should be located immediately around the base of the tower. This should have a direct current loss of less than 10 ohms to earth ground. This low resistance may be obtained by using ground wires buried in the soil. Six radials spaced 60° if possible, buried as deep in the soil as possible and running out up to 150 ft (46 m) each, should provide a suitable ground of less than 10 ohms, even if the soil is shallow or rocky.[26]

Guyed tower anchors should also be grounded. This is covered in the chapter on "Design, Erection, and Maintenance of Antenna Structures." It is important to install the proper number of ground rods and/or copper wire radials in order to obtain a connection to earth ground of less than 10 ohms. In any event these ground rods or radial wires must be tied together with number AWG 4 or larger copper wire, or copper strap two inches (5 cm) minimum width. This is to provide for thousands of amperes of current flow for less than one second in the event of a direct lightning hit.

If the FM antenna is located on an AM insulated base tower, then the spark gap should be set at the lowest point providing protection for the highest AM modulation peak voltage.

Another way to protect the FM transmission line isolator (if one is used), as well as the tower and FM antenna, is to use a RF choke across the insulated tower base. This tends to reduce the static build-up voltages due to passing thunderstorm clouds, snow, hail, or dust storms. Arcovers due to these sources usually do not cause damage, but may trip the FM transmitter reflectometer since they will create a current flow through the reflectometer circuitry.

If the base insulated tower supporting the FM antenna is located in an area of regular thunderstorms, another way to protect both antennas from lightning is to ground the AM tower at the base, and shunt feed it. Several excellent methods exist. The folded unipole method not only grounds the tower for lightning purposes, but improves the VSWR bandwidth, so necessary for AM stereo. See the chapter on "AM Antennas" for several suggested methods.

FM SCA MULTIPLEXING

With a 92 kHz subcarrier and 110% modulation intermodulation products may be created due to mixing of the various subcarriers with their own harmonics within nonlinear devices. One such nonlinear device can be the antenna system.

Antenna linearity is determined by its VSWR response curve versus frequency. Phase delay in the antenna system is also important. In the past, with 67 kHz being the highest SCA frequency, the ±100 kHz bandwidth was considered sufficient. Now with a 92 kHz subcarrier and 110% deviation (82.5 kHz), the minimum bandwidth is ±130 kHz under 1.1:1 VSWR.[27] See "VSWR Bandwidth" in this chapter for more specific requirements and recommendations.

Tests have shown that 92 kHz is the frequency of choice for a new aural SCA service after 67 kHz.[28] The 92 kHz subcarrier produces lower intermodulation product levels and less interference to the main channel stereo service than 67 kHz.[29] It may be successfully operated in addition to stereo and existing SCA services.

Other nonlinearities in the exciter, and transmitter, plus multipath reception, receiver misalignment, and user mistuning are contributions to the received intermodulation distortion of the baseband signals. In addition these products can cause small levels of audible swishing beat notes in some types of FM receivers.

SPURIOUS FREQUENCIES

Interference to other stations within the FM broadcast band as well as to other services outside the band can be caused by RF intermodulation product energy developed between two or more FM broadcast transmitters. It may be due to coupling through a diplexer or coupling between two antennas. This phenomenon has been well documented.[12]

Detailed information on the susceptibility of various types of transmitters to interference from other collocated transmitters has not been thoroughly investigated. A method has been devised by which the mixing loss between two transmitters can be accurately characterized.

When RF energy from two or more transmitters is combined, new spectral components are produced by mixing the fundamental and the second harmonic of each of them. The dominant intermod product generated by each transmitter is at twice the transmitter's frequency. For example, 101.1 and 102.7 transmitters would produce two intermod signals appearing on 99.5 MHz and 104.3 MHz.

Second harmonic traps or low-pass harmonic filters in the transmission line of either transmitter prior to the diplexer have little effect on the generation of intermod products. This is because the harmonic content of the interfering signal entering the transmitter output circuit has much less effect on intermod generation than the harmonic content within the nonlinear device itself. The resulting intermod falls within the passband of the low-pass filters and outside the reject band of the second harmonic traps, so these devices offer no attenuation to intermod products.

Even the perfect diplexer by its very nature will reflect some of the undesired energy back to each transmitter, generating intermod products. The key to this problem is to keep that undesired power level as low as possible using proper transmitter output circuitry and tight diplexer specifications. Diplexed transmitter installations should be routinely checked for the presence of excessive intermod products.

HARMONIC FILTERS

FCC Rules Section 73.317(d) calls for the harmonics of FM transmitters to be up to 80 dB or more below the transmitter output. This requirement is usually met by using a low-pass filter which passes the station carrier frequency power but attenuates its harmonics.

The transmitter provides some harmonic attenuation of course, and is usually 25 dB to 38 dB for single ended amplifiers. The worst case harmonic is the third. Harmonic filters by several firms provide a minimum of 50 dB for harmonics from the second through the tenth. Adding the transmitter attenuation to that of the filter normally provides more than the required level.

The high level of rejection is made possible by using high-impedance (inductance) and low-impedance (capacity) coaxial sections for m-derived three to five section filters, with half-pi end sections. Harmonic filters are commonly made in three production schedules. One firm actually adjusts them to the customers operating frequency, so that there are no attenuation gaps in the higher harmonics. They are not tunable outside the factory as the insertion loss, and attenuation along with pass band VSWR are closely related. It requires sophisticated knowledge and equipment to properly adjust.

The insertion loss in the pass band varies from 0.05 dB to 0.08 dB while the rejection from the second through the tenth harmonic is from 50 dB to 60 dB, depending on the number of internal filter midsections. The VSWR in the pass band varies from 1.05 to 1.1:1.

Harmonic rejection is due to the very high VSWR on the harmonic frequencies which may be as high as 15 to 1. This rejected power is passed back to the transmitter amplifier.

Harmonic filters are available in straight rigid coaxial line sections and may sometimes be pressurized. Power capacity varies from 10 kW for 1⅝ EIA line size to 50 kW for the 6⅛.

ACCESSORY ANTENNA SYSTEM EQUIPMENT

Several other devices are associated with the antenna system. The dry air pressurization of coaxial transmission line was discussed under that heading in this chapter.

Reflectometers

The reflectometer is a device for detecting the ratio of power flow from the transmitter to the antenna (forward) and the rejected power back from the antenna (reverse). A short coaxial line section about 12 inches (305 mm) contains diode detectors, coupling loops and terminations to produce dc current, which drives a suitable VSWR meter.

Reflectometers are wide band devices and therefore must be placed AFTER the harmonic filter. Putting them between the transmitter and the filter causes them to read the rejected harmonic power along with the reflected, thus giving an erroneous reading.

Dummy Loads

A very useful test device in an antenna system is the terminating load. At least one is needed when two amplifiers are combined and fed to the antenna, or when a number of diplexers are used in a community antenna arrangement. Dummy loads are available in several power levels up to 50 kW and are cooled by air. Water cooling types are also available.

RF Switches

Often used with a dummy load, coaxial line switches are available to provide electrical or manual switching of transmitter power to diplexers, antennas, standby transmitters, etc. They are not pressurized.

2.7 Antennas for Television Broadcasting

Thomas J. Vaughan
Micro Communications, Inc., Manchester, New Hampshire

INTRODUCTION

This chapter begins with a review of technical terms and FCC considerations. This is followed by a review of antenna design considerations as they relate to these demands, as well as a review of specific applications. The chapter concludes with a review of current broadcast antennas and antenna systems.

TECHNICAL TERMS

Definitions of the following terms, consistent with FCC and industry usage, are important to the discussions in this chapter.

Effective Radiated Power

The product of the antenna input power and the antenna power gain is the effective radiated power (ERP).

Polarization

The polarization (the orientation of the electric field) can be linear, horizontal, or circular. If circular is used, the term ERP applies to the horizontal and vertical components separately.

Azimuth Pattern (Horizontal Plane)

An azimuthal pattern is a plot of the free-space radiated field intensity versus azimuth angle at a specified vertical angle with respect to a horizontal plane (relative to smooth earth) passing through the center of the antenna.

A horizontal pattern is an azimuthal pattern when the specified vertical angle is zero.

For higher gain antennas where beam tilt is employed, the azimuthal pattern at the specified beam tilt is significant. In general it has been customary to determine television broadcast antenna radiation by an azimuthal pattern at the specified beam tilt and a sufficient number of vertical plane patterns taken at various frequencies in the channel.

An omnidirectional antenna is defined as one that is designed to radiate the same signal in all azimuthal directions. Antennas with variations up to ±3 dB have rendered satisfactory service and are considered to be omnidirectional.

A directional antenna is one which is designed to radiate more signal in one azimuthal direction than in other azimuthal directions.

Vertical Pattern (Elevation Plane)

The vertical pattern is a plot of free-space radiated field intensity, measured in the far field versus vertical angle in any specified azimuth plane, which contains the center of the antenna and the center of the earth.

The far field or Fraunhofer region, as usually defined, extends beyond a point where the distance between the transmitting and receiving point is

$$\frac{2a^2}{\lambda}$$

where "a" is the length of the radiating portion of the antenna and λ is the wavelength.

A requirement for the broadcast service is that a free-space radiated field should not be influenced by the proximity of the earth in such a way as to set up a nonuniform field over the antenna aperture. Proper precautions must be taken to accomplish this.

Antenna Gain

Gain is the ratio of the maximum power output at any angle from the subject antenna, to the maximum power from a thin, loss-less, half-wave, horizontally polarized dipole having the same input power.

Antenna gain depends on several factors, including:

- The amount of power concentrated in the maximum direction.
- Losses in the antenna, which include ohmic and other losses such as energy radiated at polarizations other than the desired one.

The amount of power concentrated in the maximum direction can be determined by a comparison with a reference antenna or by integrating the total power flow through a sphere, which is done by taking a sufficient number of vertical and azimuthal patterns.

Both methods are capable of giving accurate results when the proper precautions are taken. Ohmic losses are taken into account in the comparison method or can be calculated when using the power integration method. Cross-polarized radiated energy can be measured. The measurement of gain must be carefully done with a full knowledge of all the problems that are involved. The measurement of gain used in the calculation of ERP for a circular polarized antenna must be made relative to a horizontal dipole. The directivity gain of a ½-wavelength dipole antenna relative to an isotopic antenna is 1.64. The gain of a circular polarized transmitting antenna relative to a "like" circular polarized receiving antenna will be 3 dB higher than that of a horizontally polarized dipole receiving antenna.

Gain requirements for a television broadcast antenna depend on the transmitter power, economics, and field-intensity requirements as determined by the terrain and population distribution.

The maximum ERP (effective radiated power) currently permitted by the FCC is:

Channels 2 to 6	100 kW
Channels 7 to 13	316 kW
Channels 14 to 69	5000 kW

Economics is a factor in antenna choice. As a general rule, for a required ERP the combined costs of transmitters and antennas are less when a higher gain antenna is used.

Impedance

Input impedance is the complex impedance looking into the antenna terminals throughout the television channel.

Most antennas are designed for the same input impedance as the standard transmission line at the antenna terminal. Impedance matching requirements for television antennas are generally more severe than for other types of service because reflected energy, which would occur when the antenna does not terminate the line properly, can cause ghosting and voltage peaks on the transmission line, which could result in damage to the antenna, couplings, and transmission line.

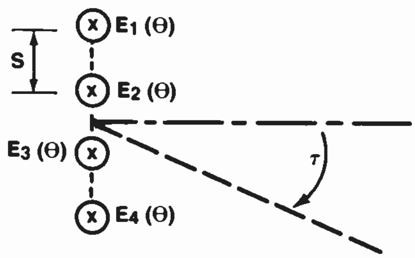

Figure 1. Elevation pattern calculation.

RADIATING CHARACTERISTICS

The television broadcast transmitting antenna should have an omnidirectional pattern in the azimuth plane and a narrow beam in the elevation plane. For an omniantenna the gain is approximately one per wavelength per like polarization. Most broadcast antenna elements are spaced one wavelength apart, therefore, the gain of a linear polarized antenna is approximately equal to the number of elements.

Elevation Pattern

The elevation pattern is the product of the element pattern times the array pattern.

$$F(\theta) = E_n(\tau) \sum_{n=1}^{N} A_n e^{j[(2\pi ns)\sin\tau + \delta_n]}$$

where: $E_n(\tau)$ = element elevation pattern
$\approx \cos^m(\Theta)$
s = element spacing
τ = elevation angle
δ_n = phase of nth element
A_n = amplitude of nth element

The resulant antenna elevation pattern for a four-element array pattern spaced 1.02 wavelength with a $\cos^2(\theta)$ element pattern is shown in Fig. 2

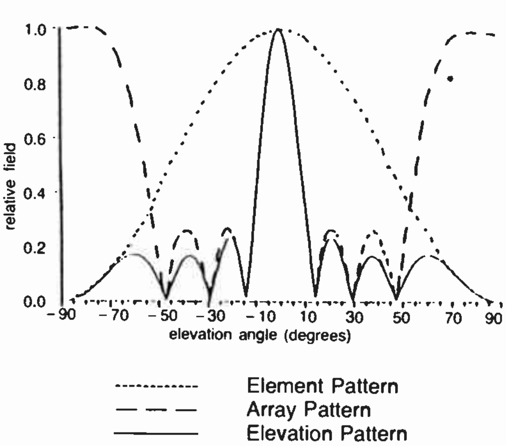

Figure 2. Elevation pattern for a four-element array with $\cos^2(\theta)$ element pattern and 1.02λ element spacing.

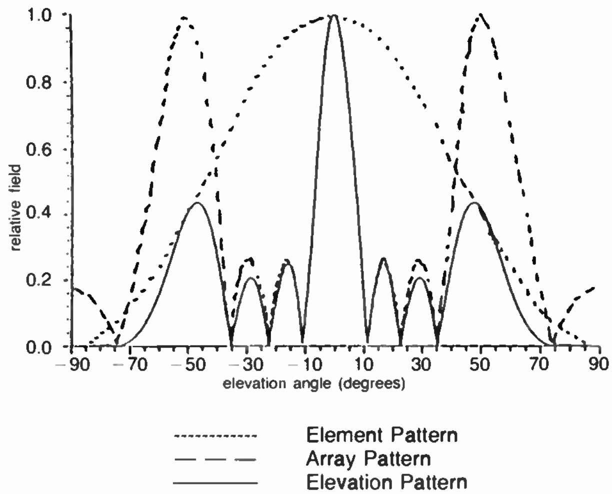

Figure 3. Elevation pattern of four-element array with $\cos^2(\theta)$ element pattern and 1.30λ element spacing.

As the spacing between the elements in the array pattern is increased, "grating" lobes begin to move closer to the main beam. The element pattern will no longer drive the grating lobe to zero at ±90°, resulting in high side lobes.

Fig. 3 shows the patterns for a four-element array with 1.30 λ spacing. Although the main beam will narrow as the element spacing increases, energy will be lost in the high side lobe resulting in an overall loss of gain. The optimum spacing is approximately one wavelength for a cos θ element pattern. Fig. 4 shows power gain versus element spacing for multiple bay antennas.

Azimuth Patterns

The ripple content of the azimuth pattern is dependent on the element pattern and the distance to the phase center as illustrated in Fig. 5.

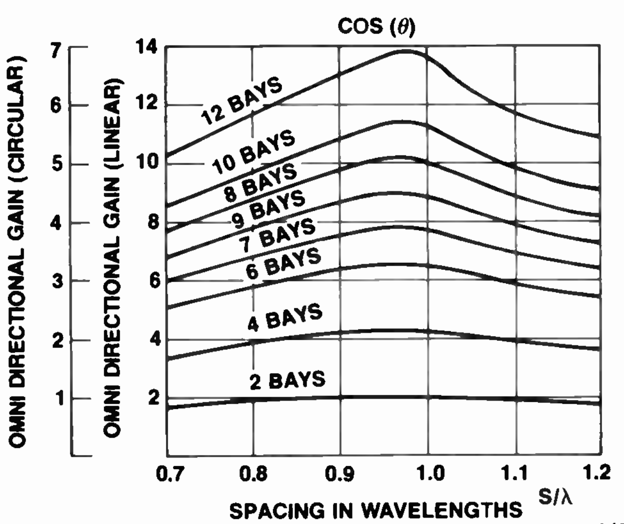

Figure 4. Power gain versus element spacing.

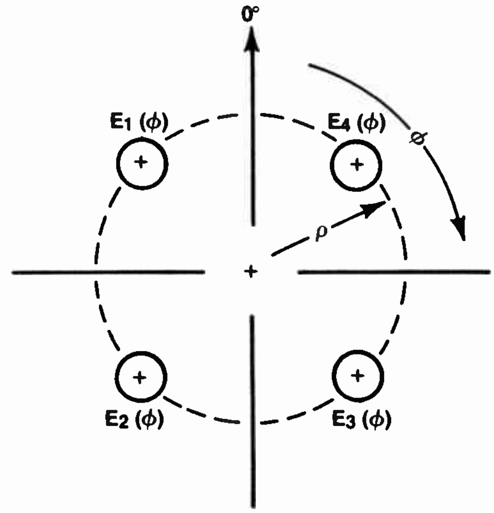

Figure 5. Azimuth pattern calculation.

$$F(\phi) = \sum_{n=1}^{N} E_n(\phi)\, A_n e^{\,j[(2\pi)\cos(\phi - \phi_n) + \delta_n]}$$

where: $E(\Theta)$ = element pattern
ϕ = azimuth angle
δ_n = phase of nth element
A_n = amplitude of nth element
ρ = distance to phase center (in wavelengths)

The value of ρ for panel antenna is dependent on the panel width. The value for a coaxial slotted antenna is dependent on the size of the coax line which in turn is dependent on the power handling capability of the line.

The value of ρ for waveguide slotted lines is dependent on the mode of operation which is a minimum of a half wavelength. This makes waveguide fed slot antennas practical only at UHF frequencies.

For some antennas, such as cross dipoles or turnstiles, the value of ρ is zero. Others such as panels, or slotted coax, or waveguide have a value of ρ from 0.25 λ to 2.0 λ. Fig. 6.

The ideal element pattern for a three-sided tower is E = cos (θ); and for a four-sided tower it is E = $\cos^2(\theta)$. The ripple content of four panels with a $\cos^2(\theta)$ element pattern and phase center spacing of ρ = 0.5, 1.5 is shown in Fig. 7.

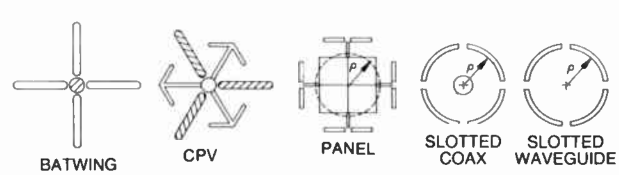

Figure 6. Azimuth pattern of four-side panel antenna viewed from the end.

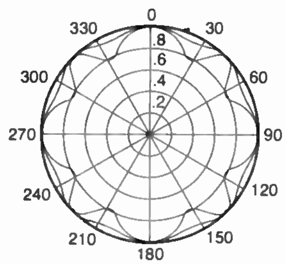

Figure 7. Arrangements of radiating elements. Azimuth versus relative field.

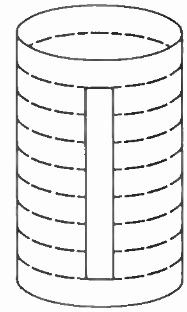

Figure 9. Slot in cylindrical sheet.

RADIATING STRUCTURES

Slot Antenna

The slot antenna is similar to a dipole.

Currents in the slot antenna spread out over the entire sheet (in which the slot is cut), and radiation takes place from both sides of the sheet.

The resemblance between the two becomes even more pronounced when it is recognized that the field patterns of the two will be equivalent if the physical dimensions of the slot and the cross-section of the dipole are the same.

Furthermore, the impedance of the slot is proportional to the admittance of the dipole of the same dimensions by the relationship

$$Z\,\text{slot} = \frac{35{,}467}{Z\,\text{dipole}}$$

and the bandwidth characteristics are essentially the same for both.

Actually, the above discussion is rigorously accurate only if the sheet is of infinite extent, but it is substantially correct if the edge of the sheet is half a wavelength from the slot.

Bending the sheet into a cylinder results in another form of slot antenna which also takes on characteristics of a stack of coaxial rings as shown in Fig. 9.

The slotted cylindrical tube can have an inner conductor and be coaxial in form or have no inner conductor and be a cylindrical waveguide.

Panel Antennas

A panel antenna has either dipoles or loops mounted $\lambda/4$ in front of a reflecting sheet. These antennas will have a directional [$(\cos(\theta)$ or $\cos^2(\theta))$] pattern in the azimuth and elevation planes depending on how it is mounted. Fig. 10 shows typical panel antenna configurations.

The pattern of a panel antenna is directional since the energy radiated from the element sees its image in the ground plane resulting in a $\lambda/2$ spaced end-fire radiator. The dipoles in the *doublet panel* are spaced $\lambda/2$ and are effective in eliminating downward radiation.

Traveling Wave Antenna

Traveling wave slot antennas can be either resonant (*standing wave*) or nonresonant (*traveling wave*). Most are bottom-fed. When the far end is shorted, an infinite standing wave is set up in the transmission line (either coax or waveguide). When the slots are appropriately sized and spaced, energy will be coupled out. The amplitude and phase developed across the aperture will result in a high-gain antenna. The bandwidth requirements for broadcast limits this technique to narrow band or single channel applications. Several traveling wave antennas are illustrated in Fig. 11.

The most common bottom-fed traveling wave array is the nonresonant slot array. The number of half-wavelength slots arranged about the periphery is dependent on the shape of the pattern desired. The slots, circumferentially arranged around the antenna structure, are usually displaced by $\lambda/4$ and spaced vertically one wavelength apart. The slot coupling from the bottom to the top increases, since the power

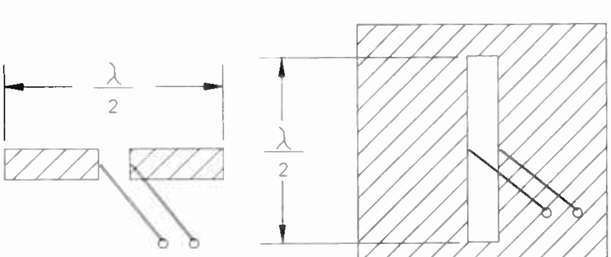

Figure 8. Dipole/slot equivalence.

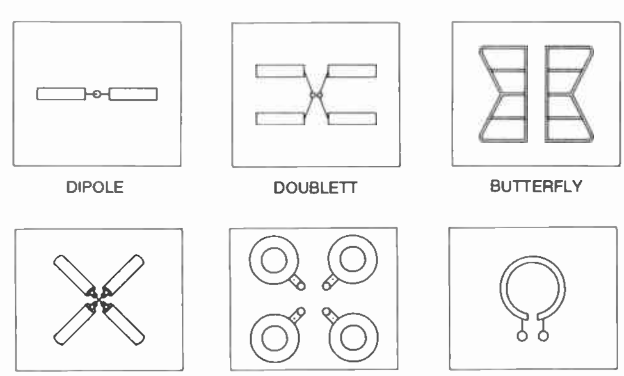

Figure 10. Panel configuration.

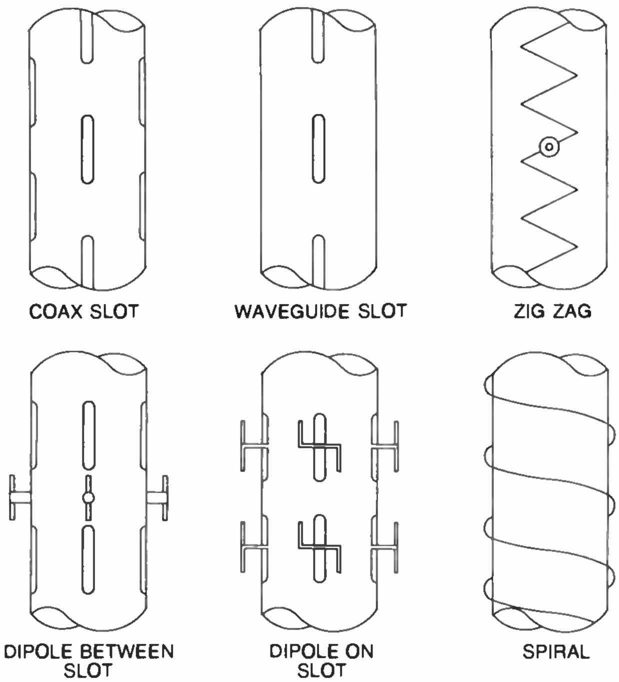

Figure 11. Traveling wave antennas.

radiated progressively reduces the power on the line. This method produces an amplitude taper across the aperture that provides null fill. With all nonresonant arrays, there is a small amount of energy left over. This is radiated in specially designed end-loaded slots or in the opposite polarization.

Circular polarization can be obtained by orienting successive slots 90° and exciting them in phase quadrature, or exciting a vertically polarized radiator located near the slot.

The linear polarized spiral (helix) is essentially a strip transmission line mounted over a ground plane; the spacing controls the radiation. Each element is a $\lambda/2$ radiator, and because of the orientation, the vertical components cancel. The choice of pitch angle and length along the circumference of the spiral, will result in very good horizontally polarized broad-side radiation.

The circular polarized spiral or multi-arm helix consists of multiple wires mounted around a large cylinder forming a current sheet. The optimum parameters are a complex function of the number of arms, the length of one coil, and the spacing to the support pole.

Excellent circularity can be obtained since in any heading the radiation is essentially that from a current ring.

ERP

In determining the ERP required to serve the area under consideration, there is a trade-off between using a low-power transmitter and a high-gain antenna, or high transmitter power and low antenna gain.

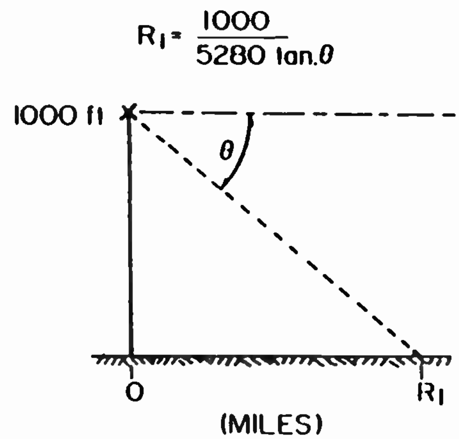

Figure 12. Elevation angle patterns for VHF antennas.

For VHF antennas, the transmitter power to antenna gain ratios are fairly well established. For channels 2 to 6, antennas usually use gain values from about four to six depending upon the length of the transmission line run. For the channels 7 to 13, band gain values vary from 12 to 18. For UHF antennas, higher antenna gains are required. Because of the much shorter wavelength at UHF frequencies, antenna with gains on the order of 20 to 30 can be built economically. At $0.10 per kW/hr, it costs $1,500/yr to generate 1 kW of RF power for a typical UHF TV station.

However, the higher gain results in narrowing the main beam. For a given transmitter input, the high gain antenna may sacrifice local coverage for more distant coverage. As the gain of the antenna increases, the beamwidth narrows. The position of the nulls and side lobes will move out from the tower.

The distance in miles from the tower is:

$$R = \frac{H}{5{,}280 \tan\theta}$$

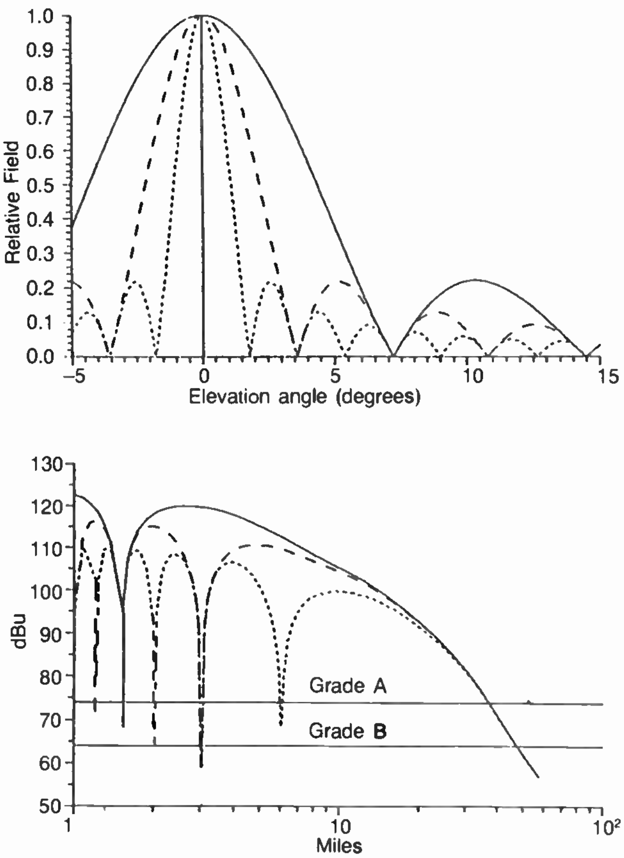
where: H is the height in feet and
θ is the elevation angle

Field Strength

The elevation pattern and single strength versus distance are shown in Fig. 13 for a UHF antenna on a 1,000 ft tower with constant ERP but different amounts of antenna gain.

Note that if the ERP and height above average terrain (HAAT) are held constant, there will be no change far in the far field signal strength. Fig. 13 shows there is no change in relative field for the three normalized antenna patterns from 0° to 0.5°. This corresponds to the radio horizon to 20 miles.

As the gain of the antenna is reduced, the main beam will widen from 1.6° (gain 40) to 7.2° (gain 10). The null will move from six miles to 1.6 miles. The signal strength near the antenna will increase by 10 to 20 dB. It should be noted that this increase makes a very strong signal (100 dBμ) much stronger (120 dBμ).



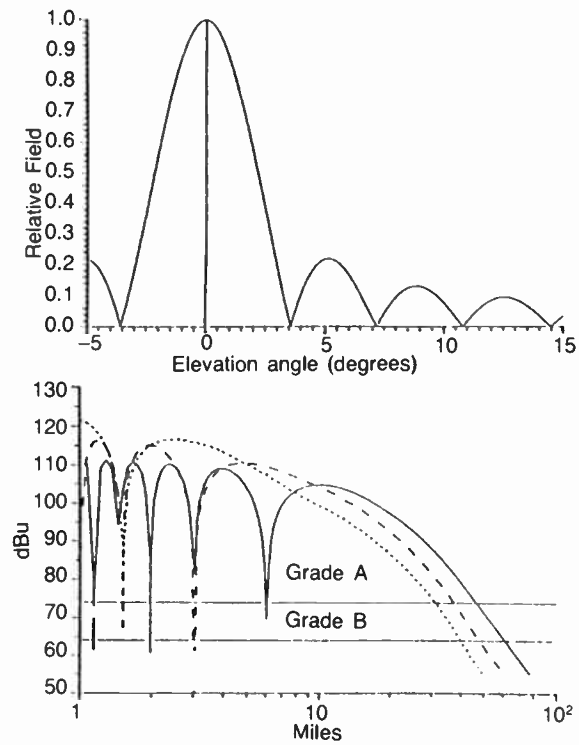
Curve	Transmitter Power	Antenna Gain	ERP
....	60 kW	40	2,400 kW
— — —	120 kW	20	2,400 kW
———	240 kW	10	2,400 kW

Figure 13. Signal versus antenna gain at UHF.

Therefore, if a higher gain antenna is contemplated, the local field intensities should be calculated, using the FCC (50, 50) propagation curves. It is desirable to maintain a 100 dBμ level over the important local area to be covered. Most UHF antennas are designed to accomplish this with an ERP of the order of 2.5 megawatt at 1,000 feet. In hilly terrain, it may be desirable to increase the field by 10 dB or more; and in heavily populated cities with large buildings, by 6 dB or more. The field intensity specified by the FCC for the different grade levels is shown in Fig. 14.

	LoV	HiV	UHF
Channel	2–6	7–13	14–80
City Grade	74 dBμ	77 dBμ	80 dBμ
Grade A	68 dBμ	71 dBμ	74 dBμ
Grade B	47 dBμ	56 dBμ	64 dBμ

Figure 14. Field intensities for specified contours.



Curve	Transmitter Power	Antenna Gain	ERP	HAAT
....	120 kW	20	2,400 kW	500 ft
— — —	120 kW	20	2,400 kW	1,000 ft
———	120 kW	20	2,400 kW	2,000 ft

Figure 15. Field intensity versus antenna height.

If fields of this order cannot be achieved with a high gain antenna, the transmitter power should be increased.

Relative field and field intensity versus distance are shown in Fig. 15 for a fixed antenna gain on a tower of 500, 1,000, and 2,000 ft.

POLARIZATION

Polarization is defined by the plane of the electric vector (E). Elliptical polarization is the most general form.

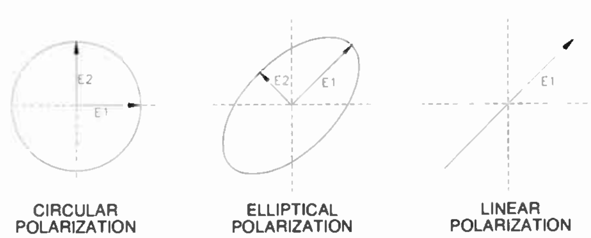


Figure 16. Polarizations.

In general, an elliptically polarized wave may be expressed in terms of x and y components given by:

$$Ex = E_1 \sin(\omega t - \beta z)$$
$$Ey = E_2 \cos(\omega t - \beta z + \delta)$$

The condition for linear polarization is when either E_1 or E_2 is zero with the orientation usually horizontal. The condition for circular polarization is when $E_1 = E_2$ and δ equals 90°, i.e., the two components must be quadrature in both space and time.

The transmitted wave of FM and TV broadcasting signals is specified by the FCC to be linear and in the horizontal plane. AM radio on the other hand is linear and in the vertical plane.

FCC regulations permit the radiation of circular polarization (CP) provided the component does not exceed the licensed ERP.

The possible advantages of using circular polarization for television are:

1. Less critical receive antenna azimuth orientation; permitting good reception on all types of indoor antennas including rabbit ears, whips, and rings.
2. Improvement in service and penetration because the two orthogonal fields (horizontal and vertical) have the same power, giving a power density twice that for a horizontal signal alone.
3. Improved coverage at the fringe area, due to twice the power density. Improvements on the order of 3 dB can be expected, moving the Grade B contour out by a calculated five to eight kilometers.

Many of the stations that changed to CP also moved their transmitting plants and changed the heights of their antennas, making a direct measured signal comparison between horizontally polarized (HP) and CP not possible. Experiences reported by stations using circular polarization indicate:

1. Receiving antenna orientation is less critical, specifically for rabbit ear and whip antennas.
2. Fringe area coverage has improved.
3. No ill effects have taken place.
4. No change in adjacent or co-channel interference has been reported.

BEAM TILT

Beam tilt is sometimes used to aim the main vertical beam tangential to the earth (toward the radio horizon), if the relative height of the antenna is such that substantial energy is being radiated above the horizon. The distance to the radio and optical horizon can be determined from Fig. 17.

Note that the height over the service area may not necessarily be the height over average terrain, especially in mountainous areas. Also, if a body of water limits the service area, or as in the case of Los Angeles, with the transmitter on nearby Mt. Wilson, it may be desirable to mechanically tilt the main beam to a point somewhat below the radio horizon.

In some cases, beam tilt may be desirable to improve

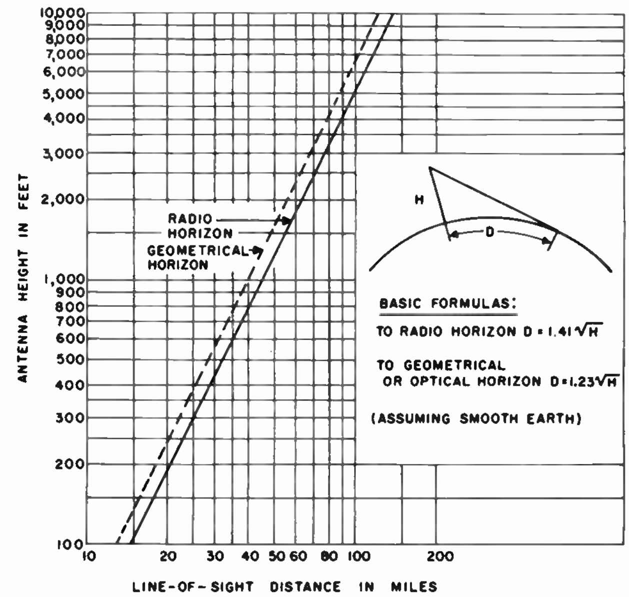

Figure 17. Distance to radio horizon versus height.

local coverage. Electrical beam tilt can be used but it reduces the power gain, especially for a higher gain antenna. However, the increase in local coverage is generally a more important consideration than the slight loss of power gain. Electrical beam tilt is accomplished by delaying the energy fed to upper elements or the upper section of a split-feed antenna, as shown in Fig. 18.

NULL FILL

The amount of null fill, and the number of nulls that need to be filled, depends upon how close the populated area is to the transmitter site. Allowance should be made for population movement towards the site in the future.

If the transmitter site is in the center of the population area or on the edge of it, consideration should be given to having null fill.

The exact amount of first and second null fill is not critical. Anything greater than 5% will usually result in signals much greater than *city grade*. The null depth (dB) in signal strength will correspond to the difference between the first null and first side lobe (dB).

The effects of null fill on signal strength is shown in Fig. 19.

A combination of null fill and beam tilt is shown in Fig. 20. A beam tilt of 1° will usually result in a 10 dB improvement in near-in coverage. Note that null fill and beam tilt have little effect on distant signal coverage.

POWER CAPABILITY

Power in television broadcast transmission systems is usually in terms of *peak power*, which is the

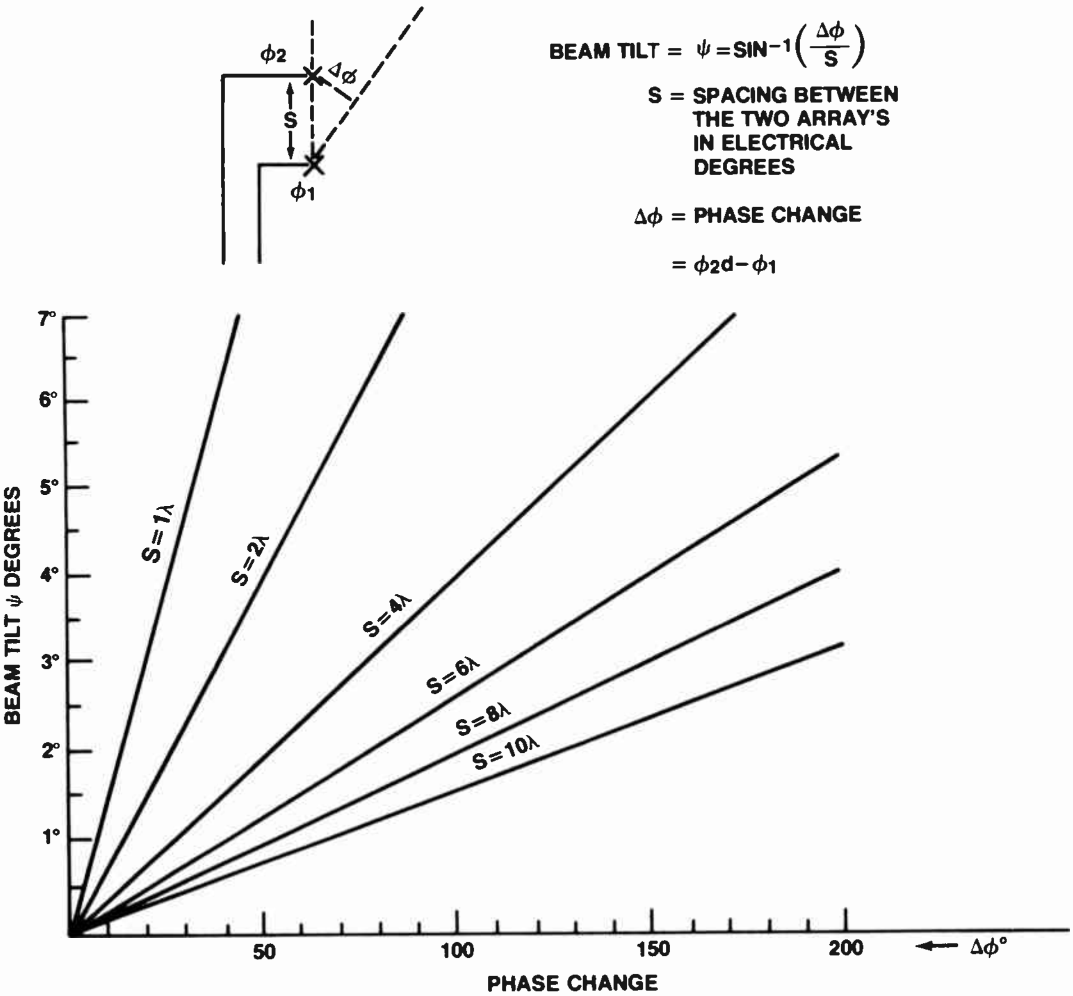

Figure 18. Beam tilt versus element phase change (Δ,φ).

instantaneous power developing during the peak of the synchronizing pulse in the visual transmitter. Since the black level signal is 0.75% of the total voltage value of the pulse, the black level power for a totally black picture is 56% of the peak-to-peak sync power. The duty cycle of the synchronizing pulses, both horizontal and vertical, adds about 4% to this power so that black level power is 60% of the peak TV power. Since the aural transmitter is usually 10% of the peak TV power, the total heating or continuous wave (CW) power of the TV signal is 66% of the peak TV power. The average power level (APL) of the video signal with typical program measures over a long period of time, 4.32 dB (37%) below the peak TV power.

The design of all TV antennas should allow for a sufficient safety margin to handle the peak-to-peak sync level, imperfections in the transmission line, VSWR, changes in pressure, and the aural power. Long transmission lines feeding the antenna will usually attenuate this figure by 10% to 20%.

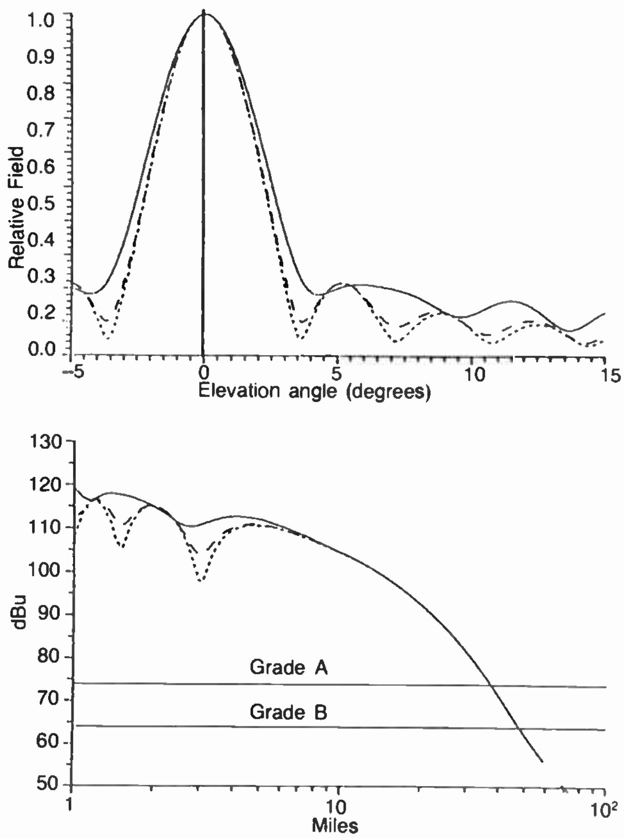
Unwanted Antenna Radiation

The antenna pattern is the product of the array pattern times the element pattern. The array pattern for one wavelength spacing has a downward and upward lobe as large as the desired main lobe. If the element pattern is not a $\cos(\theta)$ function, the element pattern will not drive the array downward lobe to zero, resulting in a very large signal in the vicinity of the tower base. Fig. 21 shows the resultant antenna pattern with a $\cos^{1.0}(\theta)$, where N = 0.0, 0.5, and 1.0.

Care should be exercised in making sure the element pattern has a distribution in the elevation plane of $\cos(\theta)$ or $\cos^2(\theta)$.

A well designed antenna system should not create a nonionizing radiation problem. The tower height is usually selected for maximum signal coverage and should therefore be high enough above the ground so the downward radiation is well below the safe ANSI levels.

Equally important would be the power density level



Curve	Null Fill	Transmitting Power	Antenna Gain	ERP
------------	5%	120 kW	20	2,400 kW

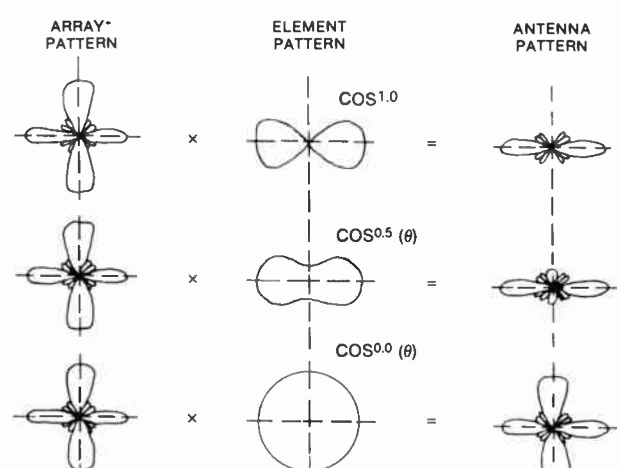
on nearby towers, which could result in tower maintenance personnel being exposed to high energy levels when in the main beam of the antenna on a nearby tower.

The distance in feet along the main beam to the 1 mW/cm^2 contour for maximum ERP and the height above ground to the 1 mW/cm^2 contour is listed in Fig. 22.

ANTENNA CHARACTERISTICS

Antenna Input Impedance

The primary purpose of an input VSWR specification is to insure a good match to the transmission line. If the mismatch is a great distance away, the reflected power may be of such magnitude that it travels back to the transmitter where it is will be re-reflected back to the antenna and radiate. It will then appear as a secondary image or ghost on the television picture.



*Six Bays, One Wavelength Spacing

Figure 21. Pattern multiplication.

Service	Low V	High V	UHF
ERP	100 kW	316 kW	5,000 kW
EIRP	164 kW	518 kW	8,200 kW
Distance to Nearby Tower	89 ft	163 ft	624 ft
Minimum Height Above Ground	43 ft	72 ft	305 ft

Figure 22. Distance to 1 mW/cm² level.

The image is delayed by twice the length of the transmission line.

Subjective experiments have established that the reflection at the carrier should be no greater than three percent of the incident voltage.

Empirically derived data of objectional reflection VSWR that will cause ghosting as a function of distance in microseconds from the transmitter to the antenna is shown in Fig. 23.

The dashed line represents the minimum detectable reflection readable on the window pulse.

Due to the concentration of energy, the VSWR at the picture carrier should be kept fairly low at this frequency. The values below visual carrier are not as critical since the slope in the receiver cuts off most of the energy below the carrier. The VSWR in the visual pass band should be as shown in Fig. 24.

There are two locations of reflections that will cause ghosts: the lower elbow complex and the combination of the upper elbow complex and the antenna. This is summarized below.

The upper elbow complex and the antenna reflection would be more objectionable than the lower elbow complex, because of its distance and displacement (1/△f) rather than its magnitude. A 5% (VSWR 1.10)

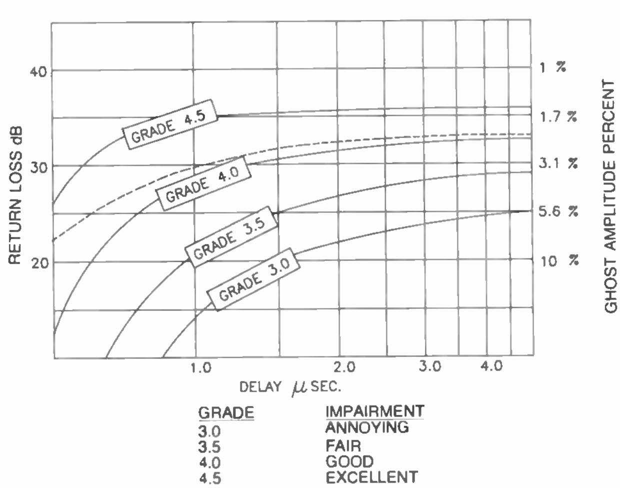


Figure 23. Signal impairment grades.

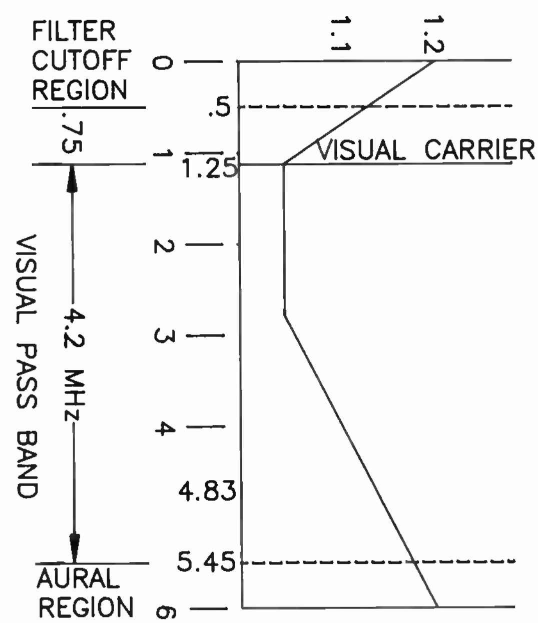

Figure 24. Acceptable VSWR levels.

echo would not be as objectionable at 0.2 μ sec as it would be at 2.0 μ sec, as shown in the following table.

Location of Reflection	Lower Elbow Complex	Antenna
Distance	100 ft	1,000 ft
VSWR	1.08	1.04
Reflection r	4%	2%
△ f MHz	4.96	0.49
Displacement in μ sec on TV Receiver	0.2	2.0

Transmission Line and Components

Testing the antenna system determines:

1. That the transmission line and components are properly assembled.
2. That the reflections from the antenna and other components at or near the tower top are sufficiently low so that no visible ghost occurs.
3. That the impedance presented to the transmitter will result in the maximum transfer of energy.

For an extremely broadband device, like a coaxial transmission line which is usually designed to cover the entire, or at least, a large portion of the TV band, the time-domain reflection (TDR) is the most effective test to determine if the line and components have been properly assembled.

Note that VSWR measurements made at the input to the transmission line measure the combined input impedance at that point only, and not the discreet reflections that can cause ghosts.

The TDR, on the other hand, will measure the reflection on a time rather than frequency basis so the exact position and magnitude of the reflection can be determined.

A high VSWR at this point is an indication of a mismatch between transmission line and antenna. For example, a VSWR of 1.22 is a return loss of 20 dB e.g., 99% of the power is transferred to the antenna system and 1% is reflected.

There are usually two sources of reflection assuming that the line itself is reflectionless:

- Lower elbow complex—V1
- Upper elbow complex and antennas—V2

When measured at the input to the system these can be thought of as two vectors. Each vector individually will rotate about the preceding vector (Fig. 25) at a frequency corresponding to the distance from the point of measurement.

The frequency of rotation can be calculated as follows:

$$\Delta f = \frac{496^*}{L} \quad \text{coax}$$

$$\Delta f = \frac{496^*}{L} \quad (\lambda_o/\lambda_g) \quad \text{waveguide}$$

*Half the velocity of light. L in feet.

Close reflections (approximately 100 feet) will have a period equivalent to 5 MHz; distant reflections (approximately 1,000 feet) will have a period equivalent to 0.5 MHz. The individual and combined reflections are shown in Fig. 26.

The use of a *network analyzer* with TDR is effective in determining the location and magnitude of the antenna system VSWR and sources of reflection. Measurement of VSWR in both frequency and time domains for an antenna and 1,700 feet of transmission line (waveguide) is shown in Fig. 27 A and B. The near and far reflections are quite apparent in the frequency domain.

At UHF frequencies where the transmission line guide wavelength is two to three feet, a 50°C temperature change on a 1,000 foot tower can result in electrical length changes of λ/4 to λ/2 wavelength. This is significant in dual feed systems where the differential change can cause beam tilt.

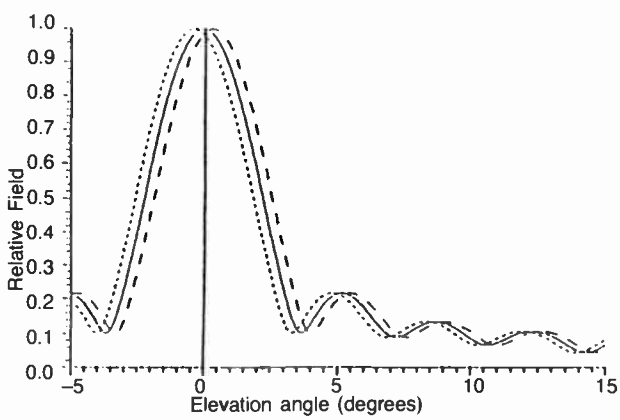
Deflection and Wind Load

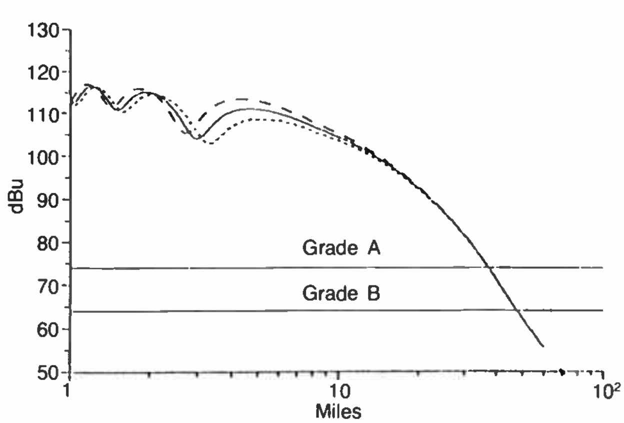
Guy tension in guyed towers is usually adjusted so that the tower deflects as a straight member.

Towers for broadcast service, when so specified, are designed for maximum deflection of 0.5°, which means that the top plate will deflect this amount for the maximum wind velocity. For instance, a 40-pound tower will thus deflect 0.5° for a 100 mph wind. Since tower deflection varies as the square of the wind velocity, the deflection will be 0.125° for a 50 mph wind.

Structurally a free-standing antenna can be considered as a cantilever beam in which the deflection increases toward the end. Antenna deflection is stated as the angle from the vertical of the chord that connects the base to the top of the antenna.

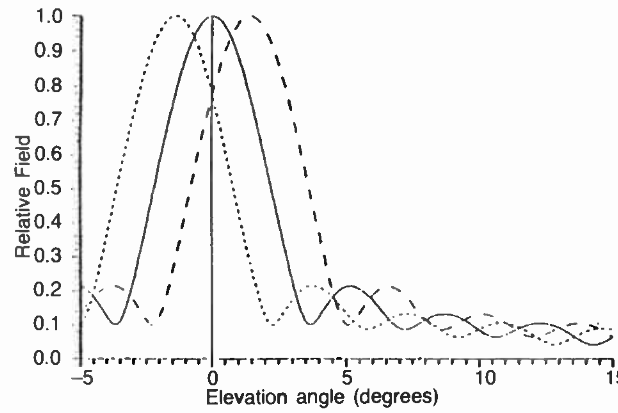
The movement of the antenna beam and the variation in signal strength for a 50 mph and 100 mph wind is shown in Fig. 28 and summarized in Fig. 29.

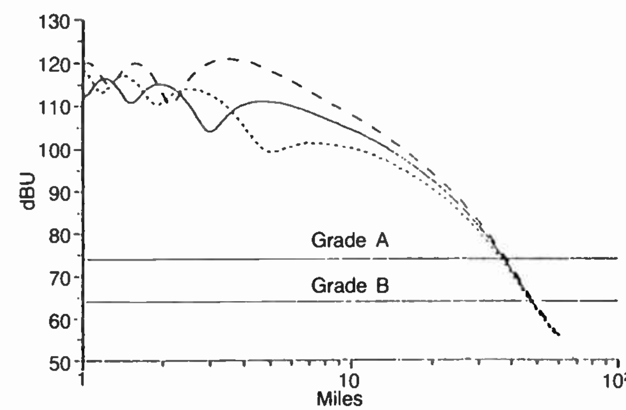




Curve	Wind	Transmitter Power	Antenna Gain	ERP
------------	Away	120 kW	20	2,400 kW
— — —	Forward	120 kW	20	2,400 kW
————	0	120 kW	20	2,400 kW

Figure 28. Field strength changes with a 50 mph wind.





Curve	Wind	Transmitter Power	Antenna Gain	ERP
------------	Away	120 kW	20	2,400 kW
— — —	Forward	120 kW	20	2,400 kW
————	0	120 kW	20	2,400 kW

Figure 29. Field strength changes with 100 mph wind.

The 50 mph wind condition is one that may occur 25 times a year at a 1,000 ft. elevation, and about four times a year at a 500 ft. elevation (Fig. 30).

The 100 mph wind is a design limit figure which rarely occurs, and one during which there would probably be little television viewing. Most outdoor receiving antennas would probably be severely damaged in such a wind, and power service seriously curtailed.

Wind Velocity (mph)	50	100

Figure 30. Antenna and tower deflection.

Antenna Feed Systems

The feed system of a television broadcast antenna is that portion of the transmission system having its input at the antenna terminal (which is at the top of the vertical run of coaxial transmission line in the tower), and its output at the radiating elements.

Most antenna gain specified by the manufacturer takes the losses of the feed system into account. Therefore, when system gains are calculated, the feed-system loss can be excluded.

In the television broadcasting field, three types of feed systems are in wide use. They are the branching, standing wave, and traveling wave feed systems. Each meets a specific need.

Branching Feed Systems

Branching feed systems are necessary for all-band antennas (i.e., an antenna that covers the full VHF or UHF band), and since they are center-fed, they eliminate beam steering or beam tilt.

This feed system progressively divides the power as shown in Fig. 31. It is used when the radiators are individual elements, each with their own terminal—such as a dipole or panel. The system shown in (Fig. 31A) will have a narrower impedance bandwidth than (Fig. 31B) since, for economy, one eight-way power divider is used. The junction impedance is $Z_j/8$. If the element impedance is 50 Ω, the power divider must transform 6.25 Ω to 50 Ω. The system shown in (Fig. 31B) uses two-way power dividers and is sometimes called a "corporate feed." Although it has a broader bandwidth, it is less economical since there are seven power dividers with additional interconnecting cables. Null fill and beam tilt is accomplished by changing the length of the feed cables or using unequal power dividers, or both.

A problem with branching feed systems is the presence of the feed line in the aperture of the lower elements. The feed lines can cause reradiation and distort the azimuth pattern. The branching feed system can be more effectively used with panel antennas that require a center support tower or mast where the transmission lines are behind the antenna.

Standing Wave Feed Systems

A coaxial or waveguide transmission line can be shorted at the far end, resulting in standing waves along the length of the line. If slots or coupling probes are appropriately sized and positioned, the RF energy can be radiated and a desired amplitude and phase distribution across the aperture can be obtained. This resonant array structure has a desirable feature; all coupling parameters are the same and equally spaced. Its disadvantages are a narrow bandwidth, and it can only be used at high VHF and UHF frequencies. (Fig. 32)

Traveling Wave Feed Systems

The traveling wave feed system operates on the principle of a gradual attenuation (radiation) of the input signal as it progresses from the input along the aperture of the antenna. An application of this principle is the *slot antenna* or *spiral antenna*. (Fig. 33)

Fig. 33A shows the principle of this feed system using short rod radiators to illustrate the theory. A number of uniformly spaced radiators per wavelength are loosely coupled to a coaxial line. Because of the number of radiators and the relatively slight reflection between them, the effect is essentially that of a uniform loading. The result is a uniformly attenuated traveling wave in the line. Since a traveling wave has a linear-phrase characteristic, the excitation of each successive radiator will be lagging from the previous one by an amount which depends on the spacing between the radiators and the velocity of propagation in the line. If the radiators are alike, their currents will have the same phase relationship as the excitation. Thus, the radiating currents will be successively lagging, and repetition of phase occurs after every guide wavelength.

To obtain an omni-directional pattern, the radiators, instead of being in line, can be moved around the

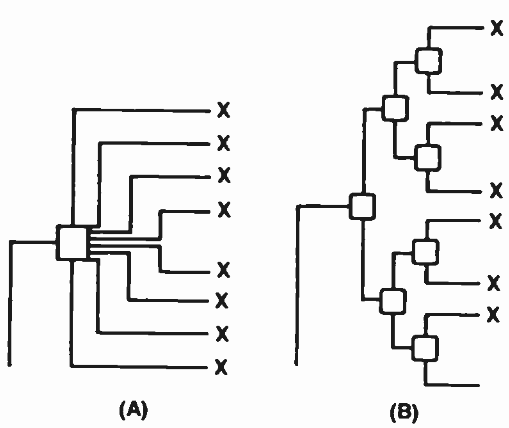

Figure 31. Branching feed systems.

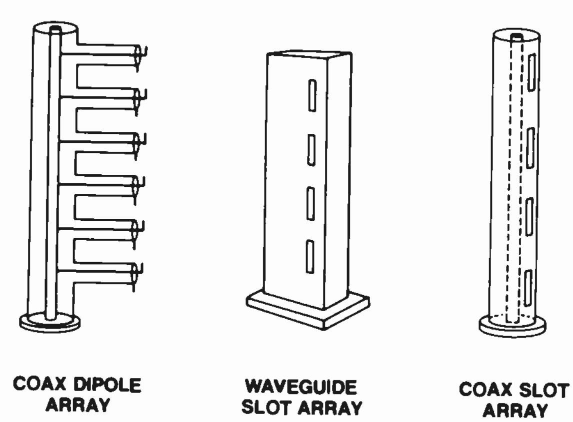

Figure 32. Slotted arrays.

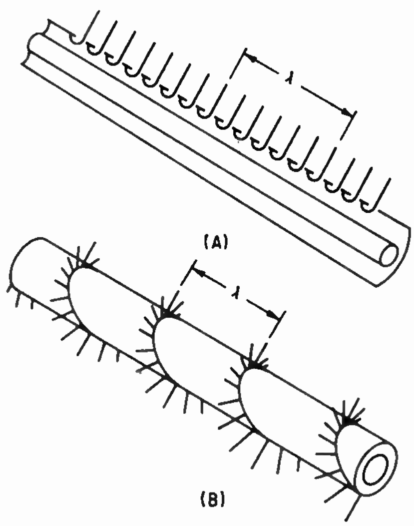

Figure 33. Traveling wave excitation.

periphery to form a "spiral" as shown in Fig. 33B. For a horizontal main beam, the pitch of the spiral has to be equal to the guide wavelength in the transmission line. In this arrangement all the radiators in any one vertical plane on one side are in phase, and the phase difference between radiators in different planes equals the azimuth angle difference between the planes. That is, the phase rotates around the periphery. The rotating phase produces a rotating field. Because of the relatively small amount of current change from layer to layer, an onmi-directional pattern is produced.

ANTENNA TYPES

The types of antennas available can be grouped into the following categories:

- Top or side mounted
- Linear or circular polarization
- High power, low power

	Horizontal Polarization		Circular Polarization	
	Top Mtd	Side or Tower Mtd	Top Mtd	Side or Tower Mtd
VHF Low Band	Batwing	Butterfly Doublett H-Panel	TDM	
VHF High Band	Batwing Traveling Wave	Butterfly Doublett H-Panel	Spiral Slot&Dipole Slot&Director	TCP CBR Arrowhead Ring
UHF	Slot Coax Wave Star Trasar	Doublett	Slot&Z Dipole Slot&Dipole Slot&Director	Slot&Dipole Slot&Dipole Slot&Director

Figure 34. Commonly used television transmitting antennas.

The prime purpose of the tower is to support the antenna. The antenna should have the required radiation characteristics to deliver a satisfactory signal to the viewer. Since it is desired to cover as large a viewing area as possible, tall towers are used. It is not uncommon for antennas to be mounted on 1,000 feet, 1,500 feet, or 2,000 feet towers. These tall towers are guyed triangular towers with face dimensions of five to ten feet.

The cost of a tower is heavily dependent on the wind load presented by the tower, the transmission line, and the antenna. For VHF antennas, the antenna wind load is the most significant parameter. For UHF antennas the transmission line or waveguide is the more significant factor.

The length of the antenna is related to the channel, or wavelength, and the gain requirements. (Fig. 35)

The ideal omni-directional antenna would be a small-diameter, infinitely stiff pole. The smallest cross section that can resonant is $\lambda/2$. Therefore, the antenna cross-section is also dependent on the wavelength.

At low VHF frequencies the resonant half-wave element of eight feet is sufficiently large so that a support pole can be used in the center with the antenna mounted outside (such as a batwing antenna). On the other hand, at UHF frequencies the resonant half-wavelength of one foot is so small that the resonant elements must be outside the support pole, or the support pole itself must be a radiator like a slotted coax or waveguide array.

Ideally, omni-directional antennas should be fed from the bottom, so there are no feed lines in the aperture of the antenna to distort the pattern. If feed lines are required for the upper elements, they should be on the inside. Of course, this is not possible for waveguide arrays. A conflicting requirement is that the diameter of the feed line be large enough to satisfy the power handling requirements, yet small enough not to create pattern distortion.

To minimize pattern distortion by the tower, the antennas should be mounted on top of the tower rather than on the side.

The wavelength of high VHF and UHF antennas is such that the resonant half-wavelength is too small to be a satisfactory structural member.

The radiating element for many UHF antennas is either the slot or dipole excited from an internal source such as coaxial or waveguide.

	Wavelength	Length for Maximum Gain	Maximum Gain
LowVHF	16 ft	100 ft	6
HighVHF	5 ft	90 ft	18
UHF	2 ft	120 ft	60

Figure 35. Dimensions of typical antenna.

Most slotted arrays are traveling wave structures which are bottom fed and contain many slots. The greater the number of slots the narrower the bandwidth, and the greater the beam steering or tilt between the visual and aural frequencies.

Some slotted arrays use the outer conductor (coax), or the waveguide itself as the structural member.

Panel antennas are fed from the back of the panel and require a secondary structural member to support the panels. This can be the tower itself. Three or four panels must be mounted around the tower to produce an omnidirectional pattern.

Panel antennas, when fed with a corporate type feed harness, can preserve the wide bandwidth of the dipole and cover the full high VHF band (174–216 MHz) or UHF band (470–800 MHz).

VHF ANTENNAS

Linear Polarized

Superturnstile/Batwing

The first antenna developed for commercial service was the Superturnstile. It consists of a central sectionalized steel pole upon which is mounted the individual radiators, or *batwings*. These radiators are mounted in groups of four around the pole in north-south and east-west planes to form a "section," and the sections are stacked one above the other to obtain the desired gain. Fig. 36 illustrates this construction.

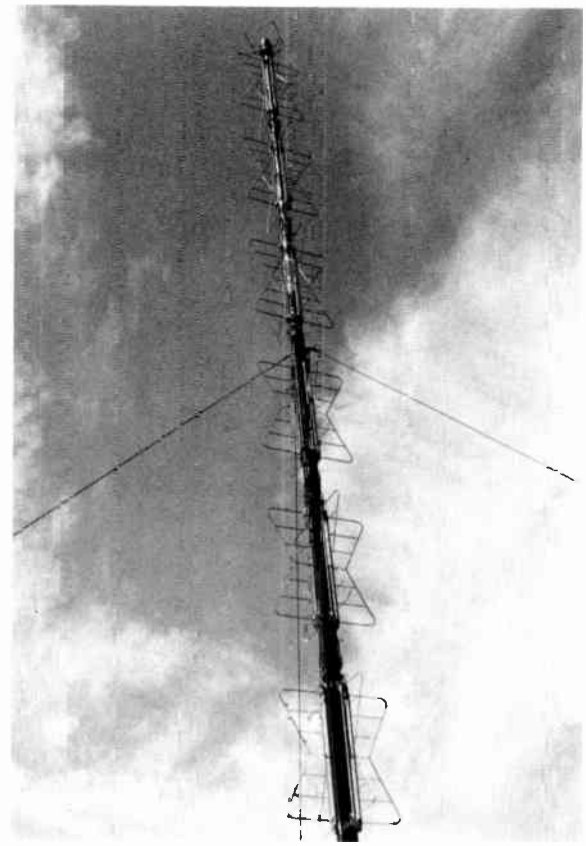

Figure 36. Superturnstile/Batwing antenna. (Courtesy of Dielectric)

Each of the radiators at the batwing antenna is fed by its own feed line. The impedances are carefully matched. The feed lines, in turn, are combined at junction boxes; which perform the dual function of feeding power simultaneously to all feed lines, and of transforming the combined impedance of these lines to that of the transmission line. This latter function is achieved by the use of three-stage transformers immediately below the junction box.

At the base of the antenna, a combining network is used when there are more than two junction boxes. These networks accomplish power division between portions of the antenna, if desired. Batwing antennas are manufactured in various gains from three to 12 for channels 2 to 6 and, gains of six to 18 for channels 7 to 13. They can also be designed for various types of null fill and they have been used in stacked and candelabra installations.

The batwing antenna is wideband and can be used for two channels. A number of them are operating at channels 4 and 5 or channel 6, an FM channel, and also in various combinations in the channel 7 to 13 range.

Traveling Wave

The traveling wave (TW) antenna is a slot antenna with a traveling wave feeding the slots. (Fig. 37).

The TW antenna is a coaxial line, with pairs of slots in the outer conductor spaced at intervals of a quarter wavelength throughout its length. Probes at the center of each slot distort the field within the line to place voltages across the slots. These, in turn, drive currents on the periphery, setting up a radiated field. Attenuation of the signal, by withdrawal of a portion of the power at each slot, reduces it to a very low value at the upper end of the antenna. There, a special pair of slots, designed to match the line, radiates the remaining power.

Operation of the TW antenna can be better understood if the section of the aperture having pairs of slots are recognized as being, in effect, dipoles.

Successive pairs of slots are alternately in one plane and in another at 90° to it, so that the antenna can be simulated by stacked dipoles with a 90° angle between successive layers.

In a given plane, reversal of the direction of feed every half wavelength (by placing the probes on opposite side of the slots), together with the half-wave change in phase of the signal as it passes along the aperture through this distance, results in all the "dipoles" in that plane being fed in phase.

The same action takes place in the other plane, except that they are fed 90° out of phase with the first plane, owing to their 90° displacement along the antenna.

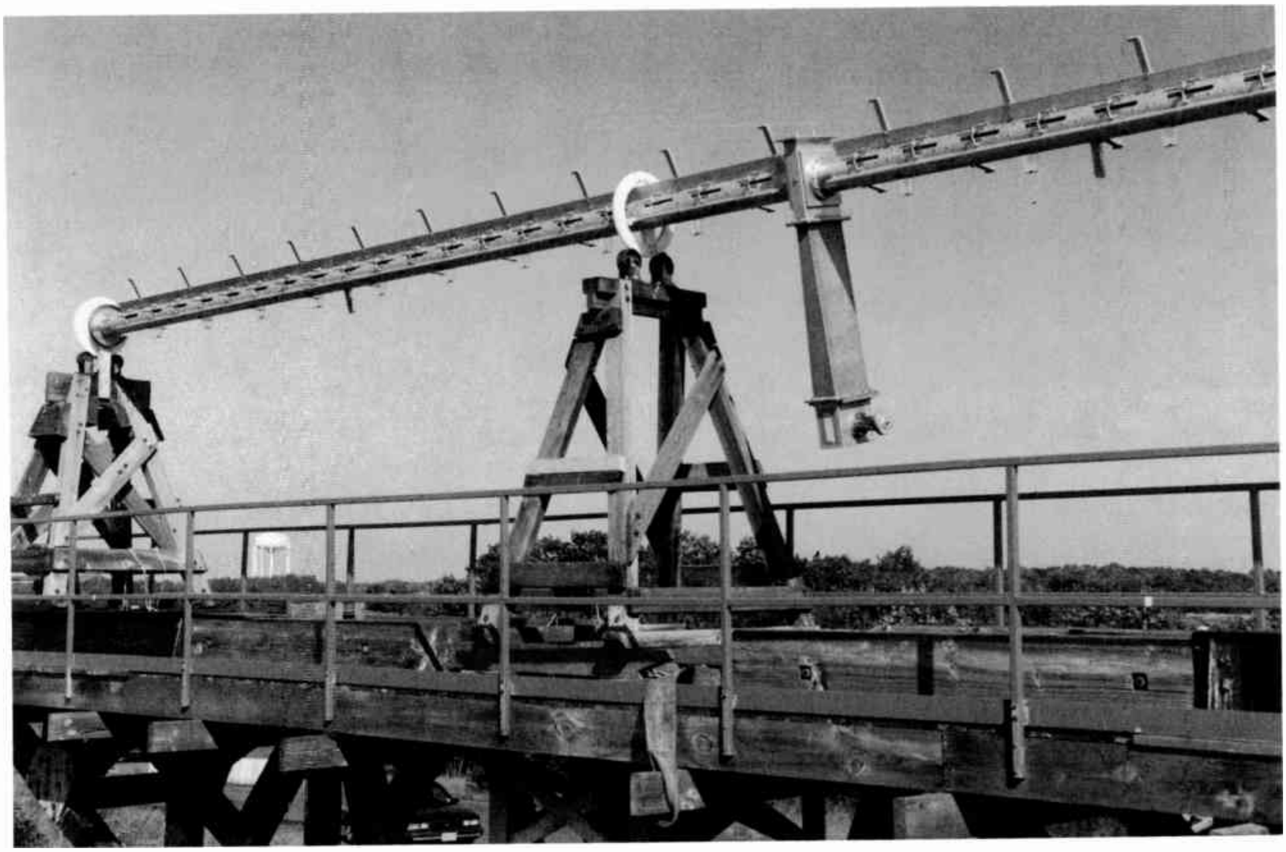

Figure 37. Traveling wave antenna. (Courtesy Dielectric)

Each plane of dipoles radiates essentially a figure-eight pattern. Since the planes are fed in quadrature, addition of the patterns results in an omnidirectional pattern. Because of the circular cross-section and the lack of obstructing radiators, the resulting horizontal pattern is almost nearly circular.

Panels

The panel antenna is designed to wrap around the tower. Four panels are needed for a square tower where each panel must radiate a $\cos^2(\theta)$ element pattern. For a triangular tower, each element must radiate a $\cos(\theta)$ element pattern for an omnidirectional pattern.

A wide variety of azimuth and elevation patterns can be obtained by using fewer panels or changing the power division to the panels.

The panels are 0.7λ to 0.9λ in vertical length and spaced approximately one wavelength.

The radiating elements may be either single dipoles like the H-panel *rhombus* in Fig. 38A or *delta dipole (butterfly)* in Fig. 38B which is essentially a folded back batwing or dual dipoles.

The *dual dipole* in Fig. 38C is designed to minimize downward radiation and consists of a pair of dipoles spaced a half wavelength apart.

The impedance bandwidth at the panel antenna is very wide and capable of handling more than one TV channel. The bandwidth can be further improved with the four-side configuration by using phase rotation. That is, 90° between each panel in the bay. The impedance at the four-way power divider will be conjugate for every two panels, resulting in wider bay impedance bandwidth than the element itself.

Circular Polarized

Transmission Dual Mode (TDM)

The TDM shown in Fig. 39 is a circularly polarized antenna for channels 2 to 6, and is designed for tower top mounting. It is capable of replacing an existing six-bay Superturnstile without any increase in tower windloading.

The TDM antenna utilizes seven layers of radiators in a slanted dipole configuration, with three radiators mounted symmetrically around the pole per layer. Each of the three radiators is fed in phase by a single feedline. Only 21 feedlines are required for the entire antenna. A branch type feed system is used to achieve excellent vertical pattern stability. One junction box feeds the upper four layers, and another feeds the lower three layers, each box fed by a 3⅛" line. This

Figure 40. CPV antenna. (Courtesy Harris)

feature allows for standby capability in the event of weather-related or other damage. The TDM can be supplied with deicers and/or radomes depending upon environmental requirements.

The unique design of the TDM provides for excellent pattern circularity and axial ratio. Axial ratio measurements are performed on a complete full scale as-built antenna standing vertically at the factory. Since all elements are excited, the mutual effects of adjacent elements are considered.

Circularly-Polarized "V" (CPV)

The CPV antenna shown in Fig. 40 is a circular, polarized, top-mounted antenna consisting of three cross "V" dipoles mounted at 120° intervals around a vertical mast. The dipoles are segmented by three vertical grids like a corner reflector, used both for isolation and to shape the element for good circularity. The cross dipoles are fed in phase quadrature and radiate circular polarization from each element.

A branching feed system is used with the lines fed up the mast. Null fill and beam tilt are accomplished by changing the electrical length of the feed cables.

Panel

The cross dipole panel antenna consists of dual dipole feed in both space and time quadrature, a necessary condition for circular polarization.

The TCP (transmission circularly polarized) series uses dipoles (shown in Fig. 41A), and are in the form of a clover leaf mounted on front of a ground plane or panel. The four elements generate the required $\cos^2(\Theta)$ element pattern. By tilting the ground plane edges forward, as a partial corner reflector, further shaping can be obtained.

The CBR (circulary basket reflector) series in Fig. 41B consists of fat dipoles mounted in a basket. The element pattern is controlled by the diameter and depth of basket. The ring panel antenna in Fig. 41C is a large resonant loop mounted against a ground plane. The ring is approximately one wavelength circumference and hence radiates a circular polarized wave in all planes perpendicular to the panel.

The arrowhead dipole in Fig. 41D is similar to the other cross dipoles. The shaping of the element pattern

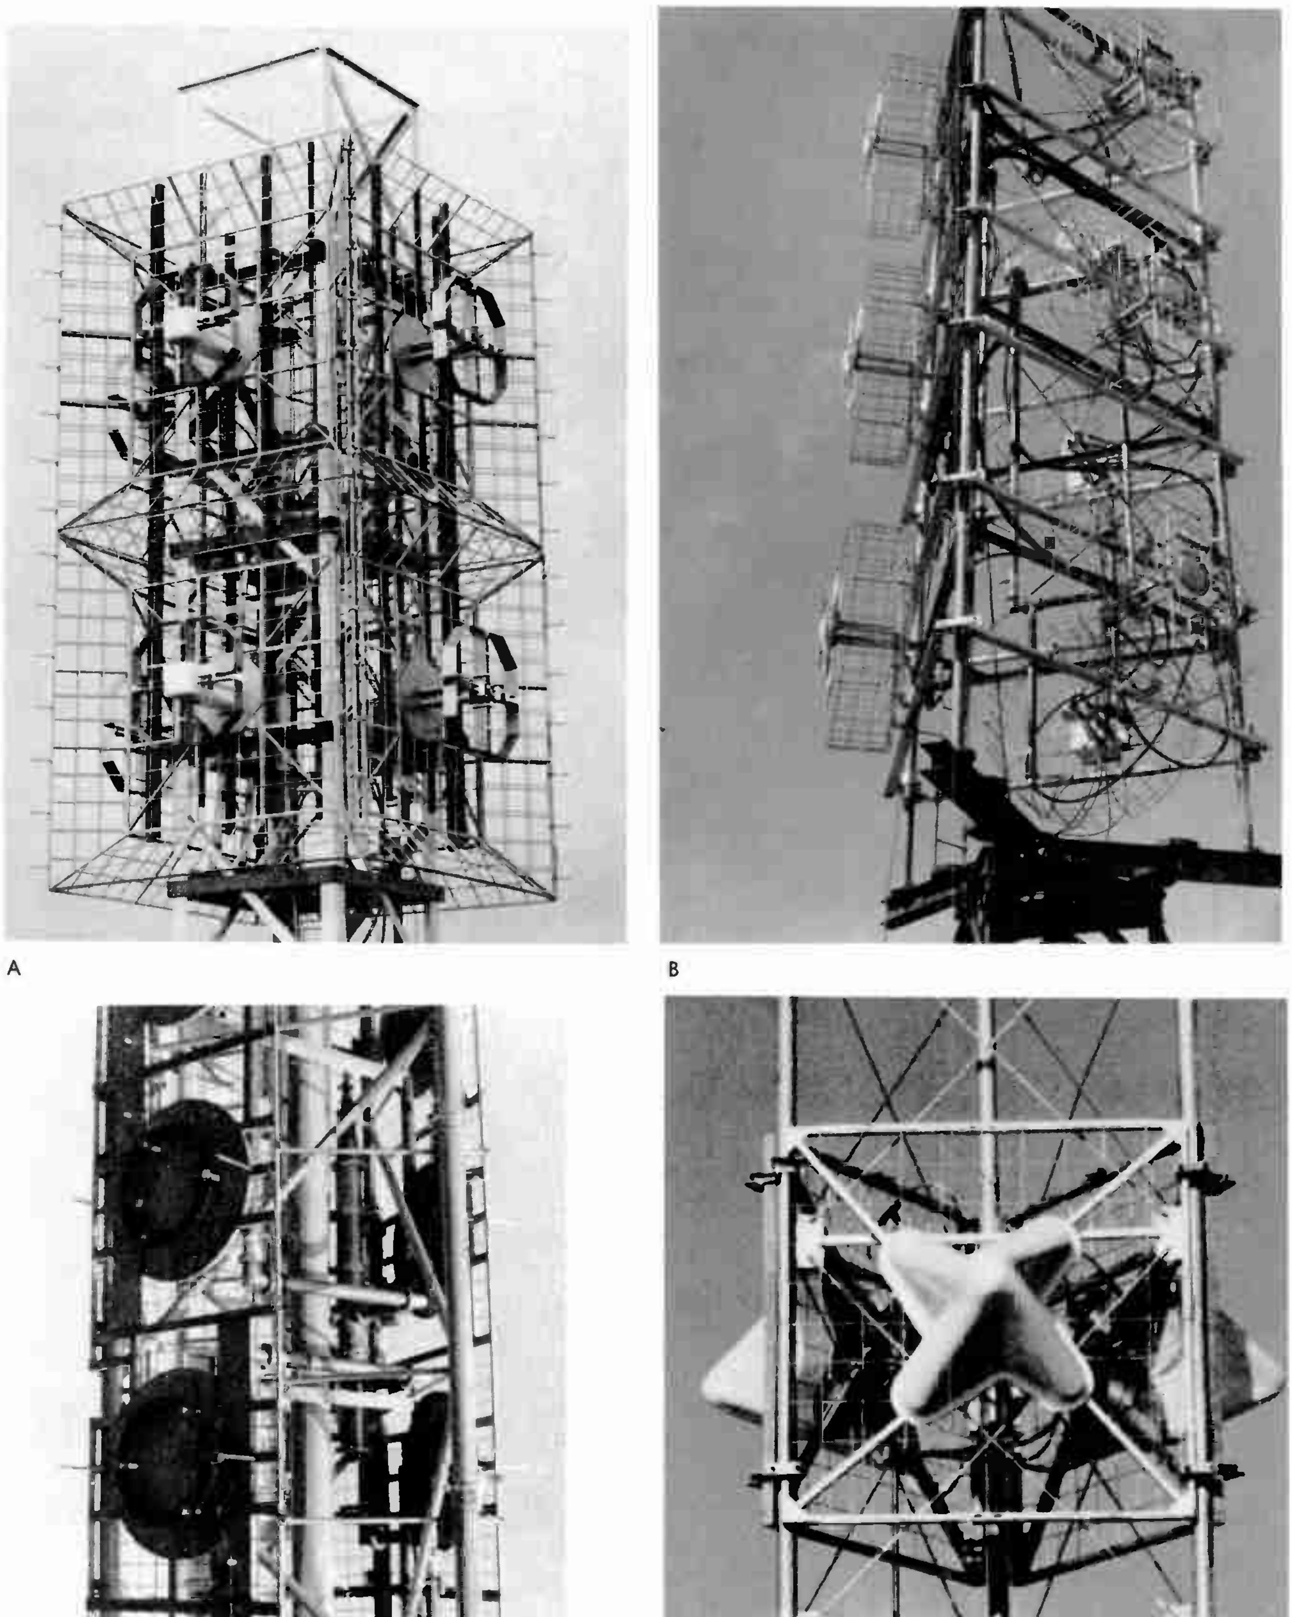

Figure 41. Panel antennas. (A) TCP (Dielectric), (B) CBR (Harris), (C) ring panel (Lampro), (D) arrowhead dipole (MCI).

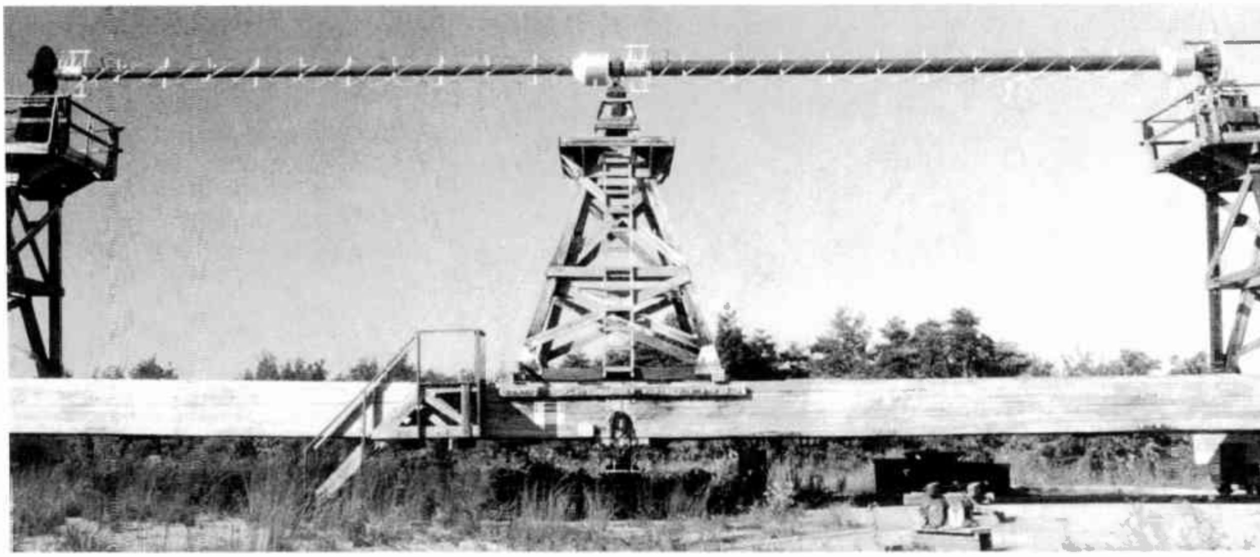

Figure 42. Spiral antenna on test range. (Courtesy Dielectric)

is accomplished by tilting back the dipole to broaden the E-plane pattern.

Spiral

The spiral antenna is designed for tower top mounting. The antenna is composed of sections, each operating under the principals of a traveling wave antenna. Each section consists of two or more stainless steel coils (radiating elements) wound around the supporting pole. A "beltline" feed system is used in each section to excite the radiating elements. The phase initiating the traveling wave is a function of the number of coils used.

Each section is terminated with radiating end loads on each coil to radiate the remaining energy. These loads minimize the reflections of energy from the far end of the radiator back toward the input, which would affect the traveling wave illumination and distort the pattern.

Vertical pattern characteristics such as gain, null fill, and beam tilt are determined by a number of factors: the number of wavelengths "wrapped" around the pole, the spacing of the radiators off the pole, the pitch (angle of wrap) around the pole, and the phasing between the vertical sections. The antenna is deiced by low-voltage, high-current dc to heat the radiating coils. A spiral antenna under test is shown in Fig. 42.

Slotted Coax

The circular polarized slotted antenna in Fig. 43 is similar to the linear polarized slotted antenna with the addition of vertical radiators.

The vertical radiators are located outside the array and the energy coupled to them from the slot is in phase quadrature.

Any polarization from elliptical to circular can be obtained by adjusting the length of the radiators.

UHF ANTENNAS

Linear Polarized

Slotted Coaxial

The UHF *pylon antenna* in Fig. 44 is a coaxial transmission line with radiating slots in the outer conductor. The number of slots (per layer) around the

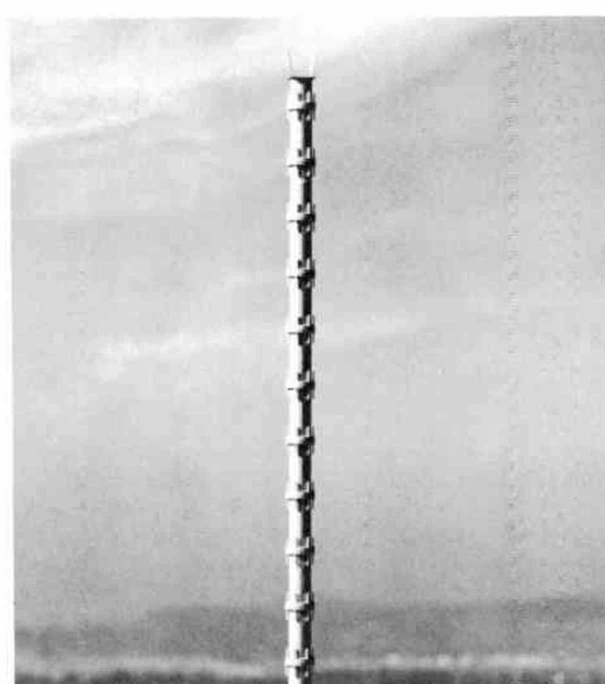

Figure 43. CP slotted antenna. (Courtesy Andrew)

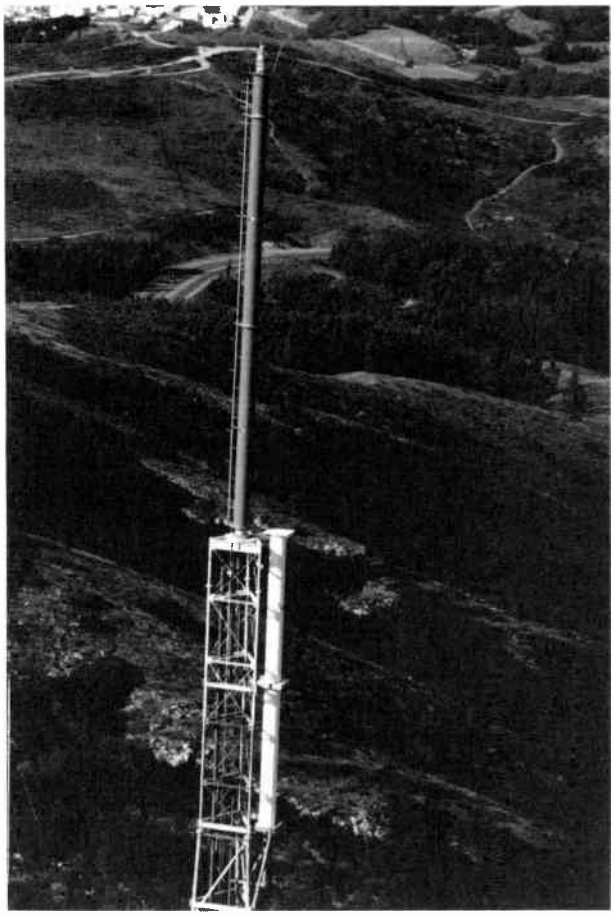

Figure 44. UHF Pylon antenna. (Courtesy Andrew)

circumference is determined by the horizontal pattern; such as one slot for a skull shaped pattern, two for a peanut shaped pattern, three for a "trilobe" pattern and four or more slots, depending on outer cylinder diameter, for an omnidirectional pattern.

The layers are located at one wavelength spacings along the antenna, with the number of layers determined by the vertical gain and pattern. The radiation parameters of phase and amplitude are determined by a combination of slot length and coupler bar diameter. This allows discreet control of the illumination along the antenna aperture at every wavelength resulting in vertical pattern control and shaping. It also allows for maximum aperture efficiency and, in conjunction with the extremely low cross-polarized radiation component of a slot, produces the highest vertical gain for a given antenna length. The antenna is a bottom fed traveling wave resonant antenna. Some antennas launch the energy into the coax radiating section at the center. Others feed the coax radiating section at the center. The bottom coax feed is located inside the radiating coax feed. The pylon uses a radome to cover the radiating slots only.

One version is an omnidirectional bottom fed traveling wave waveguide slot antenna. Since it is waveguide, no inner conductor is required. The signal propagates in the TM mode. The resultant current rings on the inside wall are interrupted by slots cut in the wall. The slots have radome covers.

Another version is designed to radiate a cardioid pattern and has a single row of slots. This is also a bottom fed traveling wave waveguide array operating in the TMOI mode. This is built by exciting the fields in a rectangular waveguide and rolling the waveguide into a cylinder.

Slotted Director

The *slot director antenna* in Fig. 45 is linearly polarized with a single row of slots with directors to fill in the low signal on the opposite side of the slots.

The slots are one wavelength long on one wavelength centers. Each is fed directly at the slot from a high-power strip line feed. Each section is up to 8λ's and four sections are usually stacked for the desired gain.

Each section is branch fed while the slots in each section are fed in a traveling wave manner.

Doublet Array

The doublet array panel antenna in Fig. 46 consists of two pairs of dual dipoles, each pair spaced slightly greater than one wavelength apart.

The dual dipole antenna is two broadband dipoles spaced a half-wavelength apart.

The half-wavelength spacing reduces the coupling

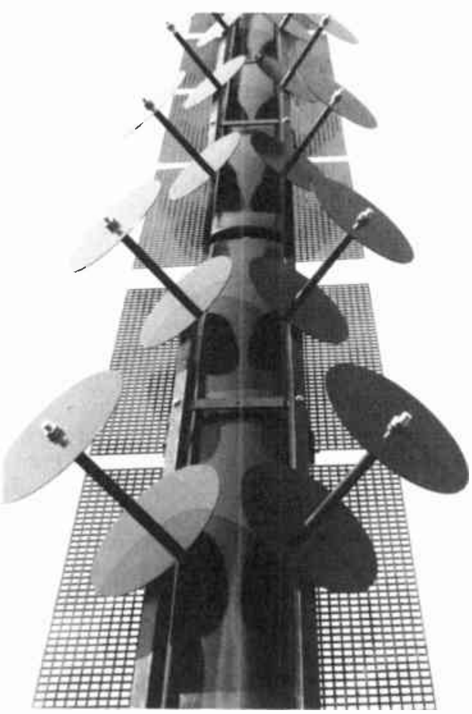

Figure 45. Slotted director antenna. (Courtesy Cablewave)

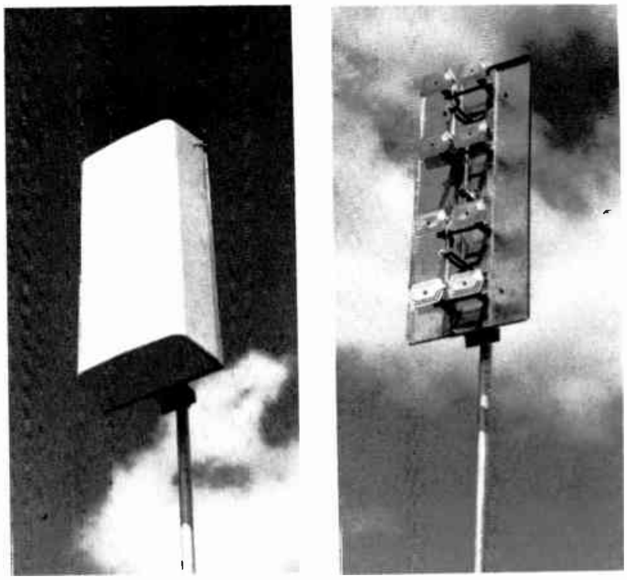

Figure 46. Doublett array antenna. (Courtesy MCI)

and cancels the downward radiation, thereby increasing the gain.

The doublet array has a VSWR less than 1.10:1 from 470 to 800 MHz.

Arrays composed of doublet arrays can be arranged to produce omni or directional patterns, and can handle four or more high power channels.

Circular Polarized Antennas

Slotted Coax

The UHF circular polarized slot antennas are similar to the linear polarized slot antenna.

The slot cut in the wall will radiate a horizontally polarized signal. If a vertical dipole is placed above or near the slot, energy will be coupled to the dipole and reradiated as a vertically polarized component.

The number of slots about the periphery of the cylinder can be varied to obtain omni or directional patterns.

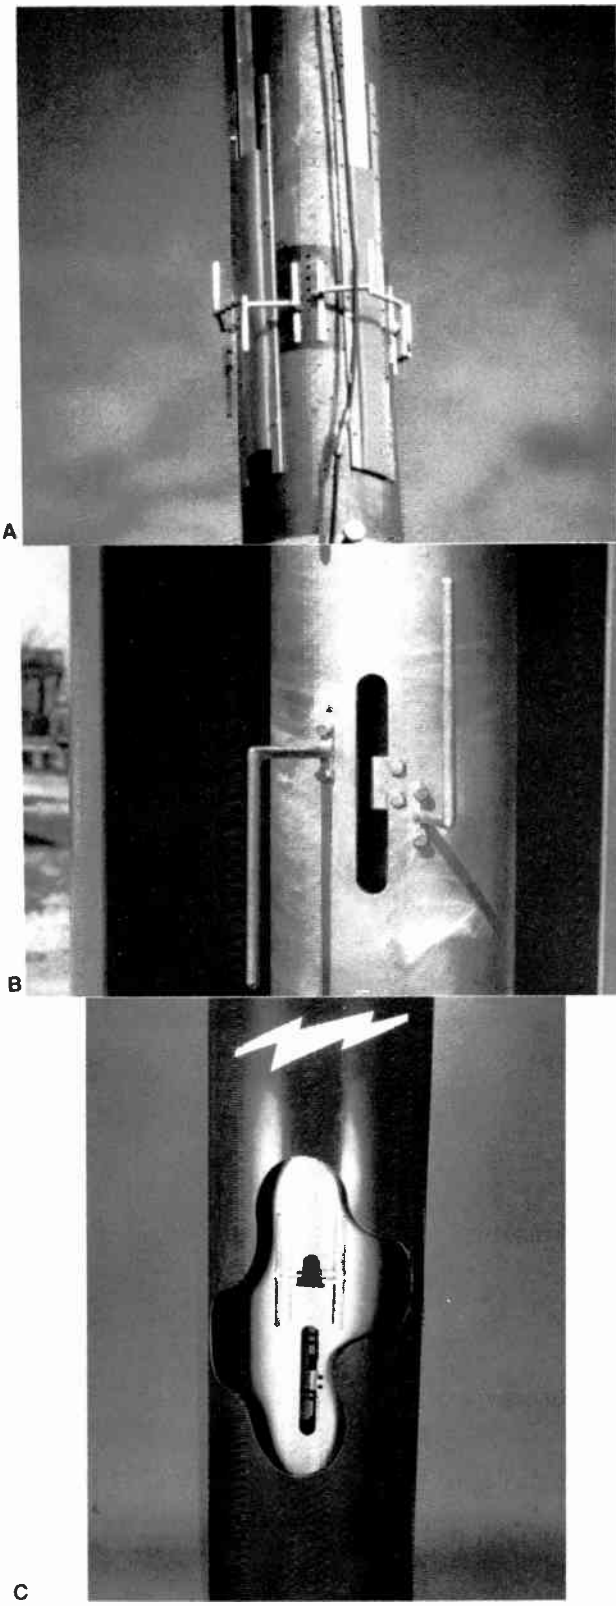
The circular polarized pylon antenna in Fig. 47A uses a Z dipole located directly above the slot, and radiates a vertical component in phase quadrature with the same elevation pattern as the horizontally polarized slot. The size and spacing of the graduated dipole can be used to control the amount of vertical component radiation.

A vertical dipole configuration is shown in Fig. 47B.

Another configuration consists of a series of slotted arrays that uses a vertical dipole, located between the slots, as shown in Fig. 47C.

The pylon circular polarized type of antennas can be either end fed or center fed. The center fed array can be fed internally for a top mounted location on externally fed for side mounted installations.

The antennas in Figs. 47B and 47C are traveling



A

B

C

Figure 47. Circular polarized antennas. (A) Z dipole antenna (Dielectric), (B) Wave Star vertical dipole antenna (Harris), (C) Trasar vertical dipole antenna (Andrew).

wave circular polarized and each have a TM_{01} mode circular waveguide feed system for very high-power applications.

All of the traveling wave slotted arrays have a cylindrical radome covering the full array.

ANTENNA TESTS

Antennas must be tested to determine if the necessary requirements for impedance and patterns are met. Impedance tests are usually run on all production antennas. Pattern tests are normally run on prototype and custom antennas.

Custom antennas are always impedance tested before shipment. These measurements should be made with the antenna completely assembled and in an area free of reflections. Using an impedance plotter or network analyzer, a determination of the antenna reflection characteristic can be made.

A pattern measurement test is conducted for two reasons: (1) to determine the gain as compared with a dipole for which a substitution method could be used; and (2) to determine the amount of radiation at all vertical and horizontal angles which have an influence on the coverage.

Pattern tests can be conducted on full or partial scale models of the final antenna. Scale models have an advantage of reduced size that permits high gain antennas to be tested in an anechoic chamber, free of reflections (from the ground or nearby objects that occur when conducting full scale tests on a range).

Additional material provided by
Kenneth D. Springer
National Association of Broadcasters, Washington, District of Columbia

Radio wave propagation is the study of the transfer of energy at radio frequencies from one point, a transmitter, to another, a receiver. Radio waves are part of the broad electromagnetic spectrum that extends from the very low frequencies which are produced by electric power facilities up to the extremely high frequencies of cosmic rays. Between these two extremes are bands of frequencies that are found in every day uses: audio frequencies used in systems for the reproduction of audible sounds; radio frequencies; infrared and ultraviolet light;, and X-rays.

All electromagnetic waves propagate at the same velocity, regardless of the frequency. Light is an electromagnetic wave, and thus the propagation velocity is often referred to as "the speed of light" (c), which for a vacuum is approximately 3×10^8 m/sec. The velocity of any wave is dependent upon the medium in which it is travelling, but for simplicity is usually considered with respect to a vacuum. The frequency of a wave is defined in terms of the number of cycles per second or Hertz (Hz) and is related to the wavelength (λ) by the expression $f = c/\lambda$. Fig. 1 shows the ranges of various bands within the electromagnetic spectrum in terms of frequency and wavelength.

Radio frequencies are generally confined to that portion of the electromagnetic spectrum below the infrared frequencies. At present, the practical upper limit of radio frequencies is roughly 100 GHz.[1] Within the radio frequency spectrum are bands of frequencies that have been allocated to the broadcast service. The following discussions and methods will apply particularly to these bands of the radio frequency spectrum.

The AM frequency allotments are contained in what is referred to as medium frequencies (MF), 300 kHz to 3 MHz. The FM frequencies and a portion of the TV band are contained in the VHF band which extends from 30 MHz to 300 MHz. The remaining TV allocations are contained in the UHF band of 300 MHz to 3 GHz. Allocations for broadcast auxiliary services such as remote pickup, studio/transmitter links, intercity relays, MDS, and ITFS are interspersed within the MF, VHF, UHF, and SHF (super high frequency) bands. Table 1 illustrates some of the allotments assigned to the broadcast service. The allocations for auxiliary services may change from time to time as the needs of various services for radio frequencies change and as technology for equipment improves. As such, Table 1 is included as an illustration of the wide band of frequencies allocated to the broadcast industry. For a discussion of the origin of the frequency allocations for broadcasting and broadcast auxiliary services the reader is referred to Chapter 1.4 of this *Handbook*, "Frequency Allocations for Broadcasting and the Broadcast Auxiliary Services." In order to keep abreast of new frequency allocations, the most current FCC Rules and Regulations should be consulted.

QUANTIFYING PROPAGATION

The energy that is emitted from a transmitter may take many different paths before it is received. The path that the radio wave will take depends on many factors, some of which include: frequency, antenna type and height, atmospheric conditions, and terrain. Radio waves that propagate along the surface of the earth are commonly referred to as ground waves. All radio waves have some ground wave component, however, because the earth is a lossy medium, it severely attenuates the radio wave. This attenuation increases with frequency, so this mode of propagation is useful only for frequencies below 30 MHz. To achieve significant distances, the atmosphere is preferred over ground waves as a transmission medium. The atmosphere is comprised of several different layers, as depicted in Fig. 2. The troposphere is the layer that extends from the earth's surface up to about 16 km. This layer is

the chief mode of propagation for frequencies above about 30 MHz, and propagation through this layer is dependent upon weather conditions. The next layer is the stratosphere which extends to about 40 km above the earth. This layer has no major effect on the propagation of radio waves. The ionosphere extends upwards of 400 km above the surface of the earth. This region is a charged environment where the air is sufficiently ionized, mainly by the sun's ultraviolet radiation, to reflect or absorb radio waves below about 30 MHz. The ionosphere is constantly changing and is usually considered as consisting of the following sublayers.[2]

1. D layer—This layer exists at heights from about 50 km to 90 km and is present only during daylight hours. The electron density is directly related to the elevation of the sun. This layer absorbs medium and high frequency waves.

2. E layer—This layer exists at a height of about 110 km and is important in the nighttime propagation of medium frequency waves. The ionization of this layer is closely related to the elevation of the sun. At certain times irregular cloud-like areas of high ionization may occur. These areas are known as sporadic E and occasionally prevent frequencies that normally penetrate the E layer from reaching higher layers. The sporadic E layer is prevalent during the summer and winter months. The sporadic E layer formed during the summer is the longest lasting from May to August, and the winter layer lasts about half as long beginning in December. During the mid-summer months when the electron density is at its greatest levels, TV signals in the lower VHF band can be transmitted over distances of hundreds or thousands of kilometers.[4]
3. F1 layer—This layer exists at heights of about 175 to 200 km and is present only during the day. Waves that usually penetrate the E layer (3 to 30 MHz) will penetrate this layer and be reflected by the F2 layer. This layer introduces additional absorption of these waves.
4. F2 layer—This layer exists at the upper boundaries of the atmosphere, 250 km to 400 km, and is present at all times; though the height and electron density will vary from day to night, with the seasons, and over sunspot cycles. During the night the F1 layer merges with the F2 layer at about 300 km. This, in addition to the reduction of the D and E layers, causes nighttime field intensities and noise to be generally higher than during the day.

FREE SPACE PROPAGATION

To evaluate and compare radio wave propagation under various conditions, it is convenient to establish a reference standard. It is customary to consider as a standard the theoretically calculated loss for waves propagated in free space between two idealized antennas. The simplest case to investigate is the radiation emitted from an isotropic source: an ideal antenna which radiates energy with uniform intensity in all directions. An analogy to an isotropic antenna is a point source of light, such as a candle. The intensity of the energy varies proportionally to the inverse of the distance squared from the source, the "inverse square law." The power flux per unit area P_a(W/m^2) at

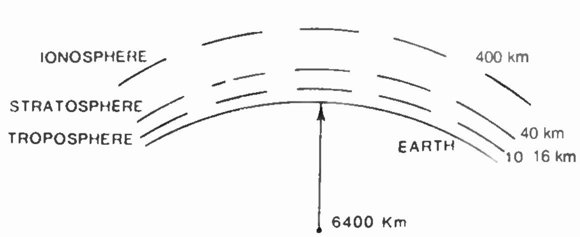

Figure 2. Atmosphere layers.

a distance d(m) from a loss free isotropic antenna radiating a power P_t(W) is given by:

$$P_a = P_t / 4\pi d^2 \quad [1]$$

where $4\pi d^2$ is the surface area of a sphere at a distance d(m) from the source. The power available from a loss free antenna P_r is the product of the power flux per unit area (P_a), and the effective aperture area of the receiving antenna (A_e). This area is related to the gain of the antenna by the expression:

$$A_e = G\lambda^2/4\pi \quad [2]$$

Aperture areas and gains for a specific antenna can be found in the sixth edition of the *NAB Engineering Handbook*, page 121.[3] For a loss free isotropic antenna, $G = 1$, the basic free space transmission loss is defined as:

$$L_{bf} = P_t / P_r = (4\pi d/\lambda)^2 \quad [3]$$

where d and λ have the same units. This equation can be rewritten in its more common form, expressing the loss in dB, as:

$$L_{bf}(dB) = 32.44 + 20\log(F) + 20\log(d) \quad [4]$$

where F is the frequency in megahertz (MHz) and d is the distance between the antennas in kilometers. In the above equation it should be remembered that ideal loss-free isotropic antennas are considered. In real world systems, antenna gain is a significant factor. The transmission loss, L, incorporates the antenna gains and is defined as:

$$L = L_{bf} - (G_t + G_r + L_d) \quad [5]$$

where G_t and G_r are the free space antenna gains with respect to isotropic for the transmitting and receiving antenna respectively. The term L_d is the aperture-to-medium coupling loss or polarization coupling loss between the antennas. The term L_d will have a value of 0 dB when the transmitting and receiving antenna have the same polarization.

In considering the potential service area coverage for a broadcast station, it is usually more desirable to express measurements in terms of field strength rather than transmission loss as previously presented. The root mean square (RMS) field strength, E(V/m), at a point where the power density of a plane wave is P_a(W/m^2) is given by:

$$E = \sqrt{120\pi P_a} \quad [6]$$

where the term 120π is the impedance of free space. The field strength is related to the power available from a loss free isotropic antenna by combining Eqs. [1], [3], and [6] above as:

$$E = \sqrt{480\pi^2 P_r / \lambda^2} \quad [7]$$

A more useful form of the free-space field can be expressed in logarithmic terms above 1 microvolt per meter (dBu) when F is in megahertz and P_r is expressed in decibels above 1 kW (dBK):

$$E\,(\mathrm{dBu}) = 107.2 + P_r + 20\log(F)\,\mathrm{dBu} \quad [8]$$

The electric field produced by a transmitter radiating a power P_t(W) at a distance d(m) in free space can be derived from Eqs. [1], [3] and [6] and is given by:

$$E = \sqrt{30P_t/d^2} \qquad [9]$$

or, in logarithmic terms, where P_t is expressed in decibels above 1 kW (dBK), d is in kilometers, and a transmitting antenna has a gain G_t in decibels above isotropic:

$$E\,(\mathrm{dBu}) = 105 + P_t + G_t - 20\log(d) \qquad [10]$$

Using the same units, the field strength E(dBu) for nonfree-space environments can be related to the basic transmission loss by:

$$L_b\,(\mathrm{dB}) = 137 + 20\log(F) + P_t + G_t - E \qquad [11]$$

These equations form the basis for characterizing propagation. They do not, however, take into account such real world factors as the presence of the earth, atmosphere, or obstructions. To adequately describe an actual radio system, additional losses will need to be added to the free-space equations derived above.

PRESENCE OF EARTH

When the transmitting and receiving antennas are placed over ground, the propagation of radio waves is modified from the free-space models presented above. Radio waves that strike the earth are partially absorbed and partially reflected. Waves that are reflected by the earth experience changes in the phase of the wave, which affects the distribution of available energy. The extent to which the waves are reflected or absorbed is dependent upon frequency and the ground constants: conductivity and permittivity.

Propagation Over Plane Earth

The geometry of the idealized situation of propagation between two antennas placed above a plane earth is shown in Fig. 3. This geometry is valid for antennas that are sufficiently closely located so that the curvature of the earth is not a factor, yet far enough apart from each other so that the energy may be described as a plane wave, and ray theory can be applied. The resultant received electric field can be represented as the sum of the direct and reflected rays:

$$E = E_d\,[1 + |\mathrm{R}|e^{j(\phi_\Delta + \phi_r)}] \qquad [12]$$

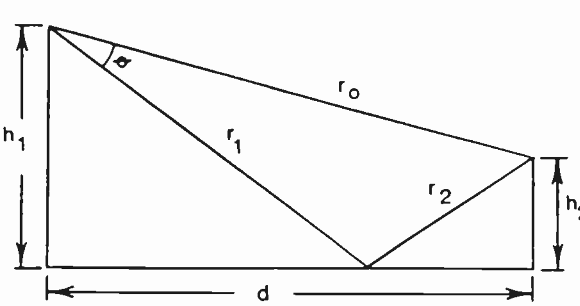

Figure 3. Path rays for plane earth.

This equation is valid for small angles of Θ and deserves some additional explanation. The term E_d is the free-space electric field that is produced at a distance d(m) by the direct ray. The terms $|\mathrm{R}|$ and ϕ_r are the magnitude and phase of the complex reflection coefficient. This term is dependent upon the nature of the surface (i.e., conductivity (δ) and permittivity (ϵ_r)), the angle between the surface and incident wave, the wavelength of the radio wave, the polarization of the wave, and the curvature of the earth. The magnitude of the reflection coefficient varies between −1 and +1. Several sources have derived equations for the reflection coefficient and plotted the effects of changing variables, and the reader is referred to these for further study.[4,5] The term ϕ_Δ is the phase delay due to the longer path that must be taken by the reflected wave, and has the form of:

$$\phi_\Delta = \frac{4\pi h_1 h_2}{\lambda d} \qquad [13]$$

It is often sufficient to assume the ground approximates a large flat surface. In such a case, a sufficiently accurate expression is given by:[4]

$$E = 2E_d \sin\left(\frac{2\pi h_1 h_2}{\lambda d}\right) \qquad [14]$$

Some cases of special merit that can be derived from Eq. [14] are:

Case I	$h_1 h_2 = d\lambda/2$	$E = 0$
Case II	$h_1 h_2 = d\lambda/4$	$E = 2E_d$
Case III	$h_1 h_2 = d\lambda/12$	$E = E_d$

Therefore, depending on the antenna heights, distances, and wavelength, it is possible to totally cancel out the field at the receiver or magnify the wave to a field strength double that which could be achieved from a free-space field. The variation of signal strength due to multipath effects can be minimized in point-to-point applications through the use of antennas with narrow beamwidths.

When considering the case of VHF antennas that are close to the ground, the effective antenna heights h_t(m) and h_r(m) will need to be substituted for h_1 and h_2 respectively for Eq. [14]. The new antenna heights h_t and h_r allow for the effects caused by the relative permittivity (ϵ_r), and conductivity (δ) of the ground. The effective antenna heights are related to the physical antenna heights above ground level by:[4]

$$h_t = \sqrt{h_1^2 + h_0^2} \qquad [15.1]$$

$$h_r = \sqrt{h_2^2 + h_0^2} \qquad [15.2]$$

the term h_0 is dependent upon the type of polarization being considered.

Vertical Polarization

$$h_0 = (\lambda/2\pi)\,[(\epsilon_r + 1)^2 + (60\lambda\sigma^2)]^{1/4} \qquad [16.1]$$

Horizontal Polarization

$$h_0 = (\lambda/2\pi)\,[(\epsilon_r - 1)^2 + (60\lambda\sigma^2)]^{-1} \qquad [16.2]$$

TABLE 2
Ground conductivity and dielectric constants.

Terrain	Conductivity (S/m)	Dielectric Constant (esu)
Sea water	5	80
Fresh water	8×10^{-3}	80
Dry sandy, flat coastal land	8×10^{-3}	10
Marshy, forested flat land	8×10^{-3}	12
Rich agricultural land, low hills	1×10^{-2}	15
Pasture land, medium hills and forest	5×10^{-3}	13
Rocky land, steep hills	2×10^{-3}	10
Mountainous	1×10^{-3}	5
Residential area	2×10^{-3}	5
Industrial area	1×10^{-4}	3

Table 2 lists values for conductivity and permittivity for various soil conditions. As a way of example, assume that an antenna is placed 3 meters (9.8 feet) above dry, sandy, flat coastal land ($\delta = 2 \times 10^{-3}$ S/m, $\epsilon_r = 10$) and operates at a frequency of 100 MHz ($\lambda = 3$ m). Then h_0 in [16.1] and [16.2] will be 1.59 m and 0.16 m respectively. The effective height of the antenna will then be increased to 3.4 m (11.1 feet) for vertical polarization and will remain unchanged at 3 m (9.8 feet) for horizontal polarization. As the frequency increases above VHF, the wavelength becomes increasingly small and the distinction between true antenna height and effective height is immaterial.

MEDIUM FREQUENCY PROPAGATION

As stated earlier, medium frequency waves lie in the frequency range of 300 kHz to 3 MHz and are characterized by their long wavelengths, 1,000 meters to 100 meters. The standard AM broadcasting band frequencies are within this range. The transmitting antenna is located right at the surface of the earth, and the receiving antenna is very close to the earth's surface with respect to a wavelength. In this case the direct and ground reflected waves cancel, and the transmission is by means of the ground wave (also known as the surface wave) and the sky wave.

Ground Waves

These waves are characterized by the fact that they are guided along the earth's surface, similar to a transmission line. The field is attenuated in this propagation mode by losses in the ground. Therefore the composition of the soil, ϵ_r and δ, have a direct bearing on the amount of attenuation the wave will experience, and subsequently how far reliable communications can be established. The attenuation is also dependent upon the frequency and polarization type. The attenuation factor, A, is a measure of the amount of attenuation present and can be determined for a ground wave using the chart of Fig. 4. The term ρ is known as the

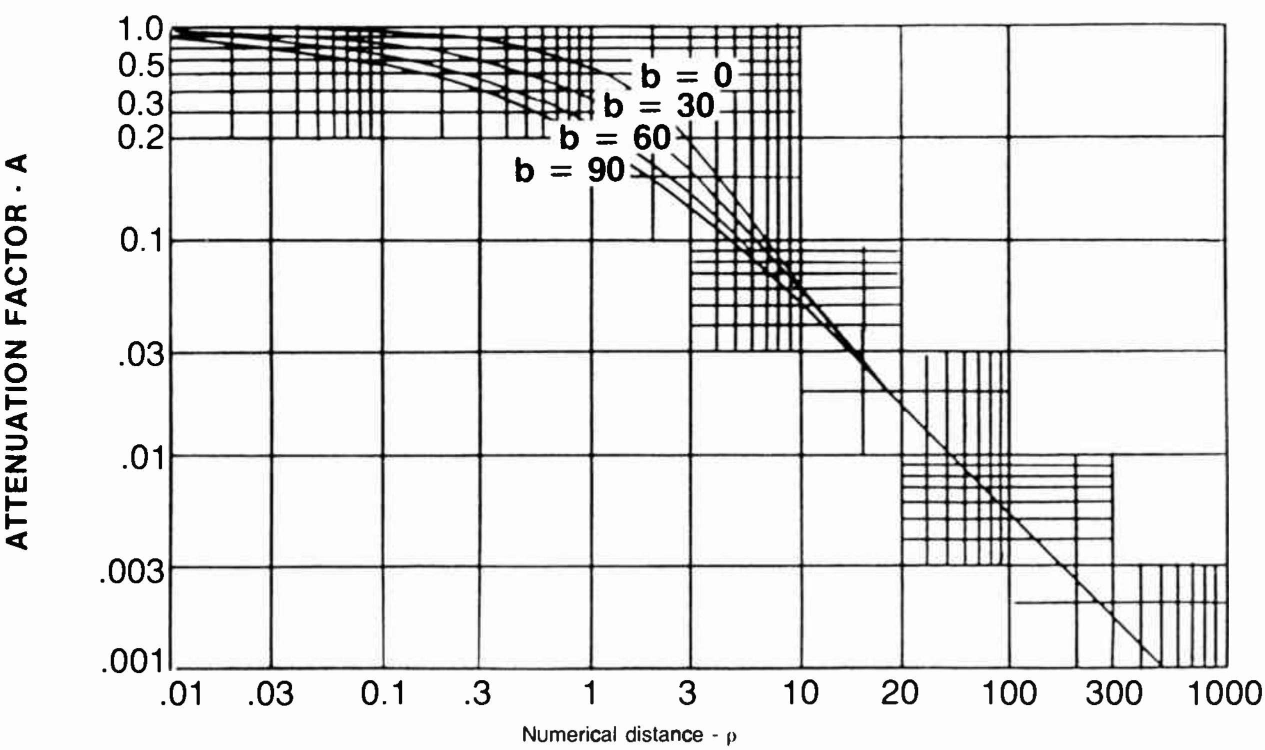

Figure 4. Attenuation factor of ground waves.

numerical distance and b is the phase constant. Values for these terms can be calculated from the following equations:[5]

$$\rho = (\pi d/\lambda x)\cos(b) \qquad [17.1]$$

$$b = \arctan[(\epsilon_r + 1)/x] \qquad [17.2]$$

$$x = 18*10^3\sigma/F \qquad [17.3]$$

To determine the electric field strength, the attenuation factor must be added to Eq. [12].

$$E = E_d[1 + Re^{j(\phi_\Delta + \phi_r)} + (1 - R)Ae^{j(\phi_\Delta + \phi_r)}] \qquad [18]$$

It is interesting to note that the same earth which acts as a conductor at very low frequencies will act as a small-loss dielectric at very high frequencies. It is also noteworthy to observe that the losses for horizontally polarized waves are much greater than for vertically polarized waves. Thus, for practical applications only, vertically polarized waves should be considered. For more detailed and accurate representations of the effects of ground wave, the works of Norton and as expanded upon by Jordan should be consulted.[6,5]

Sky Waves

While the ground wave provides the major path for medium frequency propagation, the wave attenuates relatively quickly with distance and is reliable for distances of only a few hundred kilometers. To achieve greater distances, the waves propagate via the ionosphere and are known as sky waves, and can provide sufficient signal strength at distances up to a few thousand kilometers.

The ionosphere is a constantly changing environment that begins approximately 65 km (40 miles) above the earth and extends to about 400 km (250 miles). This region of the atmosphere is composed of three major sublayers D, E, and F as discussed earlier. These layers are not present at all times. For example, the D layer is present only during the day and is a major absorber of medium-frequency waves. The E layer is a principal reflector of medium-frequency waves. Thus during the day the majority of the medium-frequency waves are absorbed by the D layer, but at night the D layer is not present, allowing the medium-frequency waves to be reflected by the E layer.

Interference Between Ground Waves and Sky Waves

Interference to a receiver may occur from co-channel stations located many kilometers from the desired station. Because of the sky wave, sufficient signal strength may be received to interfere with the local station. This effect has been minimized by the FCC by limiting two factors in the operation of some AM stations: the operating power and time of operation.

Multipath interference occurs when the waves from a transmitting antenna reach a receiver from different paths in such a manner as to cancel or severely interfere each other. This can happen at distances where both the ground wave and sky wave are sufficiently strong to interact. The geometry of this is similar to that shown in Fig. 3, except the direct ray will be a result of the ground wave and the reflected wave will be from the ionosphere. At distances relatively close to the transmitter, the ionosphere will not reflect waves back to the earth, so the ground wave is predominant. At distances beyond a few hundred kilometers, the sky wave will dominate and the ground wave will be too weak to interfere. Multipath interference can also occur where the sky wave follows more than one path to the receiver.

Effects of Solar Activity

Interference to medium-frequency waves can also be caused by solar activity such as sunspots and flares which manifest an increased or reduced emission of radiation from the sun. The changes in solar radiation levels can cause changes in the ionospheric layers that may result in unusual sky wave propagation conditions called "skip" which, in turn, can cause inter-station interference. The effects of such solar activity will have their strongest effect on propagation in the AM band during the first five to ten days after the start of a storm. This has the effect of reducing sky-wave field strengths. The effect has been observed to increase with frequency.[13]

PROPAGATION ABOVE 30 MHz

Smooth Earth Conditions

At frequencies above about 30 MHz the principal propagation mode is tropospheric. The surface wave is attenuated too severely to be of any practical long distance use and, though attenuated, the sky wave is usually passed through the ionosphere to space.

For waves that propagate close to the earth's surface the curvature of the earth will introduce additional effects that must be included in the plane earth model that was considered earlier. Fig. 5 shows the geometry of a smooth earth model. First the reflection coefficient R of the reflected wave has different characteristics than for a plane surface. Since the wave is reflected

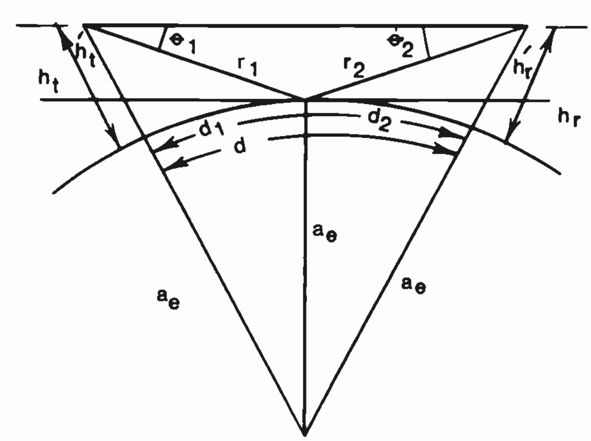

Figure 5. Reflection from smooth earth on line-of-sight path.

against a curved earth the energy diverges more than is predicted by the inverse square law and the reflection coefficient R, in Eq. [12], must be multiplied by the divergence factor D, given by:[4]

$$D = \sqrt{\frac{1 + 2d_1d_2}{2a_e(h'_t + h'_r)}} \qquad [19]$$

It should be noted that for smooth earth conditions, the heights h'_t and h'_r for the transmitting and receiving antennas above the plane tangent to the earth at the point of reflection are less than the antenna heights h_t and h_r above the surface of the earth.

Under normal propagation conditions, the refractive index of the atmosphere decreases with height so that radio waves near the surface of the earth travel more slowly than at higher altitudes. This variation in velocity as a function of height results in a bending of the radio waves. This may be represented as a modified earth radius commonly known as the effective earth radius, a_e, which allows the radio waves to be represented as straight lines. The ratio of the effective earth radius to true earth radius is commonly known as the k factor. Values of k can vary between from 0.6 to 5.0 depending on the climate being considered. For temperate climates the average value of k is 1.33, and most works refer to this as the 4/3 earth model when used in calculation.[2]

Beyond Line of Sight Conditions

In order to determine when conditions exist where propagation is considered to be beyond line of sight, the respective distances from the transmitter and receiver to the radio horizon must be calculated. The radio horizon is the distance the horizon appears from an antenna, as defined by a plane from the antenna to the tangent of the earth's surface and is depicted in Fig. 6. The equation for the radio horizon in terms of d_{lt}(km) and h_t(m) and the k factor is of the form:

$$d_{lt} = 3.57\sqrt{h_t k} \qquad [20]$$

When the sum of the distances to the radio horizon for the transmitter and receiver is less than the total distance of the path under consideration, then a beyond line of sight condition exists. Diffraction makes it possible for radio waves to travel beyond that possible for line of sight transmission, though an additional loss term must be added to the free-space loss. The amount of attenuation can be determined by diffraction methods. The geometry of beyond line of sight propagation is shown in Fig. 7.

The exact calculation of the field strength at any

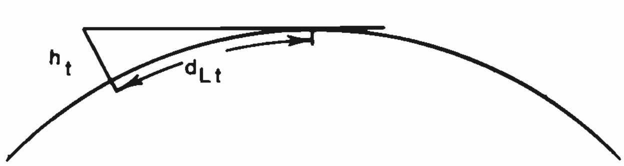

Figure 6. Distance to radio horizon.

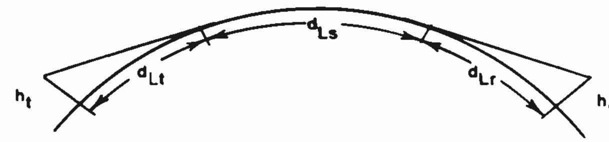

Figure 7. Beyond line of sight.

point beyond the line of sight for a smooth earth is rather complex and the presentation of such a method is beyond the scope of this text. However, nomograms have been developed that apply to a large number of cases. For the reader interested in the actual prediction of the losses to be expected for smooth earth diffraction, the National Bureau of Standards publication may be consulted.[9]

Fig. 8 is a nomogram that can be used to determine the loss that must be added to the free-space loss. In order to use the nomogram, the distance d_{lt} must be less than d_{lr}. The total loss (L) is the sum of the three losses L1, L2, and L3. By way of example, assume a system that has the following parameters: h_{lt} = 14 m (45.9 feet); h_{lr} = 178 m (583.8 feet); F = 100 MHz; k = 4/3; total path length of 85 km; and the wave is vertically polarized over land. The distances are calculated to be: d_{lt} = 15 km (9.3 miles), d_{lr} = 55 km (34.2 miles), and d_{ls} = 15 km (9.3 miles). The total loss relative to free space is thus L = L1 + L2 + L3 = 22.9 + 3.8 + 4.3 = 31.0 dB.[7]

Effects of Obstacles on Propagation

In the previous sections, a perfectly smooth sphere was assumed for earth. Only the effects of the atmosphere were accounted for in the k factor. The assumption of a perfectly smooth earth allowed for a relatively simple calculation of the expected field strengths and transmission losses at various points within the line of sight and regions beyond the line of sight. However, the real world is much less than ideal, and the presence of hills, buildings, foliage, as well as the atmosphere all have a bearing on the computation of field strengths. These obstacles have a complex effect on the propagation of radio waves which makes it virtually impossible to predict the field strength or transmission losses at discrete points close to these obstacles. However, the path being considered may be quantized by use of earth profiles, and through the use of some simplifying assumptions, predictions of the field strength which are more accurate than smooth earth approximations can be performed.

Hills

Perhaps the most common obstructions that will appear in the path of a radio wave are hills. The amount of attenuation the hill will introduce into a path is a function of the distance from the antenna terminals to the hill, and the height of the hill above or below the line-of-sight ray between the transmitting and receiving antennas. The hill's height and distance from the antenna can be determined by constructing a path profile and plotting the terrain features on special graph

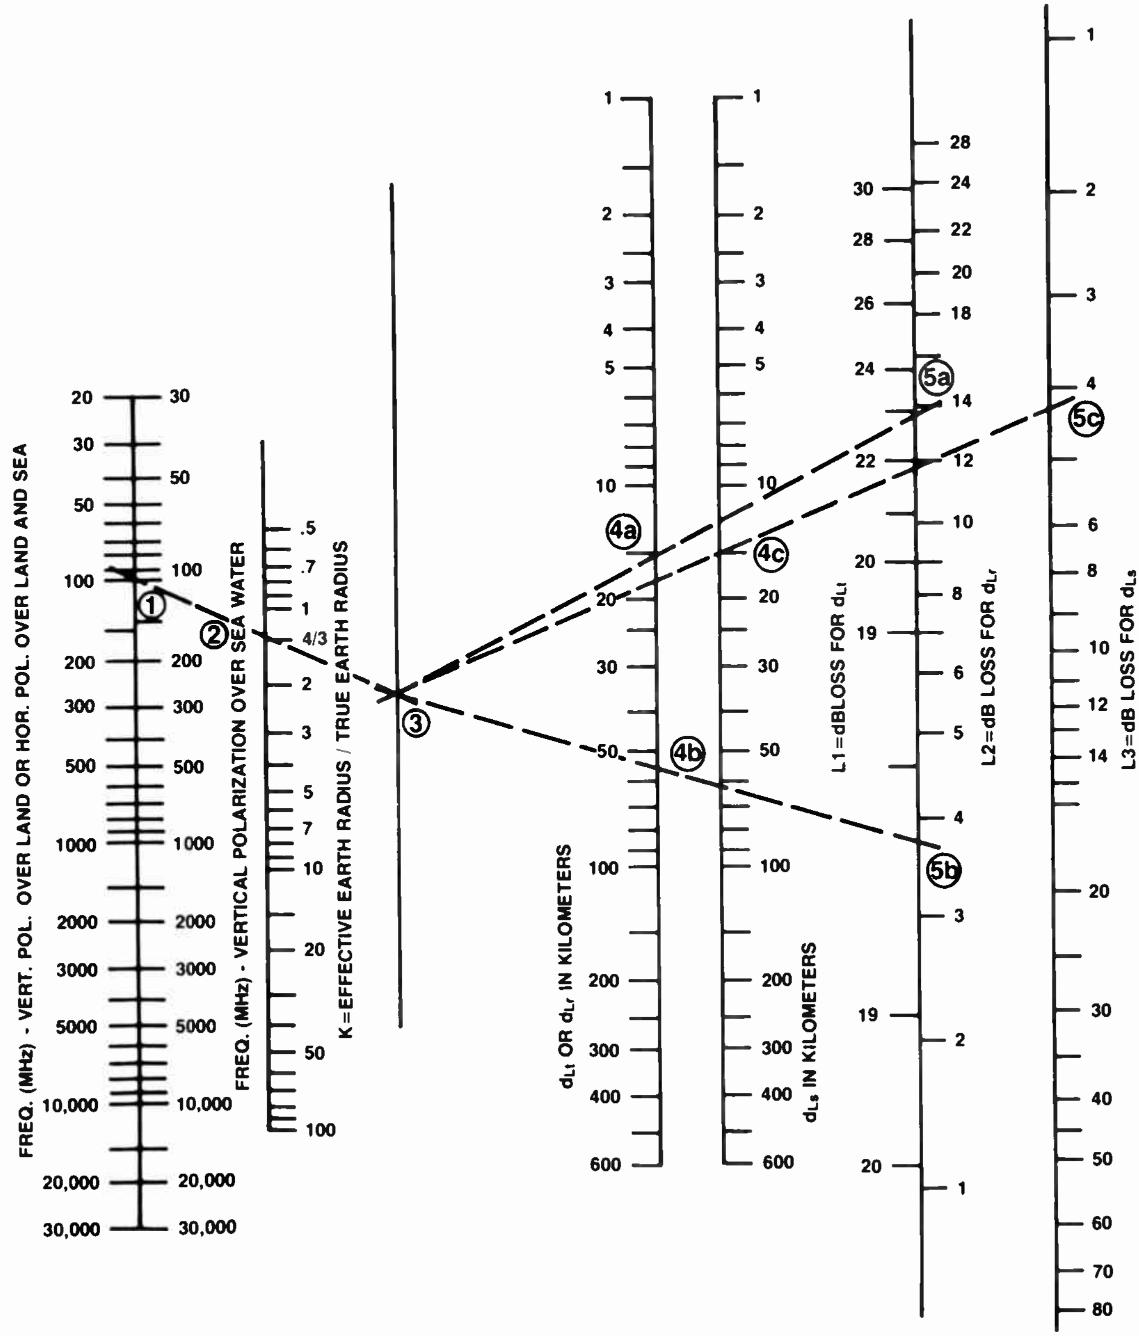

Figure 8. Diffraction loss over smooth earth.

paper that includes the effect of refraction. The most common charts are defined for a factor of k of 4/3. A typical path is shown in Fig. 9. Terrain elevations necessary to construct a path profile can be obtained from topographical maps of the area, or from computer databases. To obtain the best accuracy in using topographical maps the smallest scale available should be used, 1:24,000. These maps can be obtained from the United States Geological Survey in Denver, Colorado or from any of its branch dealerships. Computer models exist that can map the terrain along a propagation path and are available from many sources.

In order to determine when a hill is sufficiently removed from a path to allow free-space conditions to exist, the Fresnel zone clearance equation can be used. This equation was initially developed to explain the diffraction of light around knife edged obstacles, and has since been applied to radio theory. This equation

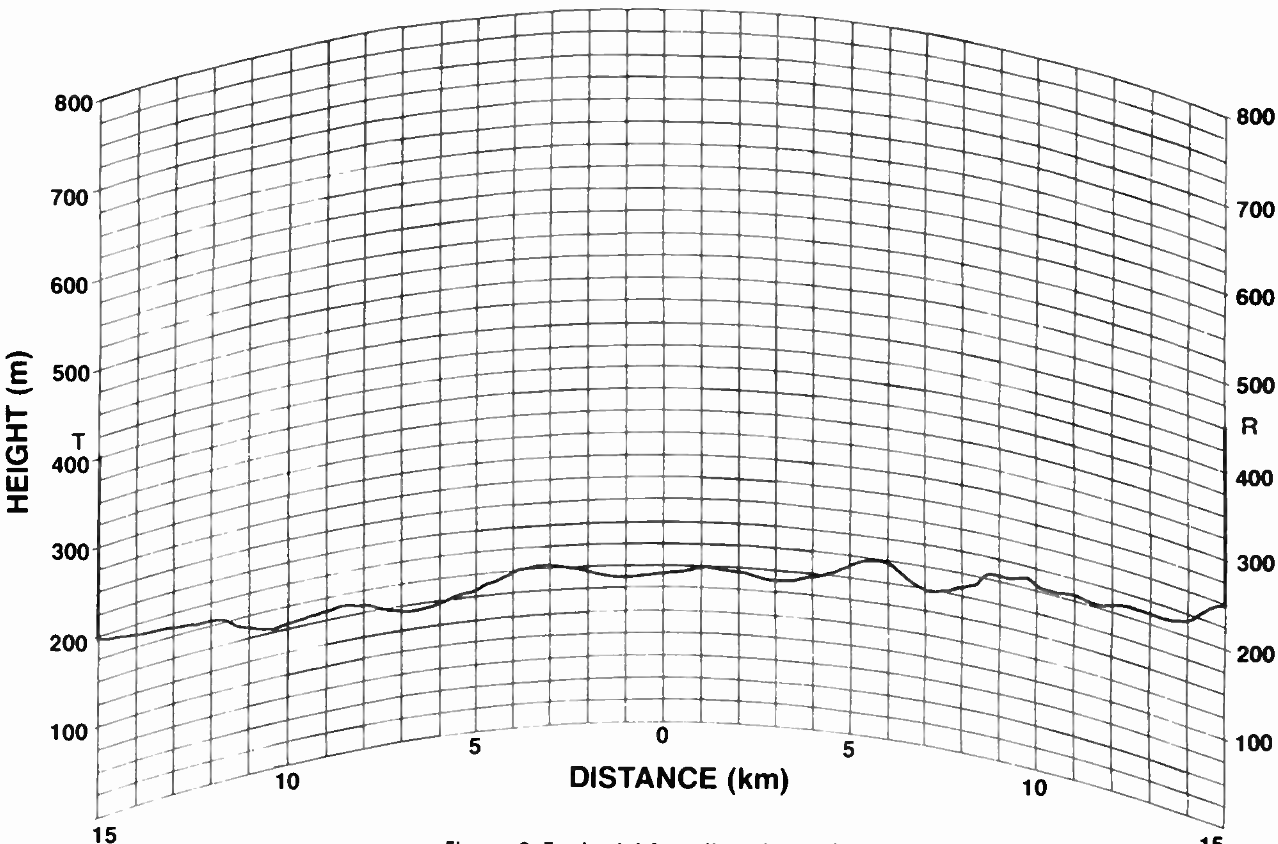

Figure 9. Typical 4/3 earth path profile.

describes a radio path as an ellipsoid with the transmitting and receiving antenna located at the focal points of the ellipse. As Fig. 10 depicts, the curves for various reflection coefficients intersect at 0 dB from free space when the clearance is equal to six-tenths of the distance to the first Fresnel zone clearance. Thus free space conditions exist when obstacles are outside the $0.6F_1$ zone radius. This distance can be calculated by:

$$h = 0.6F_1 = 328.6\sqrt{d_1 d_2/Fd} \qquad [21]$$

where the height of the $0.6F_1$ zone is in meters; d_1 is the distance from one antenna to the obstacle in kilometers; d_2 is the distance from the second antenna to the obstacle in kilometers; d is the total path distance in kilometers; and F is the frequency in megahertz. When determining whether a path clears a hill, an additional height, typically 15 meters, should be added to the height of the hill to account for any trees that may be present.

If the hill lies within the calculated Fresnel zone radius then nonfree-space conditions exist and additional losses will be present. When the frequency is high enough for the hill to be considered as a sharp ridge, and the transmitter and receiver are far enough away from the hill, then the loss may be calculated using diffraction from a knife edge, as shown in Fig. 11. The height of the hill H(m) is measured from the line joining the centers of the two antenna to the top of the ridge. The amount of attenuation or shadow loss with respect to free space may be read from the graph shown in Fig. 12. The value of ν, the diffraction parameter, can be calculated, with respect to the distances measured in kilometers and the frequency F(MHz) from:[4]

$$\nu = 0.00258H\sqrt{dF/d_1 d_2} \qquad [22]$$

When considering paths that are obstructed by hills that appear rounded rather than knife edged, the attenuation can be calculated using diffraction around a cylindrical surface, as depicted in Fig. 13. This condition predominates when the elevation of the hill changes drastically within a wavelength. This can occur when considering paths at the lower end of the VHF spectrum that pass over older mountain ranges, i.e., Appalachian, Blue Ridge, Catskill.

The amount of attenuation can be found from the chart of Fig. 12. The term ρ from the chart is a dimensionless quantity known as the index of curvature of the cylinder's radius R and is calculated from:[4]

$$\rho = 0.83R^{1/3}\lambda^{1/4}\sqrt{d/d_1 d_2} \qquad [23]$$

where all distances are in the same units. For those interested in incorporating the calculation of losses due to diffraction over knife edge and rounded obsta-

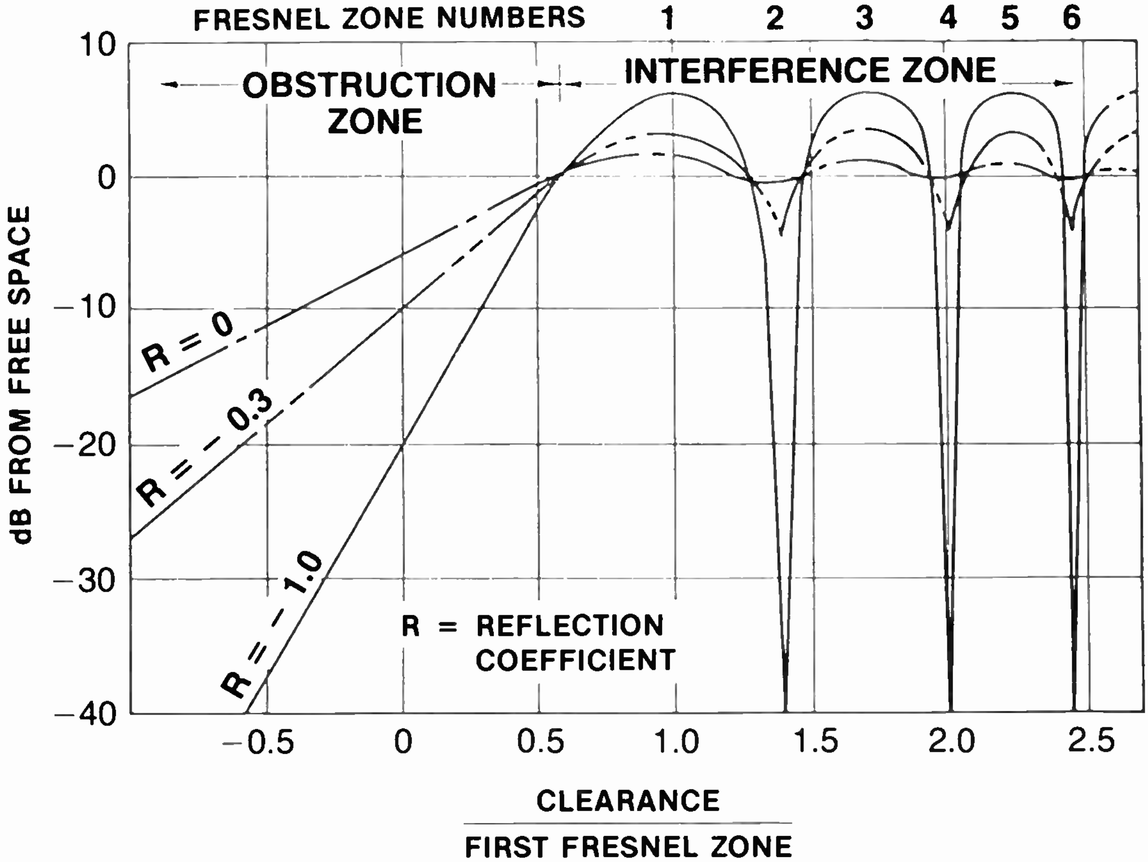

Figure 10. Effect of path clearance on radio propagation.

cles into digital computers more exact equations can be found in Rice, et al.[9]

While the method for calculating the loss due to a single obstacle is relatively straightforward, there are times when successive obstacles are present in a radio path as shown in Fig. 14. In order to determine the loss associated with multiple diffraction regions, an approximation method has been developed based on an extension of single-edge diffraction. The obstacle which would singly produce the greatest diffraction loss is determined using the methods discussed above. Lines are drawn joining the summit of this obstacle to the transmitter and receiver antenna locations. The additional attenuation caused by the remaining obstacles should be calculated using their heights, H_a and H_b, above these lines. These additional losses are then

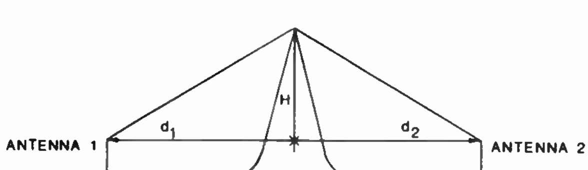

Figure 11. Ray path for knife edge diffraction.

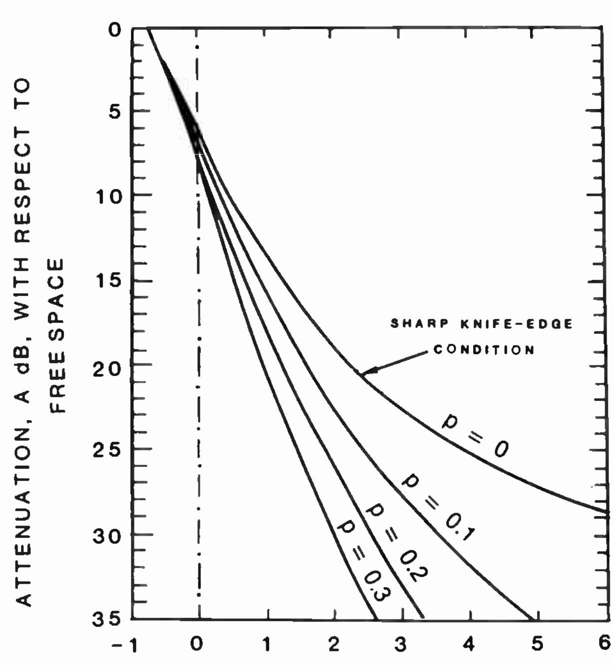

Figure 12. Attenuation due to various diffraction conditions.

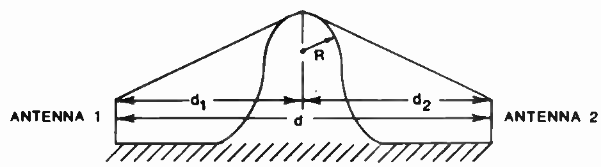

Figure 13. Diffraction due to cylinder.

added to the loss due to the main obstacle in calculating the nonfree-space loss. It is important to note that even if H_a and H_b are slightly negative, i.e., below the lines, they may still produce a small amount of attenuation due to the Fresnel zone clearance requirements.[4]

Buildings

When planning for radio locations within built-up areas of cities or residential areas, buildings will have an effect on radio propagation. For radio relay stations such as studio-to-transmitter links it is the normal practice to select sites that will be clear of buildings. However, where this is not feasible and the path geometry is known, i.e., height and location of buildings, then the diffraction methods discussed for hills may be applied. In planning for broadcast systems, it is not practical to relate attenuation measurements made in built-up areas to the particular geometry of buildings. Therefore it is more conventional to treat the losses in a statistical manner, dividing the general classifications of building types into loss groups, so that a loss can be derived for a particular type of building, i.e., multi-story made of concrete and steel or single-story residential made of wood.

Within built-up areas there is much more back scatter than in open country. Additionally, due to the fact that buildings are more transparent to radio waves than the earth, there tends to be less shadow loss caused by buildings. However, the angles of diffraction due to buildings are usually much greater than in open country for natural terrain and thus the loss resulting from the presence of buildings tends to increase. Measurements indicate that at 100 MHz the median field strengths are 4 dB to 6 dB below that expected for a plane earth and drop off to about 10 dB for 200 MHz.[3] These measurements were made in areas containing some large buildings and open areas, but mainly consisting of residential areas. Some recent measurements conducted in the 850 MHz band indicate field strengths 20 dB to 34 dB below that expected for free space for path distances of 1 km to 25 km.[10]

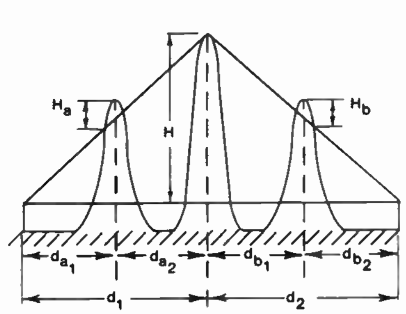

Figure 14. Multiple knife edge diffraction.

Vegetation

Among the many factors that have an effect on the determination of the losses present in a propagation path, vegetation is sometimes the most overlooked. Depending on the type of terrain in consideration, i.e., open or forest, the effect of vegetation can add several dB loss to the system. The amount of attenuation present is dependent upon the frequency and polarization of the wave, see Fig. 15. As can be seen, the attenuation for a horizontally polarized wave for frequencies below about 1000 MHz is much less than for a vertically polarized wave. At around 1000 MHz, trees that are thick enough to block the field of vision can be modeled as an almost solid obstruction and the attenuation over or around these obstructions can be predicted from knife edge diffraction methods.[3]

The effect of vegetation on a radio path varies seasonally in the case of deciduous trees. During the winter months the losses due to shadowing and absorption are less than those during the spring and summer. It is interesting to note that the greatest losses will occur during the spring since new growth has more sap and moisture content which adds to the absorption losses. When the antenna is raised above trees and other vegetation, the prediction of field strengths depends upon the estimation of the height of the antenna above areas of reflection and the reflection coefficients. For areas of fairly uniform growth and for angles of incidence approaching grazing, the reflection coefficient will approach -1 at about 30 MHz. Even low growth that is uniform, i.e., a wheat field, may yield a value of -0.3 for the reflection coefficient.

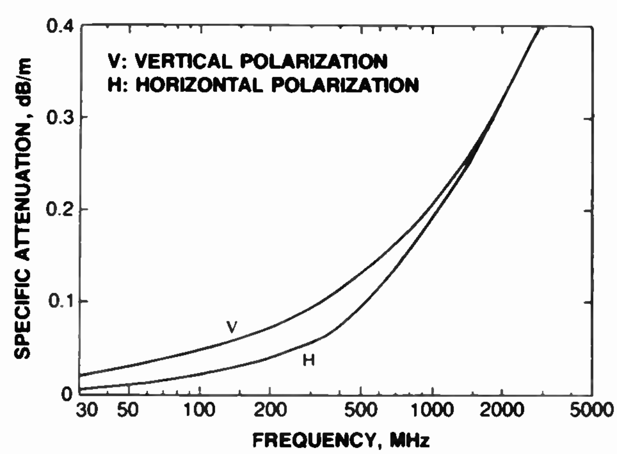

Figure 15. Attenuation through vegetation.

Atmosphere

As was discussed earlier the troposphere is the major medium for propagation at VHF frequencies. The refractive index (n) of air has a value near unity (typically 1.00035). The index is dependent upon the dielectric constant, and can vary depending on the pressure and temperature of the air and on the amount of water vapor present. Therefore the refractive index changes with weather conditions and with the height above the earth. The velocity of radio waves is dependent on the refractive index of the atmosphere. As a general rule the velocity of a wave is slower at the earth's surface than at higher altitudes. So a horizontally polarized wave will be refracted back towards the earth, though unusual atmospheric conditions may change this. Because there are numerous constantly changing variables involved in the prediction of field strengths due to atmospheric conditions, some simplifying assumptions are generally needed to obtain a solution under known meteorological conditions.

Ducting

Changes in the index of refraction of only a few parts per million can have dramatic effects on radio waves. Therefore it is usually more convenient to refer to the refractive index in terms of the refractivity, N:

$$N = (n - 1) \times 10^6 \qquad [24]$$

Under meteorological conditions where the refractive index decreases rapidly with height over a large horizontal distance, radio waves can become trapped and experience low propagation loss over long distances. This phenomenon is known as ducting. Although ducting is frequent with some locations and meteorological conditions, due to its randomness and long range unpredictability it is not a reliable mode for communications. However, due to the strong fields over the horizon caused by ducting, inter-station interference can result. In addition, line of sight paths may be affected by severe fading.

In order for atmospheric ducts to occur, two conditions must exist. First the refractive index gradient must be equal to or more negative than −157 N/km. The refractive index gradient is a measure of the change of the refractivity across a vertical height h, dN/dh. When this condition is present, the radio waves will remain close to the earth's surface beyond the normal horizon. Secondly, the refractive index gradient must be maintained over a height of many wavelengths. The duct may be thought of in the same manner as a transmission line waveguide. However, unlike metallic waveguides, natural ducts do not have sharp boundaries, although there is a wavelength cut-off above which waves will not propagate. Since the duct does not have sharp boundaries, the thickness (t) will not be rigid. Therefore the cut-off wavelength (λ) will not be fixed, but an estimate can be obtained from:[4]

$$\lambda = 2.5 \times 10^{-3}\, t^{2/3} \sqrt{\frac{\delta N}{t} - 0.157} \qquad [25]$$

where the wavelength and thickness are in meters. The term δN represents change in refractive index across the duct. As an example, a duct near the ground that is 25 meters thick and has a refractive index change of 10 N, i.e., −400 N/km, will have a cut-off wavelength of 0.15 m (2 GHz). However, a duct with the same refractive index gradient will have to be about 87 meters thick to propagate a wavelength of 1 meter (300 MHz).

A duct spreads the energy within it in the horizontal direction, but is constrained in the vertical direction as the distance from the transmitter is increased. Thus, in principle it is possible for the field strength within a duct to be greater than the free-space field at the same distance. However, a duct will 'leak', or allow energy to escape at the boundary, adding to the transmission losses so that field strengths are seldom greater than free-space values.[4]

There are typically two types of ducts: ground based and elevated. A ground-based duct, as its name implies, forms close to the earth's surface. Energy is propagated in this duct by being refracted back to the earth, reflected off the earth, then refracted again, see Fig. 16A. An elevated duct forms above the earth's surface and is generally very short lived. Energy in an elevated duct is refracted back and forth between boundaries without coming in contact with the earth, similar to the way coherent light propagates in a graded index optical fiber. (See Fig. 16B.) Shadow regions are formed along the area outside of a duct where, due to the nature of the duct, radio waves are not present. Receiving antennas placed in such a region will experience a loss of signal. As can be seen from Figs. 16A and 16B these regions can form not only above the earth's surface from a ground-based duct, but can also form along the earth's surface in the case of an elevated duct. Therefore a shadow region, that can result in

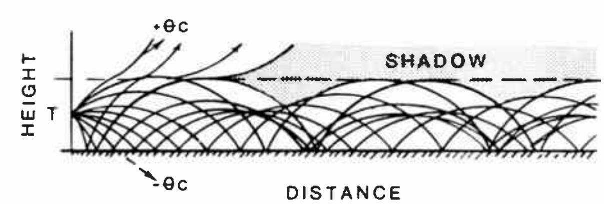

Figure 16A. Ray propagation in a ground based duct.

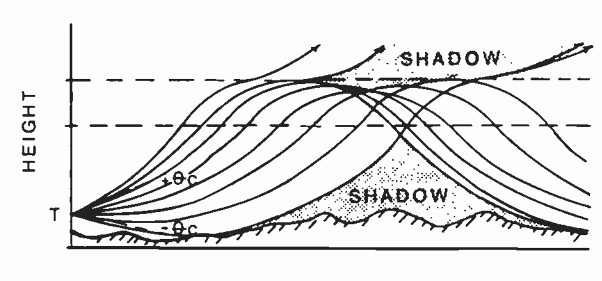

Figure 16B. Ray propagation in an elevated duct.

loss of communications, can form at a receiver that is located relatively close to the transmitter.

Radio waves that leave the transmitting antenna at an angle greater than a certain angle, the critical angle, will not become trapped in a duct. These radio waves will propagate through the boundary of the duct, though they will experience some bending due to the change in the index of refraction at the duct's boundary.

Atmospheric Absorption

Radio systems using frequencies above 1 GHz experience another loss that must be accounted for when planning the system: atmospheric absorption. Relay links and STLs that are inadequately engineered may experience outages during periods of heavy rainfall due to this loss. The amount of attenuation due to rain is dependent upon three factors: (1) the rate the rain is falling, (2) the frequency of the wave, and (3) the length of the rain cell a wave must propagate through. If the path length is only several kilometers long, it is usually adequate to approximate the length of the rain cell by the total path length. The average rainfall rate varies from one section of the country to another, however typical rainfall rates are given in Table 3. The specific attenuation $\lambda_r \left(\frac{dB}{Km}\right)$ is given by[9]:

$$\lambda_r = KR_r^{\alpha} \quad [26]$$

where R_r is the rainfall rate in millimeters per hour, and the terms K and α are found[9] as:

$$K = [3(F-2)^2 - 2(F-2)] \times 10^{-4} \quad [27.1]$$

$$\alpha = [1.14 - 0.07(F-2)^{1/3}] \times [1 + 0.085(F-3.5)e^{(-0.0066F^2)}] \quad [27.2]$$

where F is the frequency in GHz. These equations give a good approximation to attenuation curves published by the CCIR for frequencies below 50 GHz.[14]

In addition to rain, attenuation can also be caused by water vapor and oxygen that is present in the air. The attenuation due to water vapor and oxygen is less than that for rain and usually can be neglected. However, as radio systems employ higher microwave frequencies, attenuation due to these losses will become significant. A description of how these losses can be calculated has been presented in previous works.[9]

COVERAGE AREAS

Engineering a radio or television broadcast station using the methods presented previously are too cumbersome to be of any practical use in determining the service area of the station. While radio waves actually behave in the manner described in the previous sections, it would be too involved to use these methods at every point surrounding a station. Therefore other quantitative methods are needed to determine field strengths quickly and reliably. Considerable work has been conducted in this area and is still being carried out.

TABLE 3
Rainfall amounts.

Characteristics	Rate
Drizzle	0.25 mm/hr
Light Rain	1.00 mm/hr
Moderate Rain	4.00 mm/hr
Heavy Rain	16.00 mm/hr
Very Heavy Rain	100.00 mm/hr

As can be seen from the previous sections, the received field strengths are subject to natural and manmade phenomena. These can cause the field strengths to vary over periods of time and from one location to another. These changes can be long term such as seasonal changes, i.e., weather, temperature, and foliage, or short-term changes such as weather disturbances, i.e., storms and fronts, and vehicles passing in front of the receiver. These variations have an effect on radio systems that is difficult to account for when determining service areas. Thus it is appropriate to describe the field strength statistically, by what percentage of locations will receive a particular field strength for what percentage of time. By describing field variations in this manner, it is possible to determine the service area of a station. However, the terrain still needs to be defined. In preparing propagation curves, this is accomplished by incorporating a terrain roughness factor h. The terrain roughness factor is a generalization of the local terrain and is defined as the difference in elevation between the levels exceeded for 10% and 90% of the terrain along a path. The average value of h for the United States is 50 meters.[11] In using the propagation curves found in the FCC Rules and Regulations for FM and television stations, the local terrain is accounted for by determining the height of the antenna above average terrain along a radial.[12]

Field Strength Prediction

To simplify field strength prediction, curves have been developed to determine the service area of a station. These curves are generally developed using measured values taken from different geographical areas over certain periods of time. The median values are incorporated into a family of curves that describe the field strengths for various antenna heights, frequencies, and distances. A detailed discussion of how to perform field strength measurements may be found in Chapter 2.11 of this *Handbook*, "FM and TV Field Strength Measurements." The FCC curves for FM and television broadcast stations were derived in this manner.[11] The curves used by the FCC for FM and TV describe the field strengths for service at 50% of the locations for 50% of the time. These curves are referred to as F(50,50) and are based on an effective power of 1 kW radiated from a half-wave dipole in free space. The F(50,10) curves used by the FCC describe the field strength for 50% of the locations for 10% of the time. These curves can be used in conjunction with the method described by Allen to estimate the service provided by FM and television stations.[3]

Computer Databases

Through the use of personal computers, field strength estimates can be made quickly, allowing designers to try more options and see the effect on the service area. The designer can change transmitter locations, power levels, and tower heights to optimize the station. There are typically four modules which comprise a computer simulation package: (1) the environmental data base, (2) the equipment data base, (3) the propagation loss module, and (4) the graphical output module.

The environmental data base defines the conditions in which the radio station must operate. For stations operating in the AM broadcast band, this data base is a digitized version of ground conductivity constants for an area. Programs are available which allow a user to search an area to determine appropriate ground conductivity values. For stations operating in the frequency range above 30 MHz this is a topographical data base. The U.S. Geological Survey (USGS) and National Geophysical Data Center (NGDC) provide computer tapes containing digitized terrain elevation data. Several third party sources have adapted these computer tapes to personal computer disk format. The most common resolution provided for terrain elevation provides data spaced at 30 arc-second intervals. The 3 arc-second data base is beginning to become widespread with the acceptance of high density CD-ROM drives for personal computers. The 30 arc-second data base still provides acceptable results for area of coverage predictions, but should be used with caution for STL or microwave planning as it may underestimate significant terrain features. For detailed point-to-point profiling, the 3 arc-second data base is recommended.

The equipment data base defines variables relating to equipment used in the radio system. This includes transmitter output, receiver sensitivity (or field strength), and feed line losses. More sophisticated packages will allow the user to define additional losses such as foliage and buildings to be accounted for by the propagation loss program. In addition, these packages may allow a user to define additional standard deviation values to Rayleigh fading losses. Many packages account for transmitter antennas in varying degrees of sophistication. The simplest accounts for only omni-directional patterns. More in-depth packages allow the user to define directional antenna patterns.

The propagation-loss module uses the information contained in the environmental and equipment data bases to calculate the propagation loss for the area. There are two typical methods for calculating the propagation losses, theoretical and empirical. Theoretical methods are based on well understood physical equations as presented earlier in the chapter. These methods typically do not account for such clutter factors as foliage and buildings. These losses must be accounted for by the user. Empirical methods are based on measured observances of actual propagation characteristics for a particular frequency band and geography. These methods typically employ measurements taken throughout a range of environments, and hence account for such factors as foliage and buildings.

The graphical output module presents the data derived from the propagation loss module in a form easily understood by the user. The output may take two forms. The data can be presented on the computer's CRT terminal. In addition, it may be possible to obtain a hard copy output from a plotter. The plotter output is usually on a clear or translucent film at a scale suitable for overlay to a topographic map.

INTRODUCTION

The possibility of biological damage from strong radio frequency (RF) fields has been brought to the attention of broadcasters in relatively recent years. Although the scientific community had been conducting experiments on the effects of RF exposure on animals, tissue, and cell cultures for a number of decades, broadcasters were not alerted to a need to consider such effects until the Federal Communications Commission (FCC) issued a *Notice of Inquiry* in 1979.[1] *A Notice of Proposed Rule Making*[2] followed the *Inquiry* and, in 1985, rule changes were made incorporating criteria for exposure to RF fields.[3] In the absence of a federal RF exposure protection guide, the FCC included in its Rules the criteria set forth in the current standard of the American National Standards Institute (ANSI),[4] the best documented consensus standard available.

Commencing with the effective date of January 1, 1986, broadcasters have been obliged to certify to the FCC that their operations comply with the radiation exposure criteria of the ANSI Standard. Such certifications are required at the time application is made for new facilities, for changes in existing facilities, and for renewal of station license. Certification may not be made without specific knowledge of the facts derived either from appropriate calculations or measurements, both of which will be discussed in this chapter.

In addition to the absolute need to comply with the FCC Rules, broadcasters have become aware of increasing interest on the part of both their employees and the general public to possible hazards from exposure to RF energy. Books, magazine articles, newspaper stories, and radio and television reports have both educated and misled the public. Much of the information disseminated has presented a distorted viewpoint not supported by credible scientific evidence. The existence of such articles and reports puts a special burden on broadcasters to know the facts about RF, including the protection guides, in addition to ANSI, that have been adopted by responsible standards-setting organizations.

The objectives of this section of the *Handbook* are to provide an understanding of applicable RF protection criteria, to define those situations where calculations are appropriate or where measurements are necessary, to provide guidance in the planning of new facilities, and to describe both calculation and measurement procedures.

RF EXPOSURE STANDARDS

In 1966 the American National Standards Institute (ANSI) issued its first standard that recommended maximum exposure values for electromagnetic field intensities. This early guide on exposures was relatively simplistic in that it set a power density limit of 10,000 μW/cm² across the frequency range of 10 MHz to 100 GHz. Since 1966, the ANSI Standard has been twice revised and is presently in the stages of being revised again to reflect new research findings that are relevant to the setting of realistic and accurate RF exposure standards. In addition to the ANSI Standard, there have been developed numerous standards, guidelines, ordinances, exposure policies, and recommendations by federal, state, and local governments. This section is intended as an overview of some of these documents to provide a perspective on what presently exists in the regulatory world of RF fields and some of the trends that are occurring in regulation development.

Virtually all modern RF exposure guides are now frequency dependent; i.e., the recommended maximum exposure levels vary according to the frequency of the exposure fields. This fundamental commonality is based on the finding that the body absorbs RF energy from electromagnetic fields differently at different frequencies. While research continues to provide a better understanding of how RF fields interact with the human body, there have been no substantially different findings which argue for a totally different approach to evaluating the physiological significance of exposure to RF fields. Thus, the rationales that have been developed for different standards or protection guides are merely the result of different judgements about what represents an adequate margin of safety, reflecting a difference in opinion over the magnitude of the margin of safety that is appropriate for the general public rather than any fundamentally different evaluation of what represents a hazardous effect in laboratory animals.

Coupling of Fields to the Body—SAR

In the quest for finding a suitable dosimetric parameter to use for quantifying biological effects of RF fields, the concept of the specific absorption rate (SAR) has been used extensively for many years. This parameter, the result of the complicated manner by which RF fields interact with the body, is the rate at which energy from the incident fields is absorbed, expressed in units of watts per kilogram (W/kg) of body mass. Fig. 1 shows how the SAR for a prolate spheroidal model of the human body exhibits a peak in the so-called body resonance range, that frequency range in which the body is approximately one-half wavelength in height. Three different curves in Fig. 1 correspond to conditions of alignment of the body's long axis with the electric field (curve labeled E), alignment with the magnetic field (curve labeled H), and alignment with the direction of propagation of the RF field (curve labeled K).

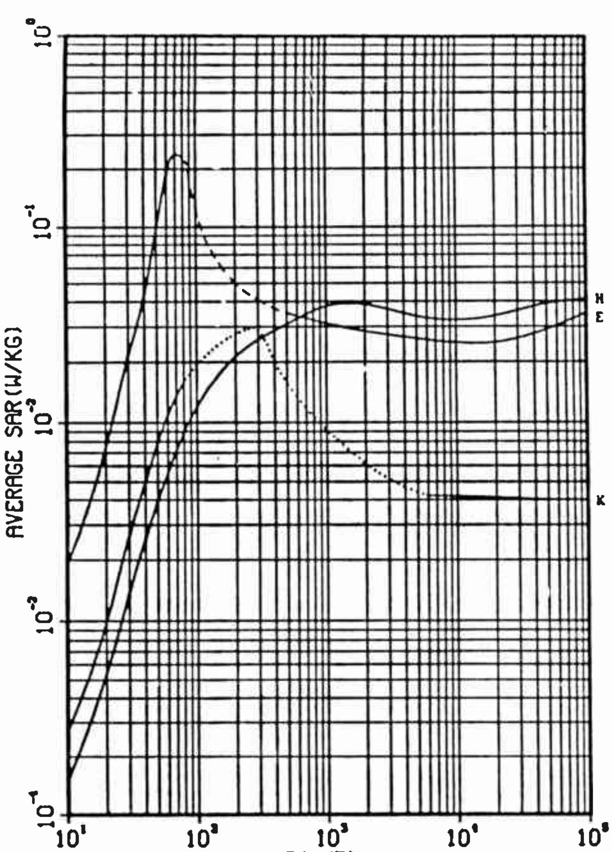

Figure 1. Specific absorption rate (SAR) for electromagnetic fields for an average adult sized human for an incident RF field power density of 1 mW/cm². Curves E, H and K refer to conditions of alignment of the electric field, magnetic field or direction of propagation with the long axis of the body with the assumption of the body being suspended in free space (not grounded). (From Durney et al [1986].)

ANSI Radiation Protection Guide

The current ANSI Standard, C95.1–1982, is a frequency-dependent radio frequency protection guide (RFPG) that specifies maximum values of RF exposure for individuals. Fig. 2 illustrates this frequency dependence. The varying limits are due to the fact that the human body exhibits a frequency response much like a radio antenna, absorbing RF energy more effectively in its resonance range and not absorbing as well at other frequencies. The Standard specifies RF field intensities in two different ways: the permitted electric and magnetic field strengths (actually, the ANSI Standard limits the squares of field strength) and the power densities that would be associated with plane waves having the equivalent electric and magnetic field strengths (plane-wave equivalent power density).

In deriving the RFPG, the ANSI subcommittee elected to assume that man would respond much like the laboratory animals, for which energy absorption rates greater than four to six watts per kilogram, if maintained for protracted periods of time, could eventually be hazardous. To take into account the many variabilities in translating from animal to man, and the range of susceptibilities that individuals might exhibit to RF field exposures, a tenfold margin of safety was introduced to obtain the working limits of the ANSI RFPG. Thus, the specified limits in the ANSI RFPG for RF fields are designed to keep the energy absorption rate, when averaged over the whole body, to less than 0.4 W/kg, ten times less than the presumed hazard level. Since absorption of RF fields within the body is highly nonuniform, ANSI also prescribed limits intended to limit the local SAR value to no more than 8 W/kg in any one gram of tissue.

The plane-wave equivalent power density of a RF field and the associated electric and magnetic fields are related as shown in the following equation:

$$S(W/m^2) = E^2/_{377} = 377\,H^2$$

where S is the power density, expressed here in watts per square meter, and E and H represent the electric and magnetic field strengths, in units of volts per meter and amperes per meter, respectively. The factor of 377 is the impedance of free space in ohms. However, ANSI chose an arbitrary value for the impedance of free space equal to 400 ohms rather than the empirical value of 377 ohms. For this reason, in the ANSI

Frequency Range (MHz)	Electric Field Squared (V^2/m^2)	Magnetic Field Squared (A^2/m^2)	Equivalent Far-field Power Density (mW/cm^2)
0.3 - 3	400,000	2.5	100
3 - 30	4,000 x ($900/f^2$)	0.025 x ($900/f^2$)	$900/f^2$
30 - 300	4,000	0.025	1.0
300 - 1,500	4,000 x (f/300)	0.025 x (f/300)	f/300
1,500 - 100,000	20,000	0.125	5.0

Note: f = frequency (MHz)

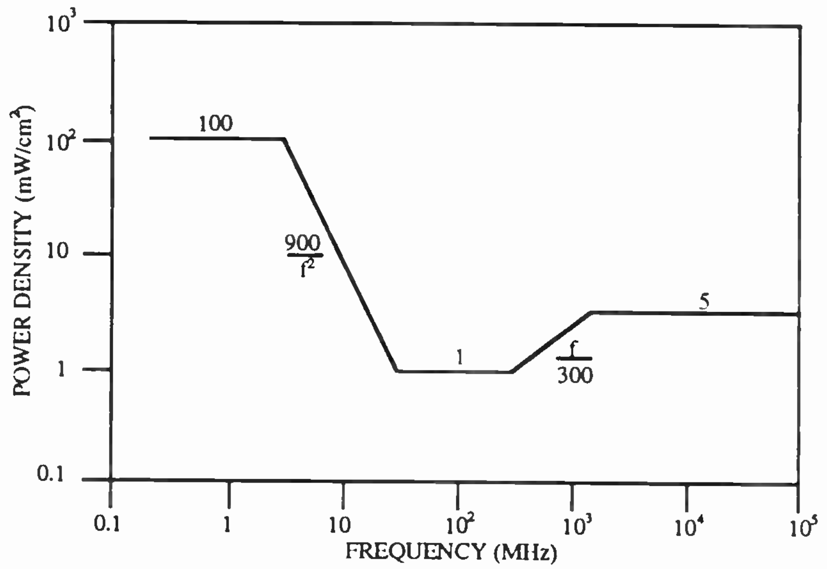

Figure 2. Summary of ANSI C95.1-1982 RF Protection Guide.

standard, 1 mW/cm^2 is equated to a squared electric field strength of 4,000 V^2/m^2 rather than 3,770 V^2/m^2. The equation for power density then becomes:

$$S(mW/cm^2) = E^2/_{4000} = 40\,H^2 \qquad [1]$$

Fig. 2 shows that in the very-high-frequency (VHF) part of the spectrum (30–300 MHz), the ANSI guide for exposure is the most stringent; i.e. it limits the fields to the lowest value anywhere in the electromagnetic spectrum. This is because the adult human body exhibits a whole-body resonance peak at around 70–90 MHz, while the body of a small child resonates at a considerably higher frequency, nearer 300 MHz. Thus the flat limit line between 30 MHz and 300 MHz protects individuals of all sizes from absorbing RF energy at excessive rates.

There are three additional qualifications of the limiting values of RF exposure given in Fig. 2. First, RF fields measured as being equal to the ANSI limit will normally incorporate a significant degree of additional safety since it is generally unlikely that the body will be exactly aligned with the polarization of the incident fields. A second qualification is that, while the RFPG power density limits were based on the concept of a human body being uniformly exposed to a given power density (that value that would result in a whole-body averaged SAR of 0.4 W/kg), the Standard does not explicitly state that the field must be uniform over the body to be of significance, nor does it explicitly state that exposure of only part of the body to a field greater than the specified power density limits is acceptable. Hence, a conservative view is that exposure of any part of the body to RF fields that exceed the RFPG for sufficiently long times represents noncompliance with the Standard.

The third qualification of the limiting values of RF exposure given in Fig. 2 is that they represent the time-averaged value over any six-minute period of time. Thus, the limits given in the ANSI RFPG are applicable to long-term exposure of indefinite extent. But, when the exposure duration can be controlled to periods shorter than six minutes, then higher levels are permitted. This means that RF fields higher than the values shown on Fig. 2 are acceptable, providing that the exposure time is controlled in such a way as to keep the average value over any six-minute window of time to no more than that given by the graph. For example, at 100 MHz, if the exposure time can be controlled to only three minutes in any six-minute period, then the power density can rise to 2 mW/cm^2. During the remaining three minutes of the six-minute period, however, no exposure would be permitted. This provision is helpful in those instances where transient exposures may occur as in passing momentarily through elevated field areas. In practice, determining the actual time-averaged exposure level is complicated because of having to keep track of both the RF field level and the time duration of exposure to each level.

During the development of the ANSI RFPG, it became apparent that controlling exposure to low-powered sources would be extremely difficult. Therefore, based on the concept that only limited SARs would result from exposure to low power systems, ANSI introduced an exclusion clause in the guide which exempts sources of 7 W or less power which operate within the frequency range of 300 kHz to 1 GHz from falling within the compliance requirements of the guide. In this context, most handy-talkies and studio-transmitter-link transmitters are excluded devices because of their low powers.

National Council on Radiation Protection and Measurements

The National Council on Radiation Protection and Measurements (NCRP) is a congressionally chartered, nonprofit corporation established in 1964 to collect, analyze, develop, and disseminate in the public interest information and recommendations about radiation and radiation measurements, particularly those concerned with radiation protection. The NCRP has developed exposure criteria for RF fields but has distinguished maximum recommended RF levels for those occupationally exposed from levels that are applicable to the general public, a distinction not contained in the present ANSI RFPG. The concept introduced by NCRP to recommend more stringent limits for the general public is based on a concern that a greater margin of safety is appropriate since a wider range of health conditions may exist among the public (i.e. there may be individuals that are more susceptible due to age or other factors) and those working with RF fields are more likely to be aware of the potential for hazards and can take preventive measures to limit their exposure.

The NCRP criteria for occupational exposures are the same as the ANSI criteria, shown in Fig. 2. However, the criteria for the general public are equivalent to one-fifth of these values. In the VHF band (30–300 MHz), for example, the NCRP general public exposure limit is 0.2 mW/cm^2. However, the averaging time associated with the NCRP general public criteria is 30 minutes rather than the six minutes used in the occupational exposure criteria and the ANSI RFPG. By selecting a 30-minute averaging time, the total energy absorption (equal to the product of power density and time) is the same for both the general public and workers.

NCRP took a slightly different approach to the issue of fields produced by low power devices: in this case, NCRP states that the "Use of such devices is permitted, as a personal decision by the individual, provided that the devices are designed and used as designed so that the exposure of the individual does not exceed the recommended occupational guidelines and provided that, in using the devices, the individual does not expose other persons above the population guidelines." As such, the NCRP guidelines do not contain a specific power limit for such devices.

IRPA Guidelines

The International Radiation Protection Association (IRPA), an international association of radiation protection societies, in 1988 revised its earlier guidelines for RF exposure to reflect advances that have been made in biological effects research, particularly in the field of dosimetry.

TABLE 1

IRPA occupational exposure limits for RF fields.

Frequency (MHz)	E(V/m)	H(A m)	P_{eq}(mW/cm^2)
0.1–1	614	1.6/f	—
1–10	614/f	1.6/f	—
10–400	61	0.16	1
400–2,000	$3\sqrt{f}$	$0.008\sqrt{f}$	f/400
2,000–3,000	137	0.36	5

However, the limits for magnetic and electric field strengths indicated above for frequencies above 10 MHz may be exceeded for the case of near-field exposure, provided that:

$$\tfrac{5}{6}(E^2/_{377}) + \tfrac{1}{6}(377H^2) < P_{eq}(W/m^2)$$

where E is the electric field strength (V/m) and H is the magnetic field strength (A/m). IRPA recommended limits for the general public are more restrictive, with P_{eq} being one-fifth of that for occupational exposures.

Both the occupational and general public exposure limits recommended by IRPA employ an averaging time of six minutes during a 24-hour day. In this sense, the IRPA limits are more restrictive than the NCRP criteria since relatively high but momentary exposures will be more curtailed according to the shorter time over which they can be averaged. The IRPA guidelines also contain an exclusion clause, similar to ANSI, permitting the use of low powered transmitting devices which operate with powers no greater than 7 W that may produce RF fields exceeding the specified field strength limits.

OSHA RF Standard

The Occupational Health and Safety Administration adopted the 1966 ANSI standard for occupational exposure in 1971, permitting an exposure of up to 10 mW/cm^2 for frequencies between 10 MHz and 100 GHz. The OSHA standard was determined to be merely advisory in 1976 and was implemented by OSHA under the General Duty Clause of the Occupational Safety and Health Act until March 1982, at which time OSHA proposed to revoke its standard. In February 1984, OSHA determined to retain its standard because it provided useful advice for employers. Thus, while the OSHA standard remains on the books even today, it is ten times less restrictive in the 30 MHz to 300 MHz frequency range than the current ANSI RFPG.

ACGIH RF Threshold Limit Values

The American Conference of Governmental Industrial Hygienists (ACGIH) has developed it own threshold limit values for RF fields. The limiting values are similar to the ANSI RFPG in that they are frequency dependent, although, since it is assumed that workers are adults, the power density limits have been tailored to control the SAR in the adult size body and consequently exhibit a different variation with frequency. An averaging period of six minutes is used, similar to ANSI.

Environmental Protection Agency

The Environmental Protection Agency, after almost ten years of work, issued a Notice of Proposed Recommendations for public comment in 1986. This document, "Proposed Alternatives for Controlling Public Exposure to Radiofrequency Radiation," contained four alternative approaches to limit the public's exposure to RF radiation. Three of these options were regulatory and suggested possible numerical exposure limits for RF fields. The fourth option was nonregulatory: information and technical assistance programs would be conducted in lieu of adopting federal guidance.

The options on which EPA sought comment would limit whole-body average SARs to 0.04, 0.08, or 0.4 W/kg. These limiting SARs correspond to RF field power densities in the 30 MHz to 300 MHz frequency range of 100, 200, and 1,000 μW/cm^2 respectively. Thus, the least restrictive option would correspond to the ANSI RFPG while the middle option would be similar to the NCRP criterion for public exposure. Recently, though, the EPA announced that it had determined to phase out its RF program and not to issue Federal Guidance as it had intended to do, citing budgetary constraints to complete projects in apparently higher priority areas and a lack of hard scientific evidence of harm due to exposure to RF fields in the environment. The EPA Office of Radiation Programs has tasked the agency's Human Health Assessment Group (formerly called the Cancer Assessment Group) to perform a comprehensive review of the cancer literature. This project, begun in 1986, seeks to determine whether the literature, when subjected to the same guidelines used by EPA's cancer experts to judge chemicals, supports the classification of electromagnetic fields as a possible carcinogen. The question of an association of exposure to RF fields and cancer is presently unclear and the literature in this area has not been found useful by EPA, ANSI, or NCRP for the development of guidelines. The report from the EPA has reached the review draft stage and is, as of this writing, being reviewed by an external EPA Science Advisory Board committee. The review draft seems to support the contention that it is unrealistic that the cancer issue can be resolved for some years to come in terms of performing quantitative risk assessments.

Selected Foreign Standards

Numerous countries have developed recommendations, if not regulatory limits, on maximum RF fields to which workers and/or the general public should be exposed. Table 2 is intended as a brief summary for some selected countries. Most of these standards reflect the same general type of frequency dependency that the ANSI, NCRP, and IRPA recommendations are based upon, and consequently they can be relatively complex to describe:

TABLE 2

Foreign Nation	Most Restrictive Worker Limit (mW/cm^2)	Public vs. Worker	Time-Average Period
United Kingdom	1	no difference	6 minutes
Australia	1	5 x tighter	60 seconds
Canada	1	5 x tighter	6 minutes
Germany	2.5	no difference	6 minutes
USSR	0.025	2.5 x tighter	2 hrs. or 20 min.
Poland	0.20	2 x tighter	intermittent

It should be noted, however, that the very restrictive limits of the Eastern Bloc countries, such as Poland and the Soviet Union, are different from the others in that there seems to be no scientific rationale for the standards. This is in contrast to those guidelines in most western countries in which relatively clear documentation exists of the underlying database of effects, knowledge, and thinking that went into the development of the standard. The lack of this documentation makes the evaluation of such guidelines or standards more difficult and calls into question their technical validity.

Local Standards

Several states, counties, and cities have enacted, or attempted to enact, standards or ordinances which set upper limits on exposure of the public to RF fields. Some of these standards have relied on the ANSI standard and others have been developed in a manner more similar to the NCRP exposure criteria: examples include Arizona, Connecticut, Massachusetts, New Jersey, and Texas. Counties and cities active in this local regulatory area include Avon, Connecticut; Onondaga, New York; Multnomah County and City of Portland, Oregon; Jefferson and Boulder Counties, Colorado; New York City; and King County and the City of Seattle, Washington. The local codes vary from location to location, as well as within a community over time, which means that the interested broadcaster will need to research the particular restrictions that apply to him.

Pending Revision to ANSI

ANSI standards are subject to regular revision. At five year intervals, unless authority is granted for an extension, standards must be reviewed and either modified, reaffirmed, or deleted. In the case of ANSI C95.1–1982, the revision process began shortly after the issue date. At the time of preparation of this *Handbook*, a revised standard had been approved by a majority of the Subcommittee preparing the revision and by IEEE Standards Coordinating Committee 28. The IEEE Standards Board is expected to approve the revision and send it to ANSI sometime in 1991 to be issued as a revised ANSI standard.

After the revised standard receives approval by ANSI, the FCC is expected to issue a Notice of Proposed Rule Making bringing its environmental rules in line with the revision. Therefore, the expectation exists that broadcasters, at some future date, will be required to show compliance with a different Standard, one that may make a distinction between controlled and uncontrolled environments and one that may introduce new measurement techniques as a means of establishing compliance. If a trend were to be identified in the limiting levels of RF fields which exist in standards settings activities, it would seem to be comparable to the NCRP or IRPA exposure criteria for general population exposure, i.e., approximately one-fifth of the ANSI RFPG levels, at least in the VHF spectrum (30–300 MHz) and higher in frequency.

Serious thought is being given to the question of whether there is a technical basis, in fact, for differentiating between individuals who are occupationally exposed and those in the general population. Such thinking is predicated on the observation that almost all biological effects of RF field exposure appear to be threshold effects; this means that effects do not occur until the SAR is above some threshold value. If this is the case, some argue, then RF radiation is not a zero-threshold agent as ionizing radiation is considered to be. Consequently, more protection of the public is not warranted since lower level exposures are not cumulative in causing effects. RF field biological effects are believed to be principally dose rate phenomena, i.e., they depend on the rate at which energy is absorbed from the field, not the total energy absorbed as is the case with nuclear radiation. This rate concept is demonstrated in the time-averaging provisions of the standards, in which exposure to the RF field may be distributed over some period, typically between 6 and 30 minutes. The averaging time specified in various standards is not related to any cumulative biological effect, but rather to the thermal time constants of the body.

The use of induced and conducted body currents as surrogates for SAR is evolving. Currents in tissues of the body can be related to the SAR in the tissue, and thus, can be used to evaluate conformance of RF exposures with the exposure criteria upon which many protection guides are based. Often, currents, either induced from the field itself or as a consequence of contacting an object immersed in a RF field, can offer a more meaningful indication of potential hazard than the fields themselves. Measurement of contact currents can, in many instances, show that the SAR which may result from touching an object which exhibits strong surface RF fields that exceed the field strength limits of various protection guides does not, in fact, exceed the SAR limits of the guide.

CONSIDERATIONS SPECIFIC TO BROADCAST SERVICES

FCC rules implementing the National Environmental Policy Act of 1969 encompass much more than RF exposure, the subject matter of this *Handbook* chapter.[5] However, this discussion will relate only to the environmental aspects of RF exposure.

To avoid the requirement for an Environmental Assessment,[6] the broadcaster must be prepared to demonstrate by calculation or measurement that their existing or proposed operation subject to results in RF exposures not in excess of the protection guide set forth in ANSI C95.1–1982. Compliance with the protection guide (and with the other aspects of environmental considerations) establishes that Commission actions granting the license renewal or construction permit for new or changed facilities would "have no significant effect on the quality of the human environment and are categorically excluded from environmental processing."[7] Broadcast facilities sites should be selected, or the equipment designed, to achieve "categorical exclusion". Failure to meet the RF protection guide is virtually certain to result in refusal by the Commission of a requested construction permit or license renewal.

AM Stations

In AM broadcast systems, the relatively long wavelengths employed result in the fact that all RF exposures of interest from a compliance viewpoint are in the "near field". The near field is characterized by the fact that the electric (E) and magnetic (H) components are at random phase rather than in phase quadrature as in the far field. The far-field, plane-wave characteristic relationship, $E/H = 377$ ohms, does not apply. Consequently, at any point either component of the electromagnetic field may be high and the other low. Both electric and magnetic fields must be determined independently at each location of interest and checked against the separate exposure criteria for the two fields to determine whether or not compliance has been achieved.

Calculation and measurement procedures for AM will be covered in more detail below. A cautionary note may be appropriate here, however. Measurements are not always what they seem. The most commonly used meters for AM measurements, the Potomac Instruments FIM series, are calibrated in units appropriate for the electric field. However, the shielded loop antenna employed actually responds to the magnetic field. Construction of the scale has been based on an assumption that the meter is being used in the far field, where E(V/m) = 377H(A/m) and where that relationship can be used to translate meter readings to the true magnetic field that is being measured. Measurement of the electric field in the near field must be made with instruments described in the measurement section below.

Critical areas on AM transmitter sites include not only the towers themselves and their proximity, but also the vicinity of inductors used in phasing and matching networks. The highest magnetic fields in an AM transmitting plant are likely to be found near the ends of such inductors. Particularly in high-power operations, where inductors are likely to be carrying large currents, entire tuning houses may be found to exceed the present standards for continuous exposure to magnetic fields.

Transmitters, themselves, are not likely to exhibit significant field leakage from their cabinets unless door seals have been damaged. Nevertheless, leakage should be checked periodically. Windows in transmitters and phasing cabinets must be checked as possible sources of excessive exposure to operators using them for observation of internal components. At any time that work must be performed on the final amplifier stage of a transmitter, high voltage must be removed, not only to avoid excessive RF exposure, but also to reduce the danger of life-threatening shock.

FM Stations

The highest levels of RF exposure near ground level from an FM antenna may not be directly under the antenna, but some tens of feet away. Older FM antennas, in particular, may have a strong downward lobe placing the strongest field at the base of the supporting tower, but antennas of modern design can avoid emission of that "grating lobe." Depending on the number of bays, the radiation characteristics of the individual elements, the spacing between elements, and the extent of null fill and beam tilt, the magnitude and location of maximum field strength from secondary antenna lobes can vary widely.

Near ground level, and except for the effect of reflections from the ground or nearby objects, far-field conditions obtain in that the electric and magnetic fields are in quadrature phase relationship. However, reflected energy affects that relationship, generally requiring that the electric and magnetic fields be considered separately. Another factor requiring consideration is the shape of the radiation pattern. At locations relatively close to the antenna, i.e., at distances less than ten times the antenna length, irregularities not anticipated by the manufacturer's published radiation pattern may occur. Hence, maximum field strength may be found at locations not suggested by study of the radiation pattern.

Transmitter considerations are similar to those in AM except that the final amplification stage is likely to be much better shielded than in the AM case. Nevertheless, caution must be exercised in being certain that the transmitter is inoperative and that the transmission line is properly terminated when work is to be done within the cabinet.

TV Stations

Television antennas are, more often than not, on tall towers or relatively tall structures on building tops. Furthermore, the antennas used have relatively little radiation downward. Consequently, even though substantial power is generally involved, particularly in the UHF band, radiation levels near ground level are usually well below protection criteria. The result is that the major consideration may be related to tower and antenna maintenance rather than ground-level exposure.

Preferably by measurement, the limits of areas conforming to the protection guide should be defined for different power levels of the facility. As described later in this section, safe work rules should be adopted based on those determinations.

Auxiliary Services

Broadcast auxiliary services are covered by Part 74 of the Commission's Rules. Only Experimental (Subpart A), Low Power TV, TV Translators and TV Boosters (Subpart G), and FM Boosters with transmitter output power in excess of 10 watts (Subpart L) are subject to the requirement to certify compliance with the RF radiation protection guide. All other auxiliary services are categorically excluded from routine consideration, because of the low likelihood of excessive exposure problems, although no exclusion is established from the basic need for all licensed facilities to comply with the ANSI Standard.

Multi-User Sites

Joint use by multiple transmitting facilities of a single site involves special considerations relative to determinations of compliance with RF radiation criteria and the need for cooperation among user parties. The Commission has clarified responsibility with the following statement: "In such situations [exceeding of guidelines due to emissions from multiple transmissions], actions necessary to bring an area into compliance shall be the shared responsibility of all licensees, not otherwise categorically excluded, whose transmitters contribute more than 1% of applicable exposure limits."[8] ". . . [I]n the case of a newcomer, not categorically excluded. . .. whose additional contribution of more than 1% of the guidelines would cause a location previously in compliance to become non-complying, the responsibility for corrective action would rest with the newcomer."[9]

The shared responsibility of avoiding exposure in excess of the applicable exposure limits extends to workers required to enter areas of normally high signal strength for the purpose of maintaining equipment. The cooperation of all parties with transmitters at multiple-use sites is mandatory. Although the FCC can be called upon to adjudicate differences among its licensees, a far better procedure is to achieve voluntary agreements without the intercession of the Commission. The Commission has suggested that complaints in this regard should be directed to the Mass Media Bureau; the Field Operations Bureau is not expected to be prepared to intercede in specific cases.

MEASUREMENT PROCEDURES

In anticipation of the effective date for the adoption of the ANSI RFPG by the FCC, the FCC's Office of Science & Technology published Bulletin No. 65, "Evaluating Compliance with FCC-Specified Guidelines for Human Exposure to Radio-Frequency Radiation", October 1985. This document, prepared by Dr. Robert F. Cleveland, forms the basis for all submissions to the FCC regarding compliance with ANSI.

Whenever practical, field measurement of the RF power density levels is to be preferred over calculation, as the definitive method of determining those levels. Care must be taken, however, when taking measurements for the purposes of determining compliance with the ANSI RF exposure guidelines, in order that the examination of the site be complete. The principal concern when taking these measurements is to identify all areas requiring access restrictions, in order to protect fully the liability exposure of the FCC licensee(s) at the site. Failure to identify these areas begs the question of licensee candor in self-certification to the FCC at license renewal, as well as the issue of negligence in the event of legal action based upon "excessive" exposure to RF energy. It is important that the measurement process should be accurately described to allow for a high degree of repeatability in future measurements by others.

Physical Parameters

Power density is most commonly expressed in units of milliwatts per square centimeter (mW/cm^2). Instruments designed for electromagnetic field hazard surveys are typically calibrated in terms of either field strength, field strength squared units, or plane wave equivalent power density. As will be seen, many instruments use detectors that are actually responsive to the square of the field strength, either electric or magnetic, but provide meter readings in plane wave equivalent power density; the meter indications are obtained via an electronic manipulation (Eq. 1). In other cases, instruments designed to sense the magnetic field are calibrated in terms of plane wave equivalent electric field strength.

Other parameters of importance are the frequency or frequencies of the principal source(s) and the duration of the exposure. Virtually all current standards for electromagnetic field exposures are frequency dependent; this dependence takes into account the frequency response of the human body in terms of energy extraction from the incident fields. Because the body acts much like a radio antenna absorbing energy from the field better at certain frequencies, most recommended limits for exposure levels vary in accordance with this frequency selectivity of the body, with the most stringent controls in the body resonance range and less restrictive levels at frequencies both lower and higher than this range. Therefore, when performing a survey of exposure, knowledge of the frequency of the field is necessary to relate to permitted exposure limits and the instrument being used for the measurements must be capable of accurate response at the frequency of exposure.

Electromagnetic fields have a wide range of waveforms depending on their use. For example, a pulsed radar signal typically will exhibit a very high peak to average field strength ratio due to the use of very narrow pulse widths but very high peak powers. In the case of normal AM radio broadcasting, again the average value of the field will be dependent on the programming material and adjustments to the transmitter. TV broadcasting involves the transmission of synchronization pulses which have considerably greater peak powers than the associated video programming material. The waveform of some fields may be of interest because of their rapid changes in time, which, for magnetic fields, may be important from the standpoint of induced currents in the body.

Broadband Instruments

In terms of convenience, broadband instruments are considerably more popular than narrowband instruments for evaluating exposure to electromagnetic fields. Broadband instruments, as their name implies, respond over a wide range of frequencies, possessing nearly flat responses independent of frequency within their frequency pass band. Most common broadband meters feature isotropic probes, consisting of three mutually orthogonal detecting elements connected electronically in such a manner that the output of the meter becomes essentially independent of probe orientation within the field. Isotropy is typically achieved to within ±0.5 to 1 dB, but no information on the electrical phase of the fields is retained.

Probe detection elements are normally either thermocouples or diodes. Thermocouples exhibit the useful property of being average-responding detectors. When placed in a modulated field, such as a pulsed radar field, they will accurately respond to the average value of the field squared or average plane-wave equivalent power density. This same property, i.e., true root mean square (RMS) detection, of thermocouples, makes them useful in multiple frequency electromagnetic field environments since they can accurately respond to the sum of the average fields present at the probe. Diode detectors, on the other hand, tend to be peak detectors rather than average detectors unless operated within limited field strength ranges where they can exhibit so-called square law responses, i.e., they will respond correctly to the power density or square of the fields. In some instruments, special circuits are used to correct for the nonsquare law operation of diode detectors. This technique works well for single frequencies, but cannot properly correct readings when multiple signals are being measured. In summary, while diode detectors have certain disadvantages, they also have several advantages over thermocouples, including durability, ability to withstand overloads from strong fields, significantly better thermal stability, and high sensitivity.

While isotropic survey instruments have separate probe assemblies connected by cable to the meter, some survey instruments have single or multiple sensing probes mounted directly on the instrument package. Those instruments equipped with one probe element are responsive to only one field polarization component at a time. The absence of a connecting cable between the probe and the readout package, in some cases, is responsible for superior performance when used in low-frequency fields; it is common for cables to "pick up" or couple with the electric field at lower frequencies, typically below about 3 MHz, often leading to erroneous indications of field strength. Cableless instruments, or ones equipped with nonconductive, fiber optic cables, are preferred for electric field measurements at low frequencies.

Broadband instruments can exhibit flat frequency responses over large frequency ranges. For example, electric field probes can be purchased with specified passbands as wide as 200 kHz to 40 GHz. Magnetic field probes have narrower passband characteristics, such as 0.5 MHz to 300 MHz, and are not generally available for UHF measurements. Care must be used in conducting broadband magnetic field surveys in the presence of UHF broadcast stations, since the loop sensors of the instrument may exhibit high frequency resonances leading to erroneous indications of fields.

The most common broadband isotropic field strength meters, well suited to measurements taken for purposes of ANSI compliance determination, are shown in Table 3.

Most consulting engineering firms own meters of this type to support their work in this field, and some of the meters are available, as well, from certain equipment leasing companies. The total accuracy of these meters is typically ±2 to 3 dB, due to variations in frequency response, isotropicity, and repeatability. Other errors can be introduced, as well, but none which would cause the meter to read low, according to the manufacturers' literature. Therefore, while the

TABLE 3

Make & Model Series	Probe Freq. Range[10]		Suitable Applications
IFI RFH	E-field: 0.01–220	MHz	AM
Holaday HI-3000	E-field: 0.5–6000	MHz	FM, VHF, UHF, some microwave
	H-field: 0.3–300	MHz	AM, FM, VHF
Narda 8700	E-field: 0.003–40	GHz	FM, VHF, UHF, microwave
	H-field: 0.3–300	MHz	AM, FM, VHF

measurements are expected to be conservative, leeway should be allowed when establishing the locations of ANSI-threshold contours.

There is also a measurement probe that accounts for the frequency variation of present ANSI RFPG by weighting strength of the fields according to frequency such that it indicates in units of percentage of the exposure criterion permitted. As with any broadband type of instrument, however, it does not indicate how the resultant field magnitude is distributed across the frequency spectrum.

Narrowband Instruments

Broadband instruments, while convenient for conducting area surveys and rapidly assessing exposure levels of electromagnetic fields, do not yield information on the frequency of the fields at a measurement point. Because of the frequency dependence of most RF field protection guides, however, such information is often desired, particularly where frequencies are present for which different exposure limits apply. If total RF power density exceeds 1 mW/cm^2 in such a situation, the contribution that each field makes to the total must be determined in order to know whether the protection guide is actually being exceeded.

A tuneable receiver is the most common instrument for this purpose, allowing each emission frequency to be individually tuned and measured. A spectrum analyzer, which repetitively scans between a lower and upper frequency, producing a graphical display of the measured signal strengths in that range, permits rapid assessment of the relative signal amplitudes across a wide range of frequencies. It is particularly effective when the frequency of a specific source is unknown or when the presence of the field is intermittent.

In either case, however, narrowband meters and their companion sensing antennas are not as portable as broadband meters. It can be very inconvenient or simply impractical to conduct the measurement using the large antennas typically employed with narrowband instruments. This is a serious consideration when performing field measurements under difficult circumstances, such as on tall broadcast antenna towers, and in other situations where it is impractical to carry narrowband equipment. In these cases, arrangements must be made to operate the various sources individually, so that their individual contributions can be assessed with a broadband type of instrument.

Special Adaptations or Applications of Instruments

In the last several years, data processing hardware has been introduced that can be configured with portable RF survey instruments to simplify the data collection task. These devices, which have taken the form of microprocessor based data-loggers or analog devices for simply integrating exposure over some prescribed time interval, now allow direct assessment of the time-averaged exposure to electromagnetic fields. The attractiveness of such devices is that one can use them to actively manage personnel exposures in areas where the exposure levels may reach substantial values momentarily. By constantly monitoring the time-averaged value, the exposed individual has the knowledge to remove himself from the field to keep the average level within acceptable limits.

An area of instrumentation highly developed in the ionizing world of radiation, personal dosimetry, has not been successfully developed for the general case of electromagnetic fields. This has been the case because of the difficulty in relating radio frequency field strengths determined very close to the surface of the body to equivalent, unperturbed values from which SAR may be derived. At lower frequencies, however, personal dosimeters have been developed for use in power frequency fields, i.e., 50 Hz and 60 Hz. At these frequencies, especially for magnetic fields, body perturbation effects can be accounted for in a simpler manner than for higher radio frequencies. Some of these dosimeters contain advanced digital circuitry which allow the retention of data on exposure levels versus time of day. Hence, very complete exposure histories can be determined for subjects wearing these devices. Recently, new developments in the form of personal RF monitors useful in the microwave frequency range have been commercially announced.

Measurement Techniques

There are several different approaches to using broadband exposure meters, depending on the type and number of stations at the site of interest and the purpose of the measurements. In general, a top-down approach is recommended, ensuring that no areas of the site are neglected while also ensuring that potential problem areas are examined in sufficient depth.

The basic technique is to make a quick pass first, throughout the site, of ambient fields, to determine where to concentrate and what fields/boundaries to locate and record. It may be, for instance, that an area exists in which the ambient fields exceed the ANSI RFPG; this is the type of area that would be examined next. There, the location of the ANSI-threshold contour should be defined carefully, for fencing or marking at the time the mitigation measures are determined.

Next, the localized measurements are done, looking for the so-called "hot-spots." The FCC adopted under Docket 88–469[11] a relaxed distance requirement for measuring hot-spots. In the concluding paragraph (42) of the *Report and Order*, the following statement by the Commission provided somewhat conflicting directions:

> "In summary, it is recommended that during routine measurements of radio frequency fields for compliance purposes, a minimum separation distance of 20 cm be maintained between a reradiating object and the closest sensing element of a probe. However, as a precautionary measure, it is also recommended that consideration be given to the presence of intense, localized fields in the range of 10 to 20 cm from a reradiating object."

This paragraph has been interpreted by some with emphasis on the first sentence, so that measurements are generally made no closer than 20 cm from reradiating objects, but with sufficient measurements made at a distance of 10 cm to determine whether the RFPG is exceeded where "intense, localized fields" are present. Others interpret the paragraph more conservatively, reasoning that, without consistently measuring as close as 10 cm, one cannot give "consideration" to the presence of intense, localized fields in the 10 cm to 20 cm range. Nevertheless, this increase in measurement spacing, from 5 cm specified in the ANSI RFPG, has alleviated the worries at many sites about localized fields, which tended to occur frequently atop wire-mesh fences or at gates, locations where whole-body SARs would probably remain low but where reproducible measurements indicate fields in excess of the RFPG.

Finally, measurements are made inside the transmitter buildings at the site, looking for both ambient and localized fields and searching with particular care, since these are generally areas of prolonged exposure. Additional grounding will often remove or reduce the severity of localized fields. It is also often helpful for later reference, when determining mitigation measures, to temporarily ground possible sources of reradiation to evaluate the effectiveness of grounding in that specific case.

CALCULATION METHODS

Bulletin OST-65 contains in its Appendices B, C, and D tables of calculated "worst-case" distances from broadcast antennas, beyond which one may assume compliance with ANSI. These tables should be the first "calculations" one performs, and they will, in many cases, suffice. At many sites, exposure conditions are so low that no calculations other than table look-ups are required. The OST-65 tables assume only a single station at a site. In some cases, it may still be possible to use these tables where there are several stations at the site, by conservatively assuming all of the sources to exist at the lowest antenna height and using the least directive antenna pattern.

For those more complicated situations involving FM and TV stations where reference to the tables is not adequate to establish compliance, OST-65 specifies in its Section II the formulas by which predicted RF fields are to be calculated. The general form of this equation is as follows:

$$\text{Power Density } S = \frac{2.56 \times 1.64 \times RFF^2 \times [0.4 \times VERP + AERP]}{4\pi D^2} \quad \text{in mW/cm}^2$$

where: $VERP$ = Total peak visual ERP (all polarizations), in kilowatts
$AERP$ = Total aural ERP (all polarizations), in kilowatts
D = Distance from the center of radiation to the point of calculation, in meters
RFF = Relative field factor at the direction to the actual point of calculation, a unitless value between 0 and 1.

The factor of 2.56 accounts for the increase in power density due to ground reflection, assuming a field reflection coefficient of 1.6 ($1.6 \times 1.6 = 2.56$). The factor of 1.64 is the gain of a half-wave dipole relative to an isotropic radiator. The factor of 0.4 converts peak visual ERP to an average RMS value; for FM stations, of course, the value of VERP is zero. Note that the ERP is total power, so stations employing circular polarization must double their authorized ERP when using the formula. Finally, the factor of 100 in the numerator converts to the desired units of power density.

This formula contains all of the factors necessary to predict the RF power density at any point relative to the source of radiation. In practice, there are several complications which arise, including how to determine the RFF, where to calculate the RF levels, and how to handle multiple sources. The RFF factor is the product of the azimuth and elevation plane relative fields at the specific azimuth and depression angle toward the calculation point. The azimuth plane pattern is generally well defined, but elevation plane patterns beyond about $-20°$ were not published for many of the older FM and TV antennas, and may require supplemental information from the manufacturer for the specific installation being studied. In any case, there is generally enough scatter due to the antenna mounting configuration that no elevation plane relative fields less than 15% should be used for calculations.

The RF levels should be calculated, as a minimum, at locations on the site where public access is a possibility. This often means determining ground elevations at the site with greater precision and resolution than previously needed, determining the slant distance to the antenna, and determining the relative field at the appropriate depression angle for each point to be calculated. Many FM antennas have significant lobes at steep depression angles, so one should beware of the common trap of calculating at points along a radial line from the tower and assuming that decreasing fields will not increase further out when the next lobe upward is encountered. In addition, calculations should be performed for ground-level areas and at on-tower locations where occupational access is required. When calculating conditions on a tower supporting an FM or TV antenna, it must be noted that the OST-65 tables and formulas assume that the source of radiation is at a single point. For close approaches to a multibay antenna, this assumption does not hold, and the antenna should be broken down into its several bays for modeling, each with its proportionate share of the total power.

At a multi-user site, OST-65 states that the sum of the ANSI-fraction contributions from all sources must not exceed unity. This requires, of course, that the frequency-sensitive ANSI guideline for each source be used to normalize the results of the power density calculations. Also, when calculating (or measuring) RF exposure conditions at a multi-user site, attention must be paid to the effect of any auxiliary (standby) facilities that may exist, as these will often create worse exposure conditions than the corresponding main facilities. Even where a measurement program is to be followed, prior calculations can help to identify those combinations of main and auxiliary facilities which present the worst cases in need of measurement.

Computer programs can be developed for performing these calculations, using the OST-65 formulas and incorporating all of the special considerations discussed above. In particular, knowing the make and model of the antenna should be adequate to determine the elevation plane relative field pattern, from research of the FCC's original source documents. In addition, the program should have the capability of handling nonplanar-site surfaces, so that the calculations may be performed over the entire site at once. Fig. 3 shows sample results from such a program. Note the ring of higher fields, due to the lower lobe of the antenna pattern, and the rectangular shaped extension at the southwest edge of that ring, corresponding to higher calculated fields on the roof of the transmitter building.

One final note when relying on calculations to demonstrate compliance with ANSI: 'hot-spots' can not realistically be modeled. The calculation method assumes that the point of calculation is in the far-field of the radiation source. However, intense localized fields of reradiation can occur, particularly at FM and TV sites. A useful rule-of-thumb is that, when the calculated fields are within 50% of the ANSI guideline, measurements should be performed.

MITIGATION OF HAZARD

There are three distinct exposure conditions to consider when assessing whether a particular facility complies with ANSI. These are:

- Public exposures
- Ground-level occupational exposures
- On-tower occupational exposures

Compliance can be achieved in different manners for each condition, particularly since personnel author-

ized to be at a site can be instructed as to the meaning of certain markings and as to the nature of certain procedures to be followed. In those cases where measurements or calculations show that there are no potential problems with excessive exposure to RF radiation, then no special measures need to be taken. However, in almost all cases there is at least the issue of on-tower occupational exposure, therefore much of this section will be applicable to all facilities.

When action is necessary to bring a site into compliance with ANSI, whether determined by measurement or by calculation, such action can have one of two goals: (1) to limit access by the public or by workmen to the fields in excess of ANSI, or (2) to reduce those fields to levels less than ANSI. All compliance techniques involve one or the other of these objectives. The FCC *Public Notice*, "Further Guidance for Broadcasters Regarding Radio Frequency Radiation and the

Environment", dated January 28, 1986, outlines a number of situations and provides guidance on which of the above approaches is the more appropriate compliance mechanism. It is a helpful aid for deciding the extent of action required in any particular case.

Access to areas of high RF fields may be limited by means of physical barriers, such as fences, to preclude access by the public. In combination with warning signs, barriers are the preferred method of achieving compliance for public exposure. The Notice does recognize that the remoteness of a site and the presence of natural barriers may be pertinent; essentially, if one cannot build a scenario in which the public ("including trespassers," the Notice warns) would have occasion to be exposed to high RF fields, then the fields probably do not require barriers, although the Notice implies that signing is always required.

For occupational exposure considerations, lesser measures may suffice to restrict access to high RF fields. In particular, these would include procedures to take advantage of the time-averaging provisions of ANSI when only intermittent access is required for maintenance activity, such as reading AM base current meters. Areas in which specific procedures must be followed can be marked with contrasting paint or by low fencing. The meaning of these markings can be explained in a document called an Occupational Exposure Guide. This document is an 8½ × 11 inch, plastic-laminated sheet which describes the ANSI Standard and its time-averaging provisions; explains the significance of the markings and fences; defines the maximum time allowed in the marked areas; gives the reduced power factors for on-tower work; and provides several telephone numbers for obtaining additional information. Multiple copies of the OEG for a particular site should be available, so that one is displayed on the inside of each exterior door at the site. Several should also be kept at each studio location for review with any workers, such as HVAC repairpersons or two-way communications technicians, who may be authorized for occasional access to the site.

The other compliance mechanism, reduction of the fields themselves, clearly applies when considering on-tower maintenance work. The power cutback requirements for such work should be a part of the OEG. It may be, however, that changes to the antenna system(s) can remove large contributions to the ANSI limit from particular areas and achieve ANSI compliance in those areas. Typically, these changes can apply at FM or TV sites and involve raising an antenna to place it higher above the site or replacing the antenna with a model having reduced downward radiation, such as is now available from most antenna manufacturers. Yet another factor to consider is the establishment of separately-located auxiliary facilities, to which the station(s) could switch operation while maintenance work is required at the main facilities. Too often, the auxiliary facilities provide only emergency service because their operation creates RF fields above the ANSI limit at the main antenna.

One particular advantage to calculating RF levels occurs when considering on-tower conditions at a multi-user site. Here, if maintenance is to occur on any tower, the licensees must know the exposure conditions at various heights on that tower and, in order to reduce power as necessary, must know how much each station is contributing to the total fields at those heights. To acquire this information by measurement is not practical, at least not without exposing the person taking the measurements to fields in excess of ANSI. Generally, for even a few stations at a single site, the number of power-reduction combinations is so large that attempting to effect even some fraction of them is difficult and, without knowing beforehand which combinations are likely to achieve ANSI compliance, the attempt is often futile.

With regard to on-tower occupational exposures, the use of "bee-keeper" suits, such as the Lion Uniform M-Guard model, has received no specific approval from any government or industry group for use in reducing RF exposures at broadcast frequencies. Therefore, even though the material is believed to provide significant attenuation at some frequencies, it is imprudent at present to rely upon these suits to achieve compliance with ANSI.

There are, then, several good rules of thumb to follow for achieving compliance with ANSI: (1) fence all tower bases to limit access, (2) post RF warning signs so that they are visible from all approach angles, (3) establish a written policy for compliance with ANSI (have station employees sign it, and give copies to all contractors), (4) send letters (if at a multi-user site) to all other users, expressing your commitment to comply, and (5) develop an auxiliary facility that does not limit access to the main antenna.

APPENDIX

Further Guidance For Broadcasters Regarding Radio Frequency Radiation And The Environment

(Federal Communications Commission Public Notice, January 28, 1986)

"The National Environmental Policy Act of 1969 (NEPA), 42 U.S.C. Sections 4321–4361, requires all federal agencies to ensure that the environment is given appropriate consideration in agency decision-making. In a *Report and Order* in General Docket No. 79–144, 100 FCC 2d 543 (1985), the Commission decided that human exposure to radio frequency (RF) radiation was a proper environmental concern of this agency and specified that the guideline for determining the significance of such exposure will be the "Radio Frequency protection Guides" adopted in 1982 by the American National Standards Institute (ANSI C95.1–1982). As of January 1, 1986, all applications for new facilities, modifications to existing facilities, and renewals must contain *either* a specific indication that the RF radiation of the particular facility or operation will not have a significant environmental impact *or* an environmental assessment which will serve as the basis for further Commission action.[1] *See* Part 1, Subpart I of the Commission's Rules for specific regulations regarding environmental matters.

Most broadcasting facilities produce high RF radiation levels at one or more locations near their antennas. That, in itself, does not mean that the facilities significantly affect the quality of the human environment. Each situation must be examined separately to decide whether humans are or could be exposed to high RF radiation. Paragraph 37 of the *Report and Order* points out that accessibility is a key factor in making such a determination. As a general principle, if areas of high RF radiation levels are publicly marked and if access to such areas is impeded or highly improbable (remoteness and natural barriers may be pertinent) then it may be presumed that the facilities producing the RF radiation do *not* significantly affect the quality of the human environment and do not require the filing of an environmental assessment.

Because we wish to avoid burdening applicants with unnecessary work, expenses and administrative filings, we offer the following guidance as to how we will view typical situations. The term "high RF level" means an intensity of RF radiation, whether from single or multiple sources, which exceeds the ANSI guidelines.

Situations

A. High RF levels are produced at one or more locations above ground level on an applicant's tower

- If the tower is marked by appropriate warning signs, the applicant may assume that there is no significant effect on the human environment with regard to exposure of the general public.

B. High RF levels are produced at ground level in a remote area not likely to be visited by the public

- If the area of concern is marked by appropriate warning signs, an applicant may assume that there is not significant effect on the human environment with regard to exposure of the general public. It is recommended that fences also be used where feasible.

C. High RF levels are produced at ground level in an area which could reasonably be expected to be used by the public (including trespassers)

- If the area of concern is fenced *and* marked by appropriate warning signs, an applicant may assume that there is not significant effect on the human environment with regard to exposure of the general public.

D. High RF levels are produced at ground level in an area which is used or is likely to be used by people, and to which the applicant cannot or does not restrict access

- The applicant must submit an environmental assessment. This situation may require a modification of the facilities to reduce exposure or could lead to a denial of the application.

E. High RF levels are produced in occupied structures, on balconies, or on rooftops used for recreational or commercial purposes

- The applicant must submit an environmental assessment. The circumstances may require a modification of the broadcasting

1 In applications for new and modified facilities, the requirement for a specific indication is satisfied by answering the question on the form regarding environmental matters. An environmental assessment is the narrative statement described in Section 1.1311 and elsewhere in the Commission's rules.

facility to reduce exposure or could lead to a denial of the application.

F. High RF levels are produced in offices, studios, workshops, parking lots, or other areas used regularly by station employees

- The applicant must submit an environmental assessment. The circumstances may require a modification of the facilities to reduce exposure or the application may be denied. This situation is essentially the same as E. We have included it to emphasize the point that station employees as well as the general public must be protected from high RF levels. Legal releases signed by employees willing to accept high exposure levels are not acceptable and may not be used in lieu of corrective measures.

G. High RF levels are produced in areas where intermittent maintenance and repair work must be performed by station employees or others

- ANSI guidelines also apply to workers engaged in maintenance and repair. As long as these workers will be protected from exposure to levels exceeding ANSI guidelines, no environmental assessment is needed. Unless requested by the Commission, information about the manner in which such activities are protected need not be filed. If protection is not to be provided, the applicant must submit an environmental assessment. The circumstances may require corrective action to reduce exposure or the application may be denied. Legal releases signed by workers willing to accept high exposure levels are not acceptable and may not be used in lieu of corrective measures. The foregoing also applies to high RF levels created in whole or in part by reradiation.

A convenient rule to apply to all situations involving RF radiation is the following:

1. Do not create high RF levels where people are or could reasonably be expected to be present, *and*
2. Prevent people from entering areas in which high RF levels are necessarily present.

Fencing and warning signs may be sufficient in many cases to protect the general public. Unusual circumstances, the presence of multiple sources of radiation, and operational needs will require more elaborate measures.

Intermittent reductions in power, increased antenna heights, modified antenna radiation patterns, site changes, or some combination of these may be necessary, depending on the particular situation.

For further discussion see Office of Science and Technology Bulletin No. 65, "Evaluating Compliance with FCC-Specified Guidelines for Human Exposure to Radiofrequency Radiation," October 1985. Copies of this bulletin may be ordered from the National Technical Information Service, (800) 336–4700, Order No. PB 86–127081.*

For further information regarding this *Notice*, applicants should contact the AM Branch, FM Branch, TV Branch, or LPTV/Translator Branch, as appropriate."

AM Field Strength Measurements and Proof-of-Performance

Donald G. Everist
Cohen, Dippell, & Everist, P.C., Washington, District of Columbia

INTRODUCTION

An AM directional antenna is composed of at least two or more radiating elements. The amplitude and phase relations of RF energy fed to each element and the physical spacing between each element produces a predicted directional pattern shape. Each directional pattern is designed and constructed for a specific application, to provide the optimum service to the desired area while providing adequate protection for other, cochannel and adjacent channel stations.

The design and construction of the elements of an AM directional antenna are covered in Chapter 2.1, "Design, Erection, and Maintenance of Antenna Structures," and Chapter 2.5, "AM Broadcast Antennas."

The obligations of broadcasters regarding possible human exposure to RF radiation are discussed in Chapter 2.9, "RF Radiation Hazards." This chapter should be reviewed to ensure that the station is in compliance with guidelines of the Federal Communications Commission.

	73.186
Special Temporary Authority	73.1635

(This list is not comprehensive. A more extensive and general list of FCC requirements is included in Chapter 1.2, "FCC Field Operations Bureau," Appendix A.)

Monitoring Points

An important, initial step in setting up a directional antenna is the selection of monitor points along the radials specified in the construction permit. These points must be reachable in inclement weather, and free of possible reradiation objects such as underground pipes and overhead wires. Schoolyards, churches, and cemeteries often provide useful locations since the surrounding area is usually clear.

Prior to submission to the FCC, data should be taken at proposed monitoring points over a period of time until the accuracy and stability of measurements can be established. Readings must be in the direction of the station. This can be established by using a U.S. Geological Survey topographic map or by switching the antenna array to the nondirectional mode (if available).

Once the directional array has been adjusted and its performance documented, one of the often overlooked items is the monitoring of the area for new construction. Vertical structure construction or new construction authorized by governmental authorities is often very difficult to detect in the advanced stage of planning. New power-line construction and construction of other communication structures can act as reradiators if located sufficiently close to the array. Such reradiated energy can affect the pattern so as to reduce interference protection to other stations.

PROOF-OF-PERFORMANCE

The proof-of-performance is used to establish the initial operation of the directional pattern at the time of licensing; it is a condition imposed by the FCC before licensing can occur; it is used to update the performance of the antenna system at such times as may be necessary or may be directed by the FCC; and it is used as a reference for subsequent partial proof-of-performance.

Reference Proof-of-Performance

A *reference proof* is the latest complete proof-of-performance accepted by the FCC, and is the proof to which *partial proof* measurements must be referenced. The reference proof-of-performance specifies, for each monitoring point, the point number, the distance in miles from the transmitter site, the radial and the point location. Section 73.151 of the FCC Rules defines the general field strength measurement requirements to be made on the construction permit and nonconstruction permit radials for the reference proof.

A reference proof defines the nulls, suppression, and major radiation areas of the directional pattern. A reference proof-of-performance requires the taking of *nondirectional* and *directional* measurements along each radial under similar environmental conditions. While each proof has its own requirements, in general, nondirectional measurements begin (as specified by the FCC Rules, Section 73.186) at a distance of five times the height of the nondirectional antenna. They are to be made at approximately equal sets of intervals such that, as a goal, 15 to 20 measurements are established within the first three kilometers (two miles), eight to ten measurements within the next seven kilometers, (miles two through six) and 14 measurements to extend to a distance of 24 to 32 kilometers from the transmitter site (miles 6 through 15 to 20). Directional measurements are to be made under similar environmental conditions beginning at ten times the widest spacing between the elements of the antenna system. The instantaneous changing of patterns from nondirectional to directional at either a prearranged time or by two-way communications can be beneficial. This technique permits the acquisition of the measurement data in the minimum amount of time and permits the continuous measurement observation without moving the field strength instrument. The accumulation of measurement data whereby both the nondirectional and directional measurements are made at a given point at the same time will eliminate relocation and time differences.

Measuring Instrument to be Used

When field strength measurements are made in support of the partial or reference proof-of-performance, a portable instrument made solely for this purpose and of known accuracy is utilized.

For directional antenna systems, the taking of a proof-of-performance and the availability of the measurement instrument are conditions of the construction permit as provided below:

THE AUTHORITY GRANTED IS SUBJECT TO THE FOLLOWING CONDITIONS:

> Field measuring equipment shall be available at all times and, after commencement of operation, the field strength at each of the monitoring points shall be measured at least once every seven days and an appropriate record kept of all measurements so made.

A complete nondirectional proof-of-performance, in addition to a complete proof on the directional antenna system shall be submitted before program tests are authorized. The nondirectional and directional field strength measurements must be made under similar environmental conditions.

Authorization to Use an AM Directional Antenna System

The directional antenna system requires FCC approval before its operation can commence. Unlike nondirectional operations, directional operations cannot be instituted upon a notice and a promise of subsequent FCC submission to fulfill license requirements. The FCC program test authority is a telegraphic authority. The program test authority indicates that the FCC is in essential agreement that the antenna system is in compliance with the FCC Rules and indicates that permittee has met its basic obligations and authorizes that operation can commence as described in its license application. However, specific requests by the Commission may accompany the program test authority and those requests must be satisfied before the FCC will issue a license. The FCC requires for each directional operation after submission of the proof-of-performance and receipt of the program test authority from the FCC a thirty day set of measurements. This request for the data will accompany the issuance of the antenna parameter data and has language similar to the following:

> Program test should be conducted with the directional antenna system adjusted in accordance with the enclosed corrected specifications pending further action on the license application. It is requested that you check the values of field strength at each of the monitoring points at least once weekly during the next thirty (30) days, and submit this information in tabulated form to the Commission together with the following meter readings extracted from the transmitter log at the time the monitoring points are checked: (1) common point current, (2) base currents and their calculated ratios, (3) antenna monitor sample current ratios, (4) phase indications, (5) final amplifier plate voltage, and (6) plate current.

PARTIAL PROOF

Section 73.154 of the FCC Rules governs the taking of a partial proof-of-performance as presently required by the FCC Rules. A partial proof must be done, for example, when there is a change of directional operating parameters; when changes are made above the base insulator of the antenna (such as the addition or alteration of an FM antenna or transmission line mounted on the tower), when there is an increase of an existing monitor point license value, or when changes in the environment of the array dictate the necessity of demonstrating compliance with the station's instrument of authorization.

The partial proof-of-performance measurements are to be made at the same locations as specified in the reference proof, but measurements do not have to be taken at all locations. The partial proof-of-performance must contain a minimum of ten measurements at points along each of the radials defined in the reference proof. The partial proof must contain an arithmetic or logarithmic analysis of the measurement data so obtained. It must demonstrate that the antenna system is operating within its instrument of authorization. Generally speaking, the measurements should be made at an interval of three to 16 kilometers (two to ten miles). A statement that the impedance of the common point has been measured and is unchanged from the licensed value prior to the making of the measurements should be provided. A change in common point impedance at the operating frequency requires an appropriate submission to the FCC and is to be requested using FCC Form 302.

The partial proof-of-performance in those areas where ground conductivity is not constant should be made under similar environmental conditions as the reference proof. More accurate information can be obtained when the directional partial proof-of-performance is based upon current nondirectional measurements.

GENERAL REQUIREMENTS FOR MEASUREMENTS

All measurements should be made during the daylight hours in the absence of interference, and special temporary authority may be required prior to the commencement of measurements for a new station. For established stations, the FCC Rules permit considerable flexibility in operation during periods of making field intensity measurements on the antenna system.

FCC policy has been that the measurement observation to be recorded and utilized as a basis of analysis of the inverse distance radiation is that observed with the field set oriented towards the station. The field set maximum indication can have an orientation away from the transmitting source. This phenomenon can be affected by many factors, particularly the depth of a null. Other factors vary from local effects surrounding or adjacent to the measuring point, nonuniform conditions inherent in the propagation path, and the position of the monitoring point in a region where there is a sharp change in the pattern.

A record must be kept of the measurement data including the point number and description, the field strength observation, date and time, the pattern under investigation, the name of the individual taking the measurements, the general weather conditions, and the field strength instrument and date of last calibration. A sample form is provided for tabulating the field measurement data.

GRAPHICAL ANALYSIS

The inverse distance field or attenuated field intensity at a reference distance (1 km) is that radiation predicted if the earth were to behave as a perfect conductor. As the wave energy travels away from the antenna, this energy reduces in value. The value of the radiated field is reduced by the inverse proportion to the distance from the antenna. For example, if the value of the unattenuated field at 1 km is 100 mV/m, its value at 2 km will be one-half that value or 50 mV/m, and at 10 km, its value will be one-tenth or 10 mV/m.

FIELD STRENGTH MEASUREMENTS

Figure 1. Field strength measurement log.

After the distance from the transmitting antenna to each of the measuring points has been determined and tabulated opposite to the observed field strength values, a measured field strength can be plotted on log-log graph paper. The ordinate is expressed in mV/m and the abscissa is expressed in distance. The FCC, in its conversion to metric, redetermined the frequency curves.

There are 20 frequency charts that encompass the frequencies from 540 kHz to 1700 kHz. Each graph shows the uppermost portion with conductivity curves normalized for 100 mV/m/km from 0.1 km to 50 km and the bottom portion reflects the conductivity curves for 10 km to 5,000 km.

Data can be plotted on groundwave field intensity graph paper available through NAB's Station Services Department (800-368-5644).

For the logarithmic coordinate system, (log-log graph paper) the inverse distance line plots as a straight line. Each of the curves is drawn for the case of an inverse distance field of 100 mV/m at 1 km, and its use is not limited to that value. If an inverse distance field is 200 mV/m (twice the reference value) or 50 mV/m (one-half the reference number) or some other value at 1 km, and if all points on the curve are multiplied by that ratio, this would be the equivalent of moving the curve by that amount on the logarithmic coordinate paper. This is the basis by which measurements are analyzed and the appropriate graph for the frequency involved is made by matching the abscissa of the data with that of the FCC graph. By sliding the ordinate information data vertically, the best fit is obtained. By this method, both the unattenuated field at 1 km and the conductivity value along the radial path have been determined. The use of a light table or window or TV set tuned to an unused channel will serve as a back light for visual analysis of the data.

An individual attempting to analyze measurement data for the first time or not having benefit of supervision can find this a frustrating experience. One approach is to take log-log graph paper for the appropriate frequency (either the regular or expanded scale) and plot the measurement point values normalized to 100 mV/km. For example, if the nondirectional 0.25 kW operation is expected to possess an RMS field at 1 kW of 91 mV/m (70° [0.194 of a wavelength] electrical height tower with a normal ground system—see Figure 8, Section 73.190 of the FCC Rules), it has a field 91/100 less than the FCC log-log conductivity graph. Therefore, multiply all values (divide all values if the expected field is greater than 100 mV/m) of the measurement data by the ratio of 100/91 to normalize it to 100 mV/m. Plot the normalized data. The plotted values can be viewed in relation to the conductivity values if the assumption of the inverse distance field is correct. If the normalized data appears to be over the inverse distance line than the radiation value is higher than assumed and conversely if the normalized data appears abnormally low, the assumed radiation value selected is too high.

This approach can be useful when the nondirectional measurements out to 3 km in the various directions have been taken and a quick evaluation of the conductivity values/radiation efficiency around the site is desired. It also will help to assess whether or not the nondirectional radiation pattern is being influenced by other adjacent towers in the directional antenna system.

AUTHORIZATIONS

Special Temporary Authority

Special temporary authority will be generally required with any operation which has not received prior authorization from the Federal Communications Commission. Section 73.1635 of the FCC Rules provides that special temporary authorization (STA) be requested in writing (an original and two copies) to the FCC. The authorization request should delineate the station frequency, location, a complete description of the proposed operation, and the necessity of the STA. The letter should indicate the capacity of the requesting individual and their phone number so that the FCC can request additional information informally, if required.

For licensed operations, the FCC Rules provide that a nondirectional operation that has been authorized in a proof-of-performance for a daytime only. A station with a single or more than one directional pattern for day and night, etc., can utilize nondirectional power set forth in the latest proof-of-performance without further authorization from the FCC. However, this privilege is permitted only in the commission of field strength measurements. In addition, the FCC permits without further authorization the nighttime pattern's being operated during daytime hours when field intensity measurements are being taken.

Antenna Monitor System Approval

For each authorization providing for a new station, details of the antenna monitor system components and installation must be contained in the proof-of-performance in order to obtain the necessary recognition from the FCC that the antenna monitor system conforms to the FCC Rules. An antenna monitor system request accompanying a partial proof must be, for prompt consideration, in a separate submission. During construction or revision of the monitoring system, special temporary authority for variance of parameters may be required for existing stations. This authority can be obtained by submitting a request (original and two copies) to the FCC. The purpose of the request as well as its duration should be provided. For specific situations, reference should be made to Section 73.68 of the Rules; however, with the revision in Docket 85–90, the FCC is less specific as to the detail of sample-system construction. The FCC indicates as a matter of policy that the procedures methods outlined in the Rules as modified by MM Docket 83-16 would receive continued FCC acceptance. Other less conventional methods may be subject to rigorous scrutiny including observations over a period of time and a partial proof-of-performance. For convenience, Sec-

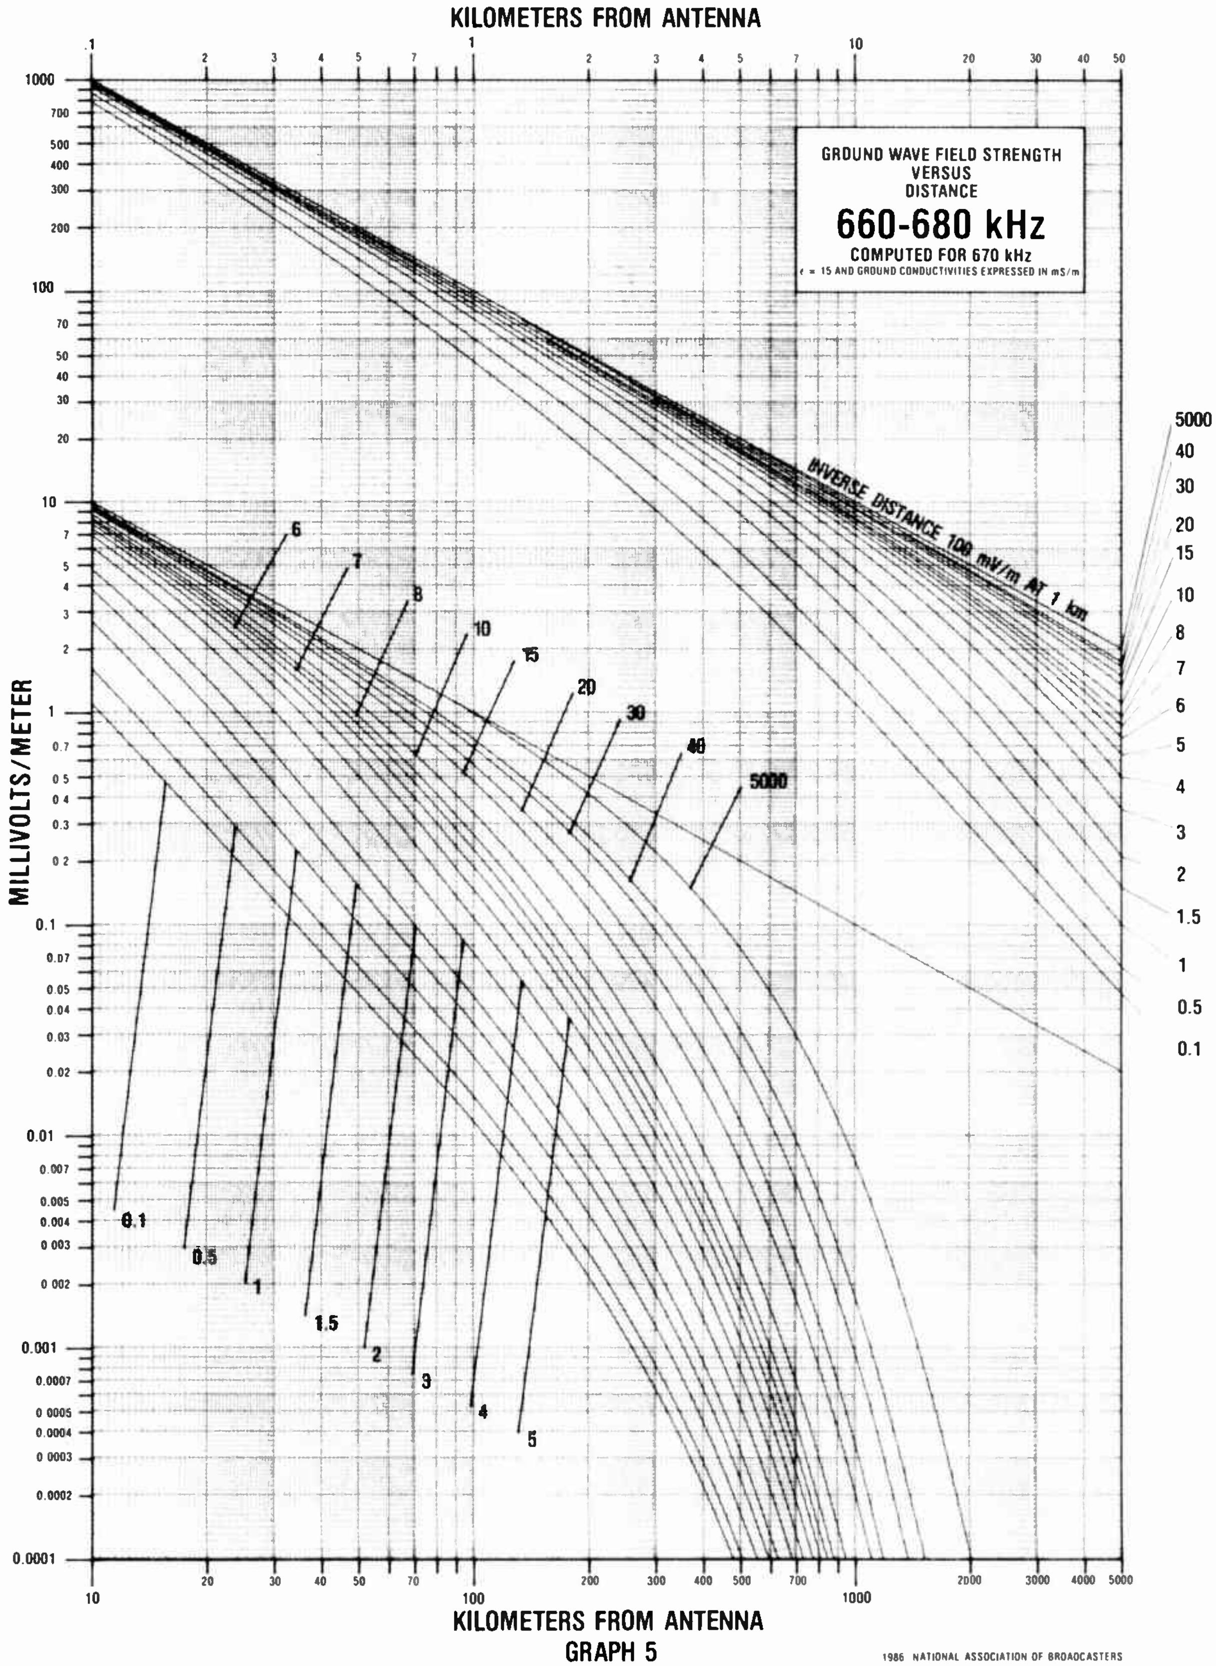

Figure 2. Ground wave field strength versus distance 660-680 kHz. (Graph paper is available from NAB Services, 1-800-368-5644.)

tion 73.68 of the FCC Rules is provided prior to alteration by Docket 85–90.

Whether contained in the proof-of-performance or otherwise, the request for approval must indicate information sufficient to determine compliance with the FCC Rules concerning the method of sample, type of sample line, and its electrical length and whether the sample lines are under similar environmental conditions. The submission should incorporate other descriptions as may be required to demonstrate compliance with the FCC Rules and for FCC Policy, and must be accompanied by a signature of authority from the station organization. A station with an approved sampling system is permitted to establish its own schedule of monitor-point measurements based on its operating conditions.

FCC Form for License

Each proof-of-performance must include the information requested in FCC Form 302. It must comply with the provisions and intent of the FCC Rules including Section 73.186 of these Rules regarding the number of measurement radials, the number of nondirectional and directional measurements made along each radial, the mathematical or graphical analysis, if utilized, the plot of the field versus distance measurements on semi-log or log-log graph paper, and the reproduction of the quadrangle maps (or other maps as required) showing the radials along which measurements were made and locations used in making each of these measurements. Section 73.186 of the FCC Rules also dictates the form and substance concerning the submission of nondirectional antenna resistance as well as the common point impedance measurements with the required graphical plots.

Furthermore, descriptions of the monitoring points complete with the monitor-point photographs and a route diagram as specified by the construction permit must be supplied (see Section 73.158 of the FCC Rules). The station must also comply with other provisions of the construction permit.

A diagram of the RF feed system as constructed (including the phasor, transmission lines, and the tower matching networks) is to be provided. A plot of the inverse distance field at 1 km for the nondirectional as well as each directional mode is to be supplied, based upon the interpretation of the measurement data. The directional pattern must not exceed the authorized pattern in any direction and must have the requisite RMS. In certain situations for new stations or revisions of existing facilities requiring a new reference proof-of-performance, the FCC will permit an adjustment of directional power which can be effected at the time of the license application.

For each directional operation, the parameters as indicated by the antenna monitor for both loop and phase (including SIGN) as well as the base currents and the ratios are to be furnished. Each field strength instrument and its type number, make and model, and date of the last calibration should be listed. If more than one instrument is utilized, a comparison of the accuracy observed for each instrument should be made.

License

The FCC license provides, among other things: the licensee name, specifies the term of the license; the station location; the main studio location, if not at the transmitter or within the boundaries of the principal community; the remote control location; the transmitter location and its coordinates; the type of antenna and ground system, if nondirectional; the frequency; the nominal power; the hours of operation and any special conditions. For stations using a directional antenna system, the second page will provide: a description of the directional antenna system; the spacing; orientation; and height of the towers and a description of the ground system. Also provided are the theoretical and operating specifications determined from the most recent partial or full proof-of-performance. The description of the field strength of the monitor points and the maximum limits that the point must not exceed are contained on the following page(s).

Changes and modifications of any of these items require appropriate notification to and concurrence by the FCC. When receiving a new license, it should be inspected for correctness as compared with that used as a basis for the license application. The operating parameters must be maintained in accordance with Section 73.62 of the FCC Rules and the directional antenna must be maintained with indicated relative amplitude of the antenna base currents and antenna monitor currents within 5% of the values specified in the license, unless other tolerances are specified. In addition, the directional antenna relative phase angles must be maintained within three degrees of the values specified in the license unless other tolerances are required.

Monitor-point values must be maintained within the values specified in the license. An increase in an existing monitor point(s) value can only be accomplished by submission of a partial proof-of-performance to the FCC. A change in monitor point location requires submission of a photograph, route diagram, description of the new monitor point, and a minimum of ten measurements including the newly-designated monitor point between two and ten miles that is shown in the latest reference proof. This information is to be submitted to the FCC.

APPENDIX A

FCC Policy Statement Entitled "Criteria for Approval of Sample Systems for Directional AM Broadcast Stations" Dated December 9, 1985

On October 31, 1985, the Commission adopted a Report and Order in MM Docket 85–90 concerning the antenna sampling systems and proofs-of-performance for directional AM broadcast stations. The new rules are based upon performance standards in terms of accuracy and stability rather than upon construction specifications. This Notice clarifies the information required for directional AM sampling system approval under the new provisions of Section 73.68(a) of the Rules. As before, stations constructing new antenna systems pursuant to a construction permit must obtain approval of their sample system when filing for a covering license. Existing stations may obtain approval by informal request to the FCC in Washington, D.C.

To obtain antenna system approval, applicants may follow either of the procedures set forth in Paragraphs A or B below:

A. Demonstrate that the system complies with the provisions of Section 73.68(a) of the Rules in effect prior to January 1, 1986.

B. Demonstrate stability of operation by submission of the following information:

1. A detailed and complete description of the antenna monitoring system installation.
2. Field strength readings taken on a monthly basis at each of the monitoring points specified in the instrument of authorization for a one year period prior to the date of the application.
3. The following readings taken daily for each directional pattern use during the thirty-day period prior to the filing of the application:
   a. Common point current
   b. Base currents and their calculated ratios
   c. Antenna monitor sample current ratios
   d. Antenna monitor phase readings
   e. Final amplifier DC input voltage and current
4. The results of either a partial proof-of-performance (Section 73.154) or a full proof (Section 73.186) conducted no longer than 3 months prior to the filing of the application and the common point impedance at the operating frequency measured at the time of the proof.

Additional sampling system components and configurations found by the Commission to be accurate and stable over a wide range of environmental and operational conditions will be included as acceptable under Paragraph A above and announced periodically via public notice.

Questions concerning sampling system approval may be directed to John Sadler (202)632–7010 and questions concerning the Report and Order in MM Docket 85–90 may be directed to John Reiser (202)632–9660.

2.11 The Measurement of FM and TV Field Strengths (54 MHz—806 MHz)

Joseph W. Stielper
du Treil, Lundin & Rackley, Inc., Washington, District of Columbia

MEASUREMENT OBJECTIVES

The purpose of this chapter is not merely to provide a cookbook describing the actual taking of television and FM broadcast field strength measurements; most field strength meter instruction books are adequate for this purpose. Taking field strength measurements is relatively easy, but planning a program and analyzing the resulting data is more difficult. That is the emphasis of this chapter.

But first, why take measurements? Television and FM field strengths may be measured to accomplish several objectives. These include: (1) determination of measured coverage contours or coverage of a particular area instead of relying only on predictions of coverage; (2) evaluation of the performance of transmitting systems; (3) measurement of spurious emission; and (4) special studies to evaluate the effect of factors such as terrain and vegetation on field strength. Special studies that require field strength measurements are also used for purposes such as interference reductions and making frequency allocation decisions.

MEASUREMENTS VERSUS PREDICTIONS

It is not necessary or even usual to take measurements to estimate the coverage of a station or even of the stations' coverage of a particular area, its city of license, for example. There are numerous propagation models available that may be used to predict field strength and coverage.[10,11,12,20,22,23] FCC Rules specify the propagation model that must be used to determine coverage for filing with the Commission, although additional showings using alternate models may be made. The FCC Rules also contain measurement and analysis procedures that must be followed if the results of measurements will be submitted to the Commission. For in-house use there are no constraints, and any propagation model or measurement scheme may be used. The engineer is thus faced with the choice between predictions or calculations and measurements. The choice is not always clear. Predictions may be made in the comfort of one's office; there is no concern over equipment availability or weather. The choice hinges on the answers to the questions: (1) which is more accurate or reliable? (2) will the results be filed with the FCC? (3) what are the relative costs?

At a given location, field strength varies with time, which limits the accuracy of measurements. Determination of the long term median field strength is usually desired. The variation may be negligible on short paths but may contribute the greatest uncertainty on long paths, particularly near the radio horizon. Time variability is usually neglected in the analysis of measurements. The effect of time variability is discussed in detail later in this chapter. Also, the effects of time variability are treated more readily with predictions than with measurements. Except for the unusual case of measurements designed to evaluate time variation factors, the effect of weather or climate on measurements should be minimized. Variations of field strength with time are generally greatest near or just beyond the radio horizon. A more detailed discussion of this problem is included in a later section.

In addition to varying with time, field strength varies with location. The variations are caused by factors such as terrain, manmade structures, vegetation, and weather. The effect of each of these on the measurements should be considered when designing the program.

Measurements are not always more accurate or reliable than predictions although the FCC tends to prefer measurements. Thus, in contested cases, measurements are generally desirable. Alternate propagation models often yield conflicting results. The FCC has difficulty resolving this conflict; hence, the preference for measurements.

All propagation models consider the terrain and the environment between the transmitting and receiving antennas in a simplified fashion. In other words, complex terrain and environmental situations involving multiple obstacles and reflections are reduced to much simpler models such as one or two diffracting obstacles. In many cases it is not clear which of the many propagation models is appropriate. Because predictions often yield contradictory answers, there is a tendency to conclude that taking measurements will resolve the problem. However, unless care is taken in the planning and execution of the measurement program, the results may not be an improvement on predictions. Generally, a haphazard measurement program is less useful than a well planned, careful prediction regime.

Many prediction routines do not consider the effect of environmental clutter such as buildings and trees. Such clutter may be more significant than terrain, particularly at UHF frequencies. The effects of clutter are described in a number of references.[8,9,21]

In summary, the methodology of any prediction or measurement program must be critically reviewed before basing decisions on the results.

PLANNING A MEASUREMENT PROGRAM

Before the start of measurements, a plan should be designed considering the objectives of the field strength survey. For example, the constraints imposed by a survey to determine coverage of a station are different and generally less restrictive than those imposed by propagation studies. Design of a program to evaluate the performance of transmitting systems is likely to be the most difficult and require even more careful planning than programs for other purposes. Suggestions for designing measurement programs for each of the above objectives are presented in the following sections, as well as a discussion of the techniques of actual field strength measurement.

There are several basic considerations affecting all types of measurement programs that should be addressed. These include the choice of antenna height for the measurements and allowance for factors such as weather that are beyond the control of the engineer.

The FCC Rules require measurements using a nine meter (30 foot) receiving antenna height. This height should be used unless there are very good reasons for using another height. The bulk of reliable data was taken at 30 feet, and the broadcast coverage contours are based upon the nine meter height. Thus, a nine meter receiving antenna height must be used for filing with the FCC, for direct coverage measurement, or for direct comparison with most other data. Use of a nine meter high antenna raises several practical problems including safety. These are discussed in a later section. For in-house use, another antenna height may be appropriate. For example, to evaluate FM reception by car receivers, a low height should be used. In many areas the height of few, if any, FM or TV receiving antennas approximates the standard nine meter height.

Measurement of Coverage

The coverage of a broadcasting station and the technical quality of the service provided are determined by the quality of the received signal including the field strength. Currently available methods of estimating field strengths within the service ranges of FM and television stations are only approximate, and even the best methods of calculating field strengths often fail to take into account variations due to important local conditions. In general, for making decisions affecting a station's operation, the most useful determination of station coverage is provided by properly made field strength measurements. This section describes measurement programs for measuring field strengths to determine coverage of FM and television broadcast stations.

The quality of service is related to field strength by considerations of receiver sensitivity and noise figure, receiving antenna gain and transmission line loss, and tolerable signal-to-noise ratios. The required fields vary with the class of service and frequency assignment. Table 1 lists the frequencies employed by television and FM broadcast stations. Interfering signals from other transmitters on the same or adjacent channels may limit service to higher values of field strength.

Table 2 lists values of median field strength required for various grades of FM and television service in the absence of interfering signals as established by the Federal Communications Commission's Technical Standards.[1] It also includes revised estimates of the fields required in the television bands to provide acceptable grades of service based on the practical experience of operating stations and the findings of the Television Allocations Study Organization (TASO).[2] The latter has not been officially adopted by the Commission and may well be obsolete. A number of changes in the definition of television coverage grades based upon the TASO studies and other data have been proposed from time to time since the adoption of the present definitions. A review of the rationale for the VHF contour definitions and some potential revisions is presented in the FCC Report FCC/OCE RS 77.01.[3]

TABLE 1
Frequencies Employed for FM and Television Broadcasting.

Service	Frequencies MHZ	Channel Nos.	Channel Bandwidth
TV	54–72	2–4	6 MHz
TV	76–88	5–6	6 MHz
FM	87.9–108	200–300	200 kHz
TV	174–216	7–13	6 MHz
TV	470–806	14–69	6 MHz

TABLE 2
Median Field Strengths Required for Various Grades of Service in the Absence of Interfering Signals.

FM Broadcasting (All Channels)

Grade of Service	μV/m	dBμ[a]
Principal City	3,160	70
Urban	1,000	60

Television Broadcasting
(FCC Technical Standards)

Grade of Service	Ch. 2–6		Ch. 7–13		Ch. 14–83	
	μV/m	dBμ	μV/m	dBμ	μV/m	dBμ
Principal City	5,000	74	7,000	77	10,000	80
Grade A	2,500	68	3,500	71	5,000	74
Grade B	225	47	650	56	1,600	64
(Based on TASO Data)						
Primary	250	48	1,400	63	7,500	75
Secondary	50	34	200	46	630	56
Fringe	20	26	55	35	180	45

Service is defined in Table 2 in terms of the median field strength, with respect to both location and time, at a receiving antenna at a height of nine meters above ground. Thus, as noted above, field strength measurements to be filed with the FCC must be taken using a nine meter receiving antenna height. It may not be necessary or even desirable to employ a nine meter antenna height for measurements that will not be filed with the FCC. For example, if comparative coverage of several stations is desired and receiving antenna heights in the area are less than 30 feet, it may be appropriate to use a lower height. In these frequency bands, field strength usually varies appreciably with antenna height, generally tending to increase with increasing antenna height. However, the variation in field with height may not follow simple laws. Measurements taken at a lower height may be, if necessary, adjusted to reflect the standard nine meter height. Because of the uncertainty of the magnitude of the adjustment, the adjusted results are ordinarily less precise than measurements taken at nine meters. Adjustment factors are discussed more fully in a subsequent section.

The presence of trees, buildings, and terrain irregularities[4-9] often results in considerable variation in field strength from one location to another, even within relatively small areas. The variation in field strength with location must be taken into account in measuring field strength as well as in specifying service. Service is usually defined in terms of the median value of field strength, which is the value exceeded for at least 50% of the time at the best 50% of the receiving locations.

The results of field strength coverage surveys are customarily presented as contour maps, showing lines of constant median field strength which represent the outer limits of various grades of service. A typical map of measured television station coverage is shown in Fig. 1. Methods of preparing contour maps are described in detail under the heading "Analysis of Measurements to Depict Coverage."

Much of the present knowledge of wave propagation in these frequency bands has been derived from field strength coverage surveys on operational FM and television stations. The information gained from these commercial coverage surveys has added to the body of scientific knowledge, but field strength measurement surveys employing special techniques are often needed to supply data for special problems. Examples of such special techniques are discussed under other headings in this article.

A measurement program to determine coverage may be laid out according to the radial route method of the FCC Rules as described for propagation studies. Unless the results will be filed with the FCC, there is no need to maintain the precision required by the Commission. However, following the FCC Rules will minimize the effect of unintended biases that may affect the data. If the program planner is uncertain about the effect of the choice of measurement location, it would be conservative to use the FCC Rules procedure. The precision required by the FCC Rules is primarily intended to insure statistical randomness for propagation studies and to assure that the propagation path is a true radial. For in-house coverage studies, there is generally no need for the measurement location to be exactly on a true radial route at random two mile increments as required by the FCC Rules. Since many FM and TV transmitting sites are located near the center of cities it is often convenient to take measurements along more or less radial roads. Selection of measurement locations need not be random but may be influenced by population density or the desire to obtain data in particular areas.

Field strength is only part of the answer that is usually sought when there are questions concerning coverage. Actual picture or sound quality is only partially correlated with field strength. For example, multipath may cause ghosts in television pictures and distortion in FM, particularly to stereo signals. Such effects can only be determined accurately by subjective observations. Care must be taken to insure that the receiving test equipment and environment represent actual conditions. Observations made with high gain receiving antennas at 30 feet will lead to erroneous conclusions if reception on low gain indoor antennas essentially at ground level predominates. Actual picture or sound recordings should be made rather than only evaluating quality using one of the grading scales. Recordings tend to significantly reduce problems such as variations among observers, repeatability, and inaccurate reporting of the type of impairment.

The following are scoring grades commonly used for visual and aural signals. The visual scale follows the TASO[2] six point system. The aural scale is taken from CCIR Recommendation 262. These first two scales are used for the subjective rating of one aural or visual signal. Comparative scales may also be used where

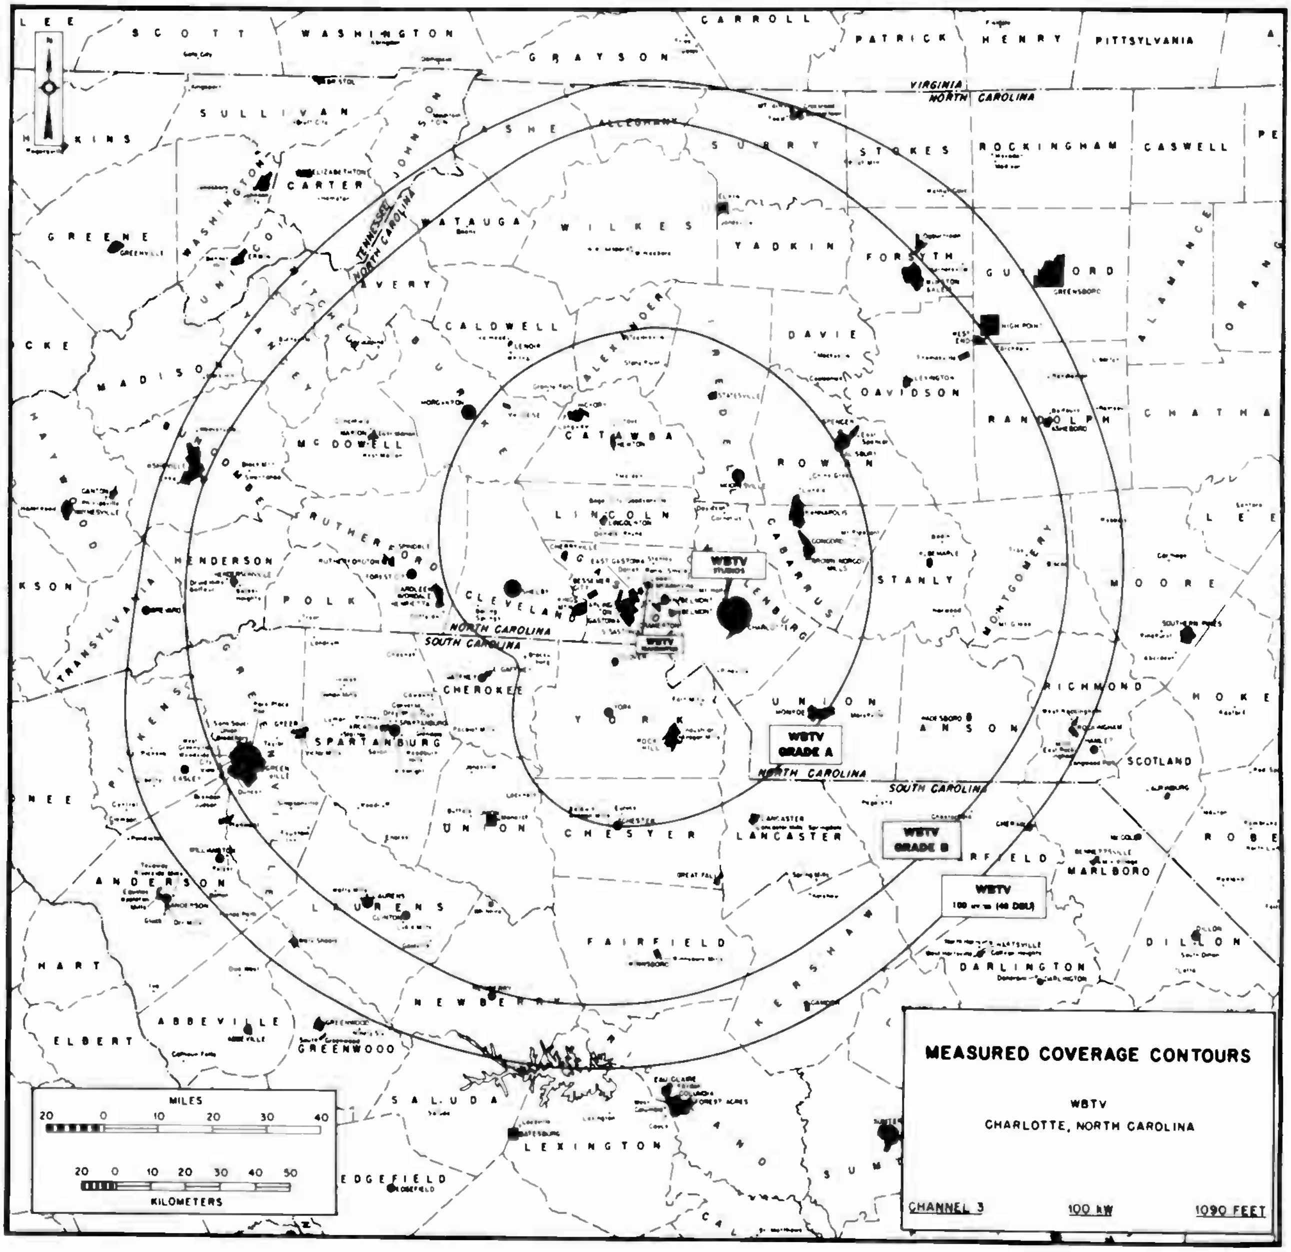

Figure 1. Map showing measured service contours for an operating television station. (Courtesy of Jefferson-Pilot Broadcasting Company)

appropriate. Comparative tests tend to yield data that is more reliable and repeatable than tests on one signal.

TASO PICTURE QUALITY SCALE

Number	Name	Description
1	Excellent	The picture is of extremely high quality—as good as you could desire.
2	Fine	The picture is of high quality, providing enjoyable viewing. Interference is perceptible.
3	Passable	The picture is of acceptable quality. Interference is not objectionable.
4	Marginal	The picture is poor in quality and you wish you could improve it. Interference is somewhat objectionable.
5	Inferior	The picture is very poor but you could watch it. Definitely objectionable interference is present.

6	Unusable	The picture is so bad you could not watch it.

CCIR AURAL SCALE

Quality	Impairment
5 Excellent	5 Imperceptible
4 Good	4 Perceptible but not annoying
3 Fair	3 Slightly annoying
2 Poor	2 Annoying
1 Bad	1 Very annoying

Obviously, with minor editing, the TASO scale may be adapted for aural use. The definitions would aid in improving repeatability in evaluation of the quality of aural signals. The following is the seven grade CCIR aural comparison scale which may also be used for visual signals.

CCIR COMPARISON SCALE

3	Much better
2	Better
1	Slightly better
0	The same
−1	Slightly worse
−2	Worse
−3	Much worse

Analysis of Measurements to Depict Coverage

If a measurement height of other than nine meters was used, the received fields must be adjusted to the field expected at a receiving antenna height of nine meters above ground to obtain the location of standard contours. An antenna height of three meters (10 feet) is often used when the results will not be filed with the FCC. It has been common practice to assume the field strengths to increase linearly with antenna height, as indicated by classical plane earth propagation theory. For this assumption the relationship between the field, E_{30}, which would be expected at 30 feet, and the field E_H, measured at a receiving antenna height H_r, is $E_{30}/E_H = 30/H_r$. For example, the ratio of the field at 30 feet to the field at 10 feet is $30/10 = 3.0$, or 9.5 dB.

The application of the linear height-gain function discussed above is recommended only in relatively flat terrain. In rolling or rough terrain the following height-gain factors were recommended by TASO to convert from three meter to nine meter fields. The values were preliminary and are not based upon measurement programs designed for this purpose.

Channel	Smooth Unobstructed Terrain	Rolling Hilly Terrain	Rough Terrain
2-6	9.5 dB	8 dB	7 dB
7-13	9.5 dB	7 dB	5 dB
14-83	9.5 dB	5 dB	2 dB

Median fields, as established in accordance with a radial or modified radial procedure described above, are plotted as a function of distance from the transmitter, and a smooth curve is drawn through the plotted points. Fig. 2 is a typical graph showing the plotted field strengths as a function of distance from the transmitter, together with the smooth curve through the plotted points. The dashed curve in Fig. 2 is the predicted field strength calculated using the propagation curves and prediction methods specified in the FCC Television Broadcast Technical Standards.[19]

Individual graphs of median field strength versus distance as shown in Fig. 2 are prepared for each of the directions along which the measurements were made; the distances to the desired field strength contours, selected from Table 2, are then plotted on a suitable map, and contours are drawn to produce a finished map such as shown in Fig. 1. In some cases a mountain ridge may cause an abrupt decrease in field strength and the curve-fitting procedure may not be appropriate.

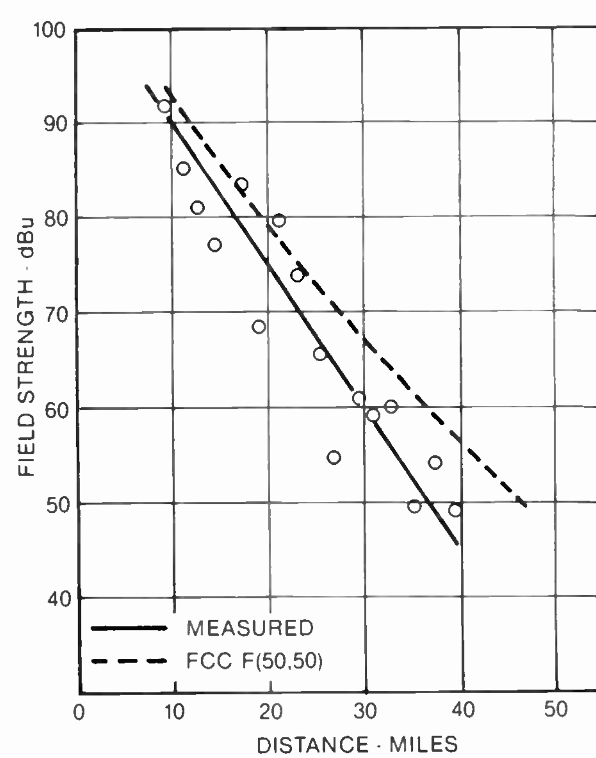

Figure 2. Graph of measured field strength versus distance for a typical radial series of measurements. The results of each mobile run are shown. The solid line is best fit curve through the points. The dashed line is the predicted field strength from the FCC curves.

Transmitting System Evaluation

Field strength measurements are occasionally used to assess the performance of a station's transmitting system, particularly the operation of the antenna. The difficulty in this case is that of separating the effect of propagation factors from the effect of the transmission system. Ideally, comparison of transmission from the antenna to be tested should be made with that from a standard antenna. The standard antenna would be a low-gain antenna of known characteristics mounted near the antenna under test. This procedure is described in detail in the TASO report.[2] The procedure is rarely feasible.

Measurements on two or more stations operating in the same frequency band are often used to determine if one is not performing properly. Differences in facilities and location must be considered in the analysis of the data. Vertical plane pattern effects may be minimized by avoiding locations near any of the stations. The uncertainty in the results is proportional to the degree of the adjustments that are made. Numerous measurements should be taken to reduce the uncertainty.

Comparisons of measured data with standard propagation curves such as the FCC Rules curves or smooth earth curves must be used with caution. The standard deviation of measured data used to draw the FCC curves is 7.7 dB at low VHF, 6.8 dB at high VHF, and 9.3 dB at UHF after adjustment for terrain.[10] Even in smooth terrain field strength is affected by other factors such as trees, buildings, and atmospheric variations.

In hilly terrain, the effect of clutter, terrain, and atmospheric variations can be minimized by selecting sites near the transmitting antenna to minimize atmospheric effects and where ray path clearance over all obstacles can be obtained. This clearance should be at least 0.6 Fresnel zone. The radius of a full Fresnel zone is given by:

$$H_O = 2280 \sqrt{\frac{d_1 d_2}{f(d_1 + d_2)}} \qquad [1]$$

where:
- H_O = Fresnel zone radius in feet
- d_1 = Distance from transmitting antenna to obstacle in miles
- d_2 = Distance from receiving antenna to obstacle in miles
- f = Transmitting frequency in MHz

Application of this criterion is illustrated by Fig. 3.

Even if such ray clearance over all obstacles can be obtained, reflections from terrain may often modify field strength. Allowance for reflections can only be achieved by taking measurements at a large number of locations to "average out" reflection effects.

Field strength measurements intended to evaluate system performance are sometimes taken in an aircraft in an attempt to reduce terrain effects. However, there are several problems associated with aircraft measurements, including: (1) Determination of the actual location of the aircraft relative to the transmitting system under test, (2) constraints on the design of the program imposed by the aircraft's performance, (3) mounting of the receiving antenna on the aircraft to minimize the effect of the airframe on the receiving antenna pattern without creating a hazard, and (4) uncertainties, such as actual path loss, that limit the accuracy of the measurement of absolute gain of the transmitting system under test.

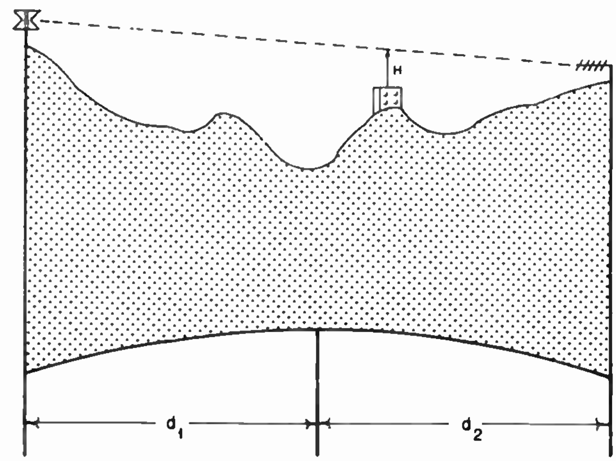

Figure 3. Illustration of required ray clearance to avoid obstacle loss.

The methods for determining the location of the aircraft or maintaining the desired location vary from simple manual techniques to control using electronic location measures such as loran. In the most basic case, an altimeter is used to maintain the desired height. A more or less circular route can be flown by flying over known ground locations. At the other end of the scale a completely electronic system can be used. Such systems are used in Europe because proof measurements are routinely required after construction.

Reflections are a limiting factor in antenna measurement whether measurements are taken on a test range, on the ground, or on an aircraft. In the latter case the standard procedure is to fly close to the antenna under test so that the reflecting ground will likely be illuminated by a relatively low ERP. The distance should not be selected arbitrarily, but should be based upon the vertical pattern of the antenna. Ideally, a helicopter should first be used to measure the antenna's vertical plane pattern at a number of locations to select the radius of the horizontal plane flight. If this is not feasible, a range measured or theoretical pattern should be used. If possible, the radius should be selected so that the depression angle of a ground-reflected ray falls in a null of the vertical plane pattern. For the case of a well smoothed vertical pattern, the flight radius may not be optimized, but the engineer should estimate the uncertainty so that excessive validity is not attached to the data. Error estimates may be made based upon theoretical reflection coefficients found in NBS Technical Note No. 101.[12]

If measurements are taken on vertically-polarized signals, care should be exercised to avoid flying at distances which permit a ground-reflected ray to fall at or near the Brewster angle. At this angle a vertically-polarized wave changes phase. Such a phase change will contribute to the uncertainty of the data. Even if Brewster angle problems are avoided and an aircraft flight path is carefully controlled, ground reflections will likely cause apparent but unreal variations in measured antenna patterns. For example, at an aircraft and antenna height of 300 meters (984 feet) and a flight radius of 2 kilometers (1.2 miles), a change of 10 meters in ground elevation at a reflecting point changes the reflected ray path length by approximately 5 meters. This is more than one half wavelength at all FM and TV broadcasting frequencies. Thus, relatively small changes in reflecting point elevation can completely change the phase of a reflected ray. In this example, if the magnitude of a reflected ray is only one-tenth of that of a direct ray, the expected variation is approximately ±0.9 dB.

Perhaps the most difficult aspect of aircraft measurements is the accurate determination of the gain of the receiving antenna as mounted on the aircraft. The aircraft and the antenna transmission line can change antenna gain significantly from the nominal "free space" value. Unless receiving antenna gain is accurately known, only relative antenna patterns can be measured. The best method would be to measure receiving antenna gain by measurements on a transmitting installation of precisely known ERP. Because of the effect of ground reflections, measurements at varying distances should be taken to average out these effects.

Analysis of Measurements to Evaluate Antenna System Performance

The following description applies to data taken on land at locations where at least 0.6 Fresnel zone clearance obtains over all obstacles. Data from aircraft measurements may be analyzed in a similar fashion. For aircraft measurements, essentially continuous data is analyzed; in ground measurements, discrete data is used.

If a station uses an omnidirectional antenna, the data may first be analyzed by neglecting noncircularity or adjusting measured data for an assumed horizontal pattern. Relative field strength may then be determined assuming free space propagation for comparison with the antenna's theoretical or range measured vertical plane pattern. The result of such an analysis is shown in Fig. 4. Data may also be analyzed by comparing measured to predicted field strengths. If the antenna is performing properly the median difference should be small and approach the accuracy of the test procedure. The median difference between measured and predicted strength for the data shown in Fig. 4 is 1.2 dB; that is, measured field strength exceeded predicted field strength.

A comparison of measured and predicted field strengths may also be used to analyze comparative measurements on different stations. Measured data may be compared with predicted values using the Commission's curves. Adjustments to allow for fairly small differences in height and location can be made directly to the measured ratio of the field strength. In decibels, a factor of 20(log(height ratio)) can be used. For example, to adjust for a height difference between 800 and 1,000 feet, a factor of 1.9 dB is added to the lower height data. For distance adjustment, a factor of 40(log(distance ratio)) may be used. In this case (for example for distances of 9 and 10 miles), 1.8 dB would be added to the data at 10 miles. By using this technique it is not necessary to calculate predicted field strength.

PROPAGATION AND OTHER SPECIAL STUDIES

Sections 73.314 and 73.686 of the FCC Rules describe the procedures to be employed for field strength measurements used in propagation studies. This procedure is basically the technique developed by TASO. The actual field strength measurement procedure is discussed later in this article. The FCC procedure is intended primarily to yield data that may be analyzed to study the effect of terrain and other local influences on field strength. Measurement programs intended for other purposes may require substantially different plans. For example, measurements primarily intended to determine the effects of clutter, such as trees and buildings, should be taken if possible, in smooth terrain to eliminate the effect of terrain.

Measured field strength for propagation studies may be compared to calculated field strength for a number of propagation models.[10-13]

Measurement programs have been conducted to evaluate field strength time variation factors. In this case field strength measurements are recorded at fixed locations over a period of time.

Field strength measurements may be an integral part of special field tests, particularly with regard to interference allocations and changes in FM and TV operation. Examples of such field tests in the past include those on VHF TV-Land Mobile channel sharing, tests relating to the problem of educational FM interference to channel 6 and on circular polarization for television. Extensive measurements were made in southern California in the study of propagation between Santa Barbara and San Diego with regard to the proposed allotment of television channel 10 to Santa Barbara. Detailed discussion of special projects is beyond the scope of this article; however, the basic techniques of field strength measurement discussed herein are valid for special programs. In addition, many of the topics discussed in planning coverage, transmission equipment evaluation and pure propagation tests are appropriate for use in special tests.

Measurement of Spurious Emission

It is occasionally necessary to measure spurious radiated field strength from FM and TV broadcast

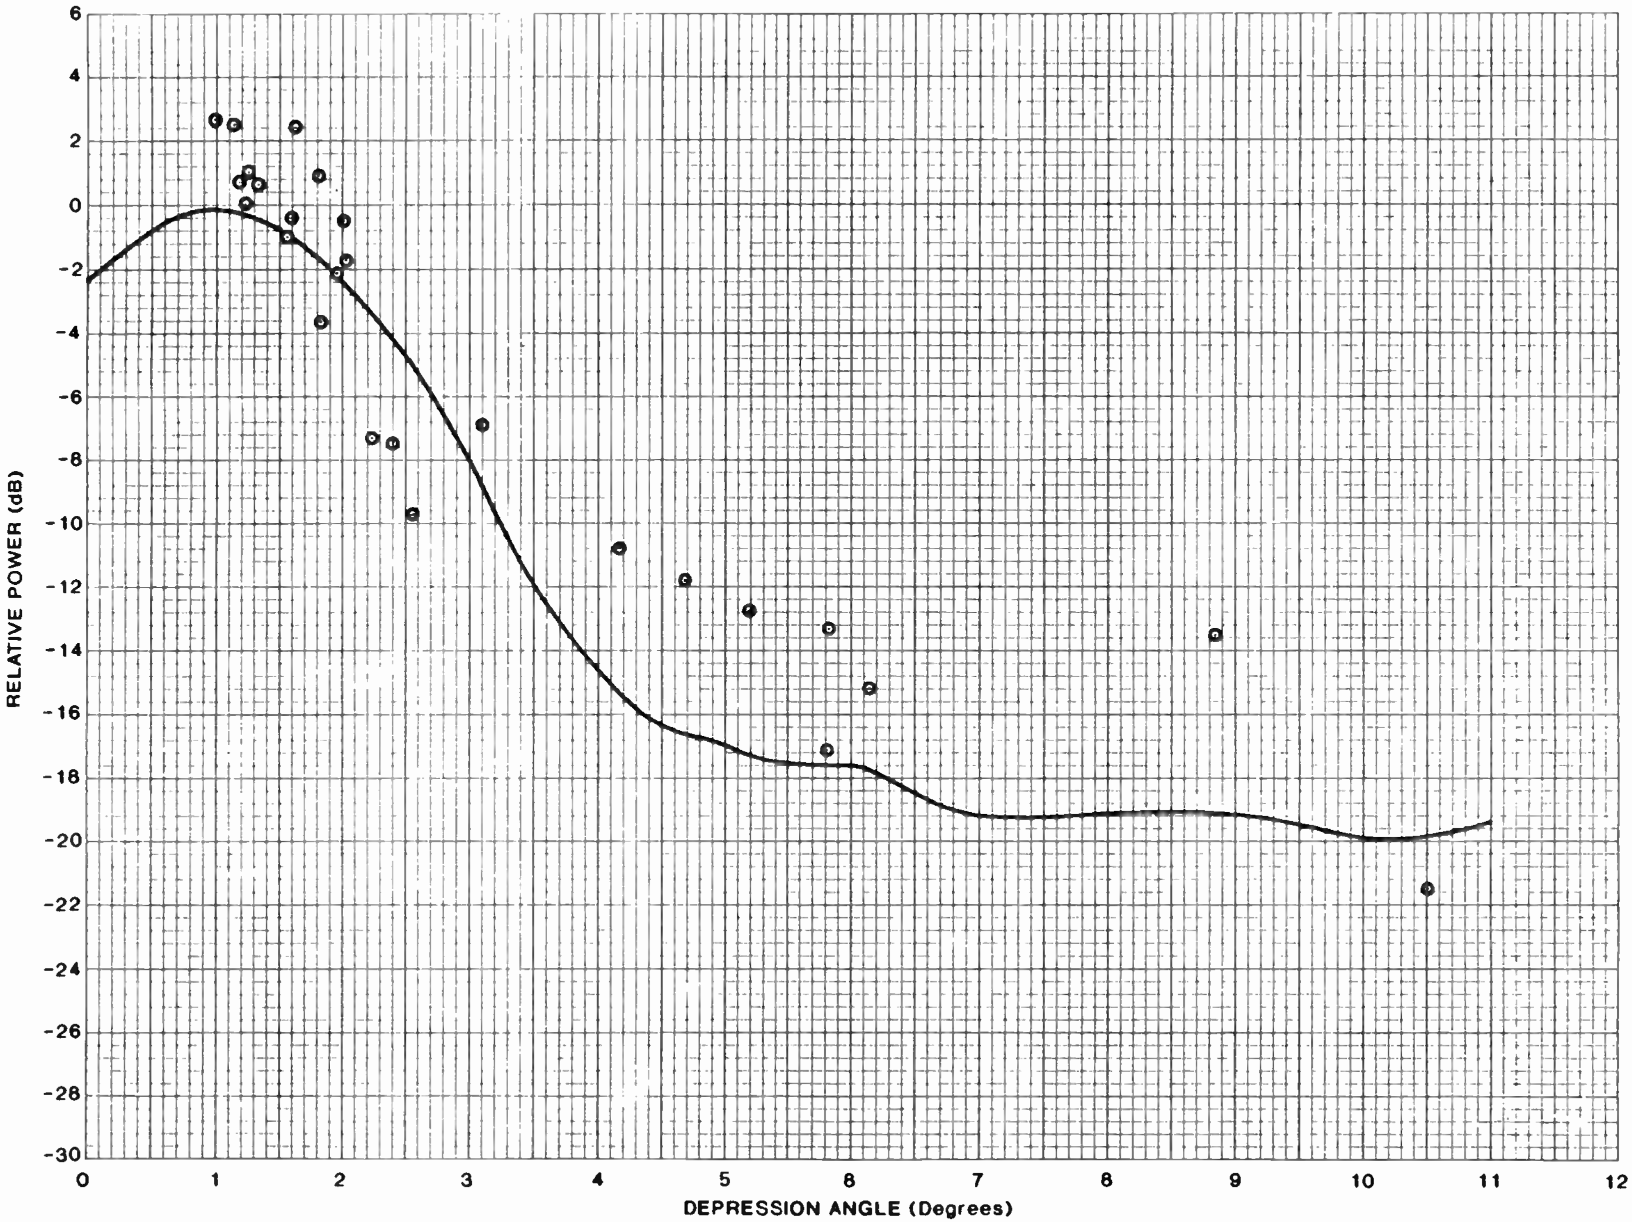

Figure 4. Comparison of data based upon field strength measurements with antenna vertical plane pattern.

facilities to show compliance with FCC Rules after installation. Requirements regarding the level of spurious signals relative to carrier level is specified in Sections 73.317 and 73.687 of the FCC Rules for FM and TV transmitting systems, respectively. Such field strength measurements are nominally regulated by Section 2.993 of the Commission's Rules.

This section is quite vague and it is recommended that the person intending to take measurements determine acceptable procedures from FCC Laboratory personnel before undertaking the measurements.

BASIC EQUIPMENT PRINCIPLES

Field strengths in the VHF and UHF bands (30 to 3000 MHz) are ordinarily measured by determining the voltage which the field induces in a half-wave dipole. The basic relationships can be expressed in several forms. The power transferred between two half-wave dipoles in free space separated by a distance, d, is given by

$$P_r/P_t = 2(1.64)(\text{£}/4\pi d)^2 \qquad [2]$$

where: P_r = Received power
P_t = Transmitted power
£ = Wavelength in same units as d

In terms of the field at the receiving dipole, the power delivered to a matched load by a half-wave dipole in a field of E volts/m is

$$P_r = (0.0186E\text{£})^2 \text{ watts} \qquad [3a]$$

where £ is expressed in meters.

Or, alternatively, in dB relative to one watt (dBW)

$$P_r = F - 20\log f - 105.1 \qquad [3b]$$

where f is the frequency in MHz and the field strength, F, is in dBμ.

For a resistive load of R ohms, the voltage V developed across a matched load by a dipole in a field E is

$$V = (E\text{£}\sqrt{R})/53.7 \text{ [volts]} \qquad [4]$$

The fundamental problem presented, therefore, is that of measuring the developed RF voltage by a practical instrument of acceptable accuracy.

The voltage measuring device is ordinarily separated from the antenna by a length of cable. The cable may introduce losses, and any impedance mismatch must be sufficiently small that calibration errors are not introduced by differences between the antenna and cable impedance and the internal impedance of the calibrating oscillator.

The following paragraphs describe the basic components used for field strength measurement using the standard FCC methods. The system described is the conventional system using chart recorders and manual analysis of recorded data. Digital sampling may be used to replace, entirely or at least in part, manual techniques. At this time an engineer, particularly a station engineer, conducting field strength measurements is most likely to use conventional equipment for reasons of cost and availability. Therefore, the following paragraphs will focus on conventional equipment. However, the principles of the measurement procedure also apply to digital equipment and a discussion of conventional equipment will illustrate these principles more clearly.

Practical Field Strength Meters

Field strength meters are calibrated receivers that fall into three basic categories: (1) receivers that contain a precision oscillator and attenuator and use direct comparison between meter readings produced by the received power and the output of the oscillator, (2) receivers that use a precision oscillator to adjust receiver gain to produce a direct reading meter, and (3) receivers that are direct reading but do not contain a calibrating oscillator. Field strength meters of Type 3 are not considered suitable for precision field strength measurements. In addition, spectrum analyzers may be used for field strength measurements, the use of such instruments is discussed below.

Fig. 5 is a block diagram of a practical Type 1 field strength meter. Type 2 meters are more common now; however, the purpose off the following discussion is to illustrate measurement principles. The Type 1 meter is more suitable for this purpose. The antenna delivers its received power to a transmission line leading to the receiver input. If the receiver input is unbalanced to ground, a balance-to-unbalance transformer (balun) is required. The transmission line between the antenna and the receiver is shielded to avoid stray pickup.

The RF attenuator shown serves two purposes: to avoid overloading of the receiver input on strong signals and to improve the impedance match when the receiver input impedance is substantially different from the characteristic impedance of the transmission line. It is frequently omitted when not required for either of these purposes.

The signal at the receiver input is amplified and converted to the intermediate frequency. Amplification and attenuation at the intermediate frequency permit operation over a wide range of field strengths; further range is provided by the receiver gain control. The rectified receiver output operates the indicating meter.

In operation, the attenuators and gain control are adjusted to provide an on-scale reading of the indicating meter. The receiver input is then switched between the output of the transmission line and the output of the calibrating oscillator, which is tuned to the frequency being measured. The output of the calibrating oscillator is adjusted to a predetermined fixed value using the RF power monitor, and the calibrated attenuator is adjusted until the indicating meter deflection is the same as that obtained from the antenna and transmission line.

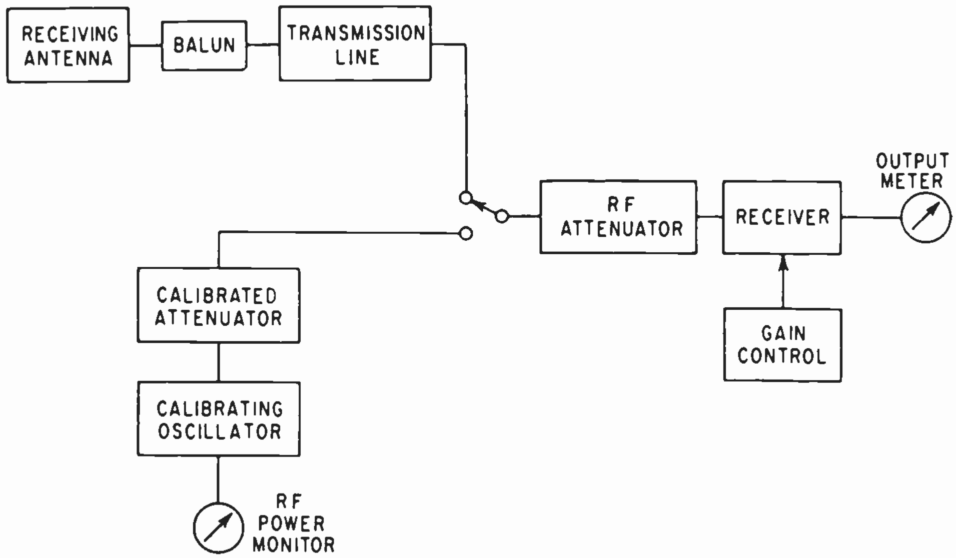

Figure 5. Block diagram of practical field strength meter.

For this condition, the voltage at the output of the calibrated attenuator is the same as that from the antenna and transmission line. By taking line and balun losses into account and applying Eq. 4 above, the field at the antenna required to produce this voltage can be determined. The relationship between field strength and receiver input voltage is usually expressed as $E = KV$, where K is a function of frequency. Fig. 6 is a typical graph showing values of K for a VHF field strength meter.

A typical commercial field strength meter of professional quality is shown in Fig. 7. The instrument shown is a Potomac Instruments type FIM-71, covering the VHF, FM, and television band from 54 to 216 MHz. A companion instrument, similar in appearance, covers the UHF television band from 470 to 806 MHz.

Accurate instrument calibration is essential in measuring RF fields. During use, the calibration of the instrument described is provided by the calibrating RF voltage source, which is usually an integral part of the field strength meter (see Fig. 7). The calibration of the oscillator and the calibration of the instrument as a whole must in turn be established and maintained by reference to laboratory standards.

The most direct laboratory calibration of the complete field strength meter is established by generating a known standard field in which the receiving antenna is placed. Standard field ranges have been developed and constructed at both UHF and VHF[14-15] and are sometimes used in primary calibration of field strength meters. Most commercial laboratory calibrations, however, are made by removing the dipole elements from the standard antenna and applying a known RF voltage at the proper frequency to the dipole terminals in series with an impedance equal to the receiving-antenna impedance. The calibration of the balun, line, and receiver is established in terms of this applied voltage, which is then related to field strength through Eq. 4.

The calibration of the internal reference oscillator section includes the calibration of both the oscillator proper and the variable-output attenuator, if employed. The attenuator is usually of the inductively coupled piston type,[16] which depends only on its dimensions for proper functioning. This can be checked against the correct dimensions or against a laboratory standard attenuator. The oscillator can be compared with a standard oscillator, or its output can be measured with a laboratory standard such as a bolometer bridge.[17] This calibration is normally, but not necessarily, performed by the manufacturer.

If measurements are made on the visual carrier of a television station, the difference between the peak and average powers of the transmission must be taken into account. This can be done by establishing a calibration in terms of average power for a still scene (such as test pattern or black picture), or a peak-reading voltmeter can be employed to indicate the level of the synchronizing peaks. Such peak-reading voltmeters are an integral part of professional commercial field strength meters such as the one illustrated in Fig. 7.

Spectrum analyzers may be used to replace standard field strength meters to permit the simultaneous measurement of multiple signals. The multiple signals must generally be arriving from a common direction, for example from the same transmitting site. Otherwise, an omnidirectional receiving antenna must be used. In the case of television measurements, care must be exercised to insure that peak of sync is measured. The total power of an FM signal is constant, so the level of an FM carrier diminishes under modulation. Thus, to obtain accurate measurements (particularly mobile measurements) on FM signals, the spectrum analyzer

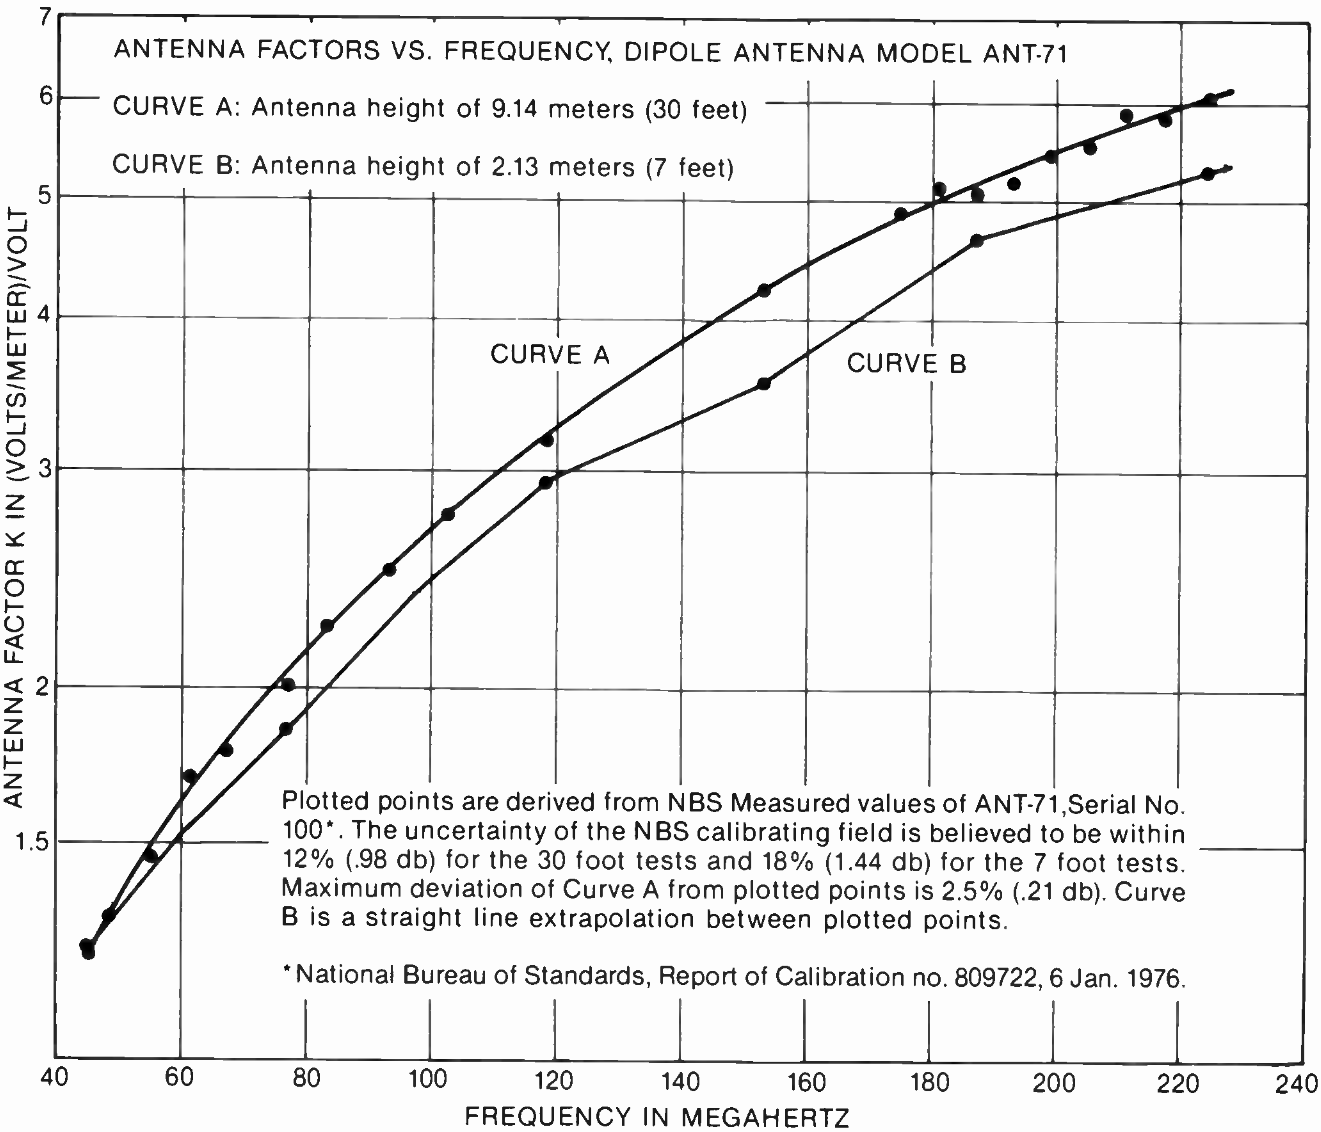

Figure 6. Graph of K for a typical VHF field strength meter. (Courtesy of Potomac Instruments, Inc.)

must be adjusted to "see" the bandwidth of each signal. In addition, intermodulation signals may be generated within the spectrum analyzer itself. If there is any doubt, the validity of signals should be checked.

In addition to the field strength meter, several accessory items are needed when making a field strength survey. The principal items and their use are described in the following paragraphs and include (1) a special receiving antenna, (2) an antenna supporting mast, (3) a chart or digital recorder, and (4) power supplies. Fig. 8 shows the field strength meter, chart recorder, and some additional equipment for a survey. The size and weight of the equipment usually dictate that it be mounted in an automobile or light truck. As discussed in Appendix A, all of this equipment, including the field strength meter, should be grounded to the vehicle frame. Fig. 9 shows a van with elevated mast supporting a UHF antenna and containing the mounted equipment of Fig. 8.

In addition to taking field strength measurements, it is often desired to use other equipment such as the television monitor shown in Fig. 8. A vehicle devoted to general field test programs should have sufficient space available for special equipment including monitors, wave-form scopes, and magnetic recorders.

Receiving Antennas

The measurement survey can be made by employing the standard dipole antenna furnished with the field strength meter, or other antennas can be utilized. It is often desirable to use an antenna other than the standard antenna for actual measurements. Standard antennas are usually not mechanically sturdy. If measurements are to be taken at a large number of

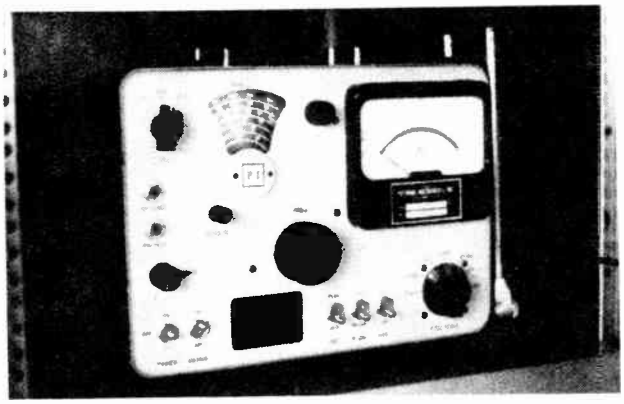

Figure 7. A VHF meter of professional quality.

locations, especially with extensive driving between locations, it is desirable to use a rugged or readily replaceable antenna and thus minimize the probability of damaging the standard antenna. For subjective evaluations the antenna should be representative of antennas actually used in the area by the public.

An antenna which is essentially omnidirectional in the horizontal plane does not require orientation as the vehicle is moved; however, it is generally desirable to use a receiving antenna with directivity. Directional receiving antennas possess gain which is useful principally for UHF measurements, and their directivity is useful to eliminate unwanted interfering signals. Directional receiving antennas also tend to discriminate against reflected signals, thus reducing apparent variation in measured field strength.

The antenna employed for the measurements must be calibrated on the measurement vehicle because of ground- and vehicle-proximity effects.[18] The difference in the calibration curves of Fig. 6 is caused by ground-proximity effects. The received field is first measured using the standard dipole antenna mounted on the vehicle at the measurement height. The antenna to be used in making the survey is then mounted on the vehicle, at the height to be employed in making the

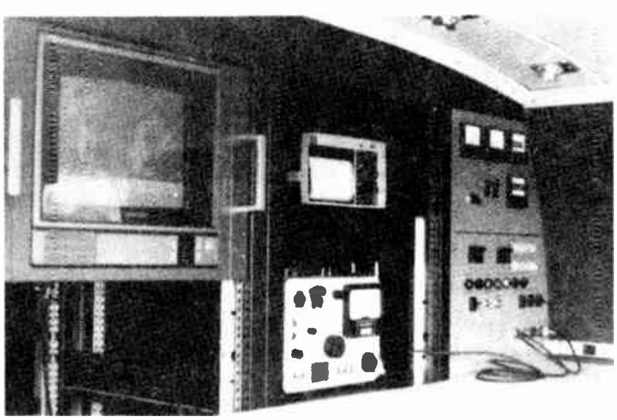

Figure 8. Equipment set up for field strength measurement.

Figure 9. Van equipped for making field strength measurements with 30 foot antenna height.

survey, and the receiver input voltage is determined with the receiving antenna at the same spot in the field. If an omnidirectional receiving antenna is employed, the circularity of the pattern of the antenna as mounted on the vehicle must be determined. The antenna pattern is best established by rotating the vehicle with the antenna mounted as for measurements, and recording field strength and measuring antenna gain as above. If the vehicle cannot be rotated, an alternate comparable procedure must be followed.

The gain of a directional service antenna can be established relative to the dipole antenna by means of measurements with the antennas stationary, but more consistent results are often obtained by making short mobile runs over identical paths and recording the signals from the two antennas. In either case a location essentially free of standing waves should be used. For either procedure, the voltage gain of the service antenna G_s relative to the standard dipole antenna G_d is $G_s/G_d = V_s/V_d$, where V_s and V_d are the voltages delivered to the receiver input using the service and standard dipole antennas, respectively.

If the transmission line or balun between the antenna and receiver is different from the standard cable and balun supplied with the instrument, the antenna calibration must include the measurement system cables and baluns.

Horizontally polarized receiving antennas are normally used for field strength measurements. At the present time, the FCC Rules require that FM and TV stations operate with horizontal only, or dual or circular polarization. Exceptions are translators and noncommercial educational FM stations. The latter may operate with only vertical polarization when there is potential for interference to a channel 6 television station. If measurements on a vertically polarized field are desired, precautions must be taken to reduce the effect of coupling between the vertically polarized antenna and the supporting mast and vertical run of transmission line. In the case of horizontal polarization, the transmission line and mast are at right angles to the receiving antenna and thus exert negligible effect on reception. For vertical polarization the line and mast are parallel and generally close to antenna elements. The receiving antenna pattern and gain may thus differ significantly from those of free space. The standard antenna furnished with the field strength meter is used for measurement or calibration of another antenna, preferably directional. The measurement antenna may then be mounted close to the mast and the gain is determined compared to the standard antenna which is offset from the mast. The standard antenna should be mounted at least one and preferably two wavelengths from all metallic vertical components. This requirement presents a mechanical problem at the lower VHF frequencies. This measurement antenna is then calibrated against the standard antenna cantilevered out from the mast about two wavelengths. Thus, in the vicinity of the standard antenna the transmission line is at right angles to the antenna. Since the mast and vertical run of transmission line are relatively distant from the antenna, the calculated variation in gain is only about ± 0.5 dB when the standard antenna is cantilevered out by two wavelengths. The result is that the effect of the mast and transmission line on the measurement antenna is compensated for in the calibration.

Antenna Supporting Mast

The receiving antenna is ordinarily supported at a height of two to nine meters (six to 30 feet) above ground, depending on the measuring technique employed. For the short heights, a simple mast of metal tubing can be used. For the standard nine meter (30 foot) height, a special mast is normally used to raise and lower the antenna, and the mast arrangement should permit the vehicle to move over limited distances with the mast elevated.

The measuring unit shown in Fig. 9 employs a telescoping mast constructed of aluminum tubing elevated by compressed air or nitrogen; the mast descends under gravity when the pressure is relieved. A handle inside the vehicle permits the mast to be rotated to orient the receiving antenna. Electronic newsgathering (ENG) vans are normally equipped with a telescoping mast. Such masts may have tilt heads that may be used for antenna orientation.

Operation with an elevated antenna involves a number of safety hazards posed by the measurement vehicle. Power lines are the principal overhead obstruction of concern. The avoidance of these hazards, equipment grounding, and operation after encountering a hazard are discussed in Appendix A. These safety procedures were taken from the TASO Report[2] with minor modifications that update the procedures and description.

Recorder

For measurements made with the vehicle in motion, a chart or digital recorder is employed. A chart recorder can be driven from the vehicle speedometer or a clock drive motor. Excitation of the recorder is provided by a dc amplifier, which usually is built into the field strength meter or may be a separate accessory.

When the chart recorder is employed, the recorder pen element must be calibrated against the receiver output indicator of the field strength meter. The dc recorder is adjusted for balance at the ends of the meter scale, and a calibration curve is prepared for intermediate values.

Instead of or in addition to a chart recorder, an analog-to-digital converter can be used to sample field strength to permit computerized analysis of the measured data. A relatively simple technique is to use a converter from a radiation hazard power density meter. Portable laptop computers can be used to store and process the measurement data.

Power Supplies

The power drain of the measuring equipment can be fairly substantial, especially if much accessory equipment is employed. It is usually preferable to provide a power source for the measuring equipment separate from the vehicle battery. This may consist of a separate battery bank to operate the meter and accessories, or a separate 115V ac alternator may be mounted in the vehicle. The latter is employed to operate the ancillary equipment shown in Fig. 8.

MEASURING PROCEDURES AND TECHNIQUES

The FCC FM and TV Technical Standards prescribe measuring methods to be employed in making measurements to be submitted to the Commission. These or similar methods are also usually employed in making other surveys such as for the measurements on station coverage. Variations from the official procedure are frequently taken; some of these variations are discussed under earlier headings. The following paragraphs summarize the present requirements of the Commission's Standards.

FCC Standard Method For the Collection of Propagation Data

The following discussion summarizes the FCC procedure in making field strength measurements for propagation studies. The forms for recording and submission of data and other technical requirements are presented in Section 73.314(b) and 73.686(b) of the Rules for FM and TV respectively.

The Commission's Technical Standards require field strength measurement surveys to be made with mobile equipment along at least eight radial lines from the transmitter. The radials need not be laid out along bearings separated by 45°, beginning with true North as is standard for contour prediction. Measurements are required to be taken from 16 kilometers (10 miles) in increments of 3 kilometers (2.0 miles) in each direction. If it is desired to establish contour location, the distance should extend somewhat beyond the field strength contour which the engineer desires to establish. The routes are selected to encounter representative terrain and to permit interpolation between adjoining radials. A precise radial line is laid out from the transmitter on topographic maps to the distance to which measurements are to be made. Along this radial line, measuring locations are marked at exact 3-kilometer (2-mile) intervals, beginning at exactly 16 kilometers (10 miles) from the transmitting antenna. The actual measurements are made precisely on the radial, at locations as close as possible to the exact 3-kilometer (2-mile) marks established as described. The ground elevation of the actual measurement location should be the same as that of the intended location.

FCC Standard Method For Measurement of Coverage of Communities

Sections 73.314(c) and 73.686(c) of the FCC Rules describe the procedures for the measurement of service to specific communities for FM and TV stations, respectively. These rules outline a measurement pattern that is in the form of a rectangular geographic grid overlying a map of the community. Measurements are made at locations as close as possible to the intersecting points on the grid.

The number of measurement points must be at least 15 or $0.1\sqrt{P}$ (whichever is greater) where P is the population of the community in thousands. Additional requirements describing documentation and calibration are contained in the rules.

The Rules also contain a statistical procedure to analyze field strength. This method fits the measurement data to a normal distribution and yields the median or average field strength in a community. The analysis may be graphical or numerical. This result is not completely compatible with other FCC Rules. The principal city coverage rule, for example, is based upon the determination of the location of a coverage contour. This difficulty can be eliminated by using a grid that is not truly rectangular but consists of radials and orthogonal arcs. This plan permits both radial and grid analysis. Since the resulting grid is not perfectly rectangular, use of this plan should be cleared with appropriate FCC personnel before undertaking measurements when the results will be filed with the Commission.

The individual measurements consist of short mobile runs (at least 30 meters [100 feet] along the road) at each location so chosen, with the receiving antenna at the nine meter (30 foot) height. If measurements are made on multiple stations for comparison purposes, it is desirable to mark the beginning or end points for each run to insure that the run is made over identical paths on each channel. Before making the measurement run, the gain of the field strength meter is adjusted to the meter reading and chart recorder indicating the initial calibration.

The chart or other recorder is used to record the field strength meter output; and the median, minimum, and maximum values of the field for each recording are determined from the chart recording. When using a chart recorder precise determination of the median is usually made after completion of the survey; however, it is useful to use the meter's calibrating oscillator to make a trace of an estimated median value on the chart paper after each run. The median of the run is estimated and the output of a precision attenuator may be adjusted to the estimated median. This provides an additional calibration check and permits a rapid preliminary calculation of field strength that is often useful to monitor the progress of a survey.

Fig. 10 shows a sample of a typical chart recording obtained by this method. With field strength meters such as the one shown in Fig. 7, there is no built-in adjustable attenuator; however, there is an oscillator output which may be fed through an external attenuator to the input to achieve this calibration.

The chart median values are then converted to received field strength by combining the individual

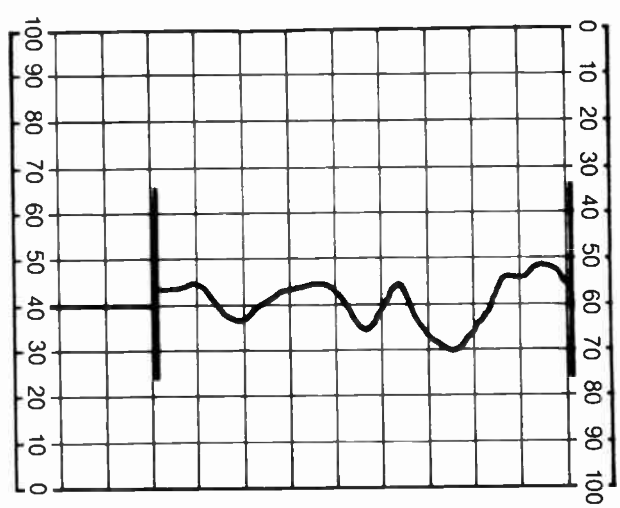

Figure 10. Sample of field strength chart recording of a short mobile run showing traces marking beginning, ending and calibration.

calibrations of the antenna, transmission line, field strength meter, dc amplifier, and chart recorder as discussed above.

PRACTICAL PROBLEMS ENCOUNTERED IN MAKING FIELD STRENGTH SURVEYS

Before any field strength measurement survey is undertaken, the radiated power of the transmitting installation must be established as closely as possible. The transmitter output power should be determined by means of the dummy load and maintained as closely as possible to the proper value throughout the survey. The radiated power is established from the measured transmitter output power, taking into account the antenna power gain and the transmission line and diplexer losses.

The use of a nine meter (30 foot) receiving antenna mounted on a vehicle requires special permission from police or highway authorities in most states. These requirements vary among the individual states, but full details can be obtained from the state police or highway headquarters in the various state capitals.

The operation of such a nine meter (30 foot) mast presents safety hazards which require the exercise of utmost caution. In addition to proper grounding (discussed earlier) the TASO field strength measuring specification includes a special appendix (included here as Appendix A) dealing with overall safety requirements. When measurements are made with an elevated antenna, the need for caution must be borne in mind at all times.

Time Variation of Field Strength

Fairly substantial variations in field strength with time are frequently noted, particularly near and beyond the radio horizon, although significant variations occur at other distances. (Factors for time variation are included in several references.[10-12]) These variations may be relatively rapid, occurring over a period of a few minutes, or slow variations may appear over periods of several hours. There are also long term seasonal variations. Average field strengths in this region are usually lowest during winter afternoons, and higher average fields may be observed during the evening hours and during summer. The variations in field strength with the passage of time must be taken into account in planning and making field strength coverage surveys.

The observed fluctuation of the field near the horizon is believed to be due principally to variations in the refractivity gradient of the lower atmosphere, which in turn is determined by the temperature, humidity, and barometric pressure gradients. Measurements for coverage surveys should not be made during changing weather conditions or if weather fronts are known to be in the area.

The variations in field strength with time often result from causes which are not readily apparent, and it is frequently difficult to determine whether typical propagation conditions prevail. One method which has been proposed and tried with some success is that of establishing fixed recording stations in one or more directions, at locations near the expected outer limit of the measurement program and recording the received signal over a period of several days. These recordings will give an indication of the signal to be expected under average conditions; the coverage survey measurements beyond the horizon can be made during a period when recordings indicate propagation conditions to be typical. Measurements should not be made on days when these recordings indicate excessively high or excessively low field strengths.

APPENDIX A—SAFETY

The following recommended safety precautions are based upon those developed by TASO for Mobile Field Strength Measurements With Antennas Elevated 30 Feet Above Ground. At the time that TASO began, the field strength measurement procedure contained in the FCC Rules specified use of an antenna height of 10 feet despite the fact that the 30 foot standard for predicted fields was in the Rules. As discussed above, the field strength height gain factor for adjusting data from 10 feet to 30 feet is not constant. Accordingly, TASO decided to use a 30 foot height and a series of surveys were begun. However, it became apparent after a series of unfortunate accidents that the measuring of field strength at television frequencies can also be extremely dangerous where observations are made at the 30 foot level. The danger here is not with the field strength measuring equipment but with contact with primary electrical power circuits and, to a lesser extent, potential traffic hazards. In view of the dangers associated with field strength measuring, there are certain precautions everyone should take in addition to the specific precautions included within this memo for safety in operation of the field strength measuring vehicle. These general precautions include the following:

1. Never take chances.
2. Do not service or work on equipment when the power is turned on.
3. Never work on electrical equipment containing high voltages unless there are at least two persons present.
4. If in doubt, keep one hand in a pocket at all times.
5. Everyone who has occasion to work on such electrical equipment must have a knowledge of the best methods of artificial respiration.

I. EMERGENCY PROCEDURE

If the procedures outlined in this memorandum for the safe operation of field strength measuring are followed, there should be no need for emergency procedures. In spite of this, it is felt worthwhile to outline some emergency procedures to be followed in the event of some unforeseen accident. Assuming that some accident has arisen involving overhead obstructions, the following precautions should be observed:

1. The obstruction which you are entangled with may carry **HIGH VOLTAGE.**
2. The vehicle you are in may be at a high potential with respect to ground, so **STOP AND THINK.**
3. Under no circumstances should the transmission line (associated with the field strength measuring gear) be touched. The grounding connections may have broken due to mechanical strain or have burned up due to extremely high currents.
4. The precautions you have taken in inspecting the vehicle before starting the day's work should prevent any high voltage from entering the vehicle.
5. Study your predicament carefully to determine your best course of action. It may be one of the following:
   a. Back the vehicle up.
   b. Drive the vehicle ahead.
   c. Lower the mast.
   d. Raise the mast further.
   e. Get away from the car — **IF YOU DO THIS, REMEMBER THE CAR MAY BE AT A HIGH POTENTIAL WITH RESPECT TO GROUND SO DO NOT TAKE CHANCES—JUMP CLEAR.**
6. Be sure no one else approaches the scene or comes in contact with the vehicle.

II. CONSTRUCTION SAFETY PRECAUTIONS

Since there is a remote possibility of the mast or antenna of the measuring vehicle coming in contact with extremely high voltages, the construction of the vehicle should be such as to reduce to the absolute minimum the possibility of these electrical voltages entering the vehicle. The secure electrical bonds referred to herein must be made with a view towards the hundreds or thousands of amperes that may be involved in the event of an accident. The first of these precautions have to do with external features of the vehicle.

1. All antenna elements which are directly connected to the transmission line must have a secure electrical bond to the mast.
2. The outer conductor of all transmission lines used with the mast must have a secure electrical bond to the top of the mast.
3. The vehicle shall be operated with blinking hazard lights when the mast is elevated.

The additional constructional details to be observed with the vehicle are as follows:

1. The outer conductor of all transmission lines must have a secure electrical bond to the vehicle as soon after entering the vehicle as possible.
2. All electrical equipment (field strength meters, recorders, receivers, and signal generators) must have secure electrical bonding to the vehicle.
3. The vehicle shall be equipped with a light readily visible to the vehicle driver which indicates that the mast is under pressure or up and/or the vehicle shall have a window in the roof from where the driver and engineer, if feasible, can directly view the mast and antenna.

The vehicle shall also be supplied with certain safety equipment, as follows:

1. A pair of high voltage rubber gloves with protecting leather gauntlets. The rubber gloves should be tested at least once a year and a memo including the date of test and the testing organization shall be included in the carrying box for the gloves. All major power companies have provision for making these tests.
2. A nonmetallic safety pole 8 foot minimum for handling hot wires.
3. A CO_2 fire extinguisher. This should be checked annually.

III. OPERATIONAL SAFETY PRECAUTIONS

The foregoing equipment safety precautions are believed to be adequate to make the inside of the vehicle safe in the event of some unforeseen accident. These precautions will only be effective as long as the equipment is in good working condition. Therefore, it is important that all safety precautions outlined in the foregoing paragraph be checked each morning before beginning the day's work. In addition to having a safe vehicle, it must be operated in a safe manner. Therefore, the following precautions must be observed when the car is used:

1. No night work is permitted without prior written approval. In the event this permission is given, it will include additional detailed precautions for the specific job for which approval is given.
2. The mast must not be elevated unless two operators are present.
3. The location for elevating the mast must be carefully chosen both to prevent contact with overhead obstructions and to avoid being a traffic hazard. The mast must not be elevated on busy urban streets or heavily traveled rural highways. The chosen area must be reasonably level and, if a mobile run is contemplated, the vehicle must traverse the path before the mast is raised.
4. Having selected the location for measuring, the following procedure shall be used for elevating the mast. The driver and the engineer will both step out of the vehicle and examine the overhead area for obstructions. The engineer may then return to the vehicle and elevate the mast. If a mobile run is to be made, the driver must walk ahead, examining the path for overhead obstructions and leave a marker at the end of the chosen path. If repeated measurements are to be made along the same path, the starting point should also be marked so that neither end of the examined path is passed.

The vehicle may then be driven between the markers.

5. When the measurements are completed, the driver shall, without stepping out of the vehicle, determine that the overhead area is free for the lowering of the mast. The driver must also make a personal observation that the mast has been fully retracted before driving to the next measuring area.

ACKNOWLEDGEMENT

The assistance of the following present and former associates in writing and editing this article is sincerely appreciated: Howard T. Head, Louis R. du Treil Jr., and Timothy Z. Sawyer.

3.1
AM Transmitters

George W. Woodard, P.E.
Radio Free Europe/Radio Liberty, Inc., Munich, Federal Republic of Germany

Broadcasting to the general public began with the process known as amplitude modulation near the start of the second decade of this century. Then, as now, the system of modulation chosen for transmission was heavily dependent on practical and economic aspects of receiver technology. The evidence is clear that amplitude detection was the only known practical method of signal demodulation when the ideas of radio communication began to be formulated in the late 1800s and early 1900s. It is apparent from some of the earliest technical writings on radio communications, that a general mathematical knowledge of angular modulation (i.e., frequency and phase modulation) did not exist until the mid-1920s.[1] These modes of transmission and the necessary receiver technology were not to be proven practical until long after amplitude modulation had become the standard of the radio communication and broadcast technological art.

As time and technology progressed, engineers could no longer ignore the problems of transmission efficiency. When, in the 1930s, the telephone industry was planning a major switch from double-sideband, full carrier, amplitude modulation (DSB-FC-AM) in favor of single-sideband, suppressed carrier (SSB-SC) for both its long distance wire and wireless services because of its higher transmission efficiency and channel capacity,[2] the broadcast industry was necessarily committed to the continuance of conventional AM because of the need for economic receiver compatibility. Therefore, broadcast engineers' attention naturally turned to improvement of transmission standards such as fidelity, efficiency of transmission, reliability of transmission, co-channel and adjacent channel interference. Of these, efficiency and reliability of transmission have seen and continue to see the greatest improvement in the views of many transmitter designers and users. Transmission fidelity, always important, reached a plateau in the late 1940s of approximately 2% to 3% total harmonic distortion (THD), 10 kHz to 15 kHz audio bandwidth, and −55 dB noise. This was not significantly improved upon until the early to mid-1980s when totally solid-state transmitters began to appear on the AM transmitter market, yielding nominally 1% or less THD, and −65 dB or better noise. In addition, pre-transmitter program processing equipment and philosophy, which influence perceived reception fidelity, continue to improve and change through use of modern linear circuit and digital design techniques.

AMPLITUDE MODULATION THEORY

Amplitude modulation in broadcasting is today more accurately referred to as DSB-FC-AM, an acronym for *double sideband-full carrier-amplitude modulation*. However, the abbreviation "AM" has been generally accepted to describe the mode of transmission currently used throughout the world. From almost the very beginning of broadcast technology, it was known that AM was not a very efficient mode of transmission, either in spectrum usage or in transmission of intelligence. The pioneers in AM broadcast transmitter and receiver engineering technology had a deep sense of responsibility toward developing this "marvelous medium" to enhance the lives of the general public with informative, educational, and entertaining programs. Some early communication technology pioneers in the U.S. and abroad had great vision for both the technical and programming aspects of public broadcasting.[3]

Amplitude modulation of a radio signal occurs in at least two basic forms, coded (digital) and linear (analog). The first amplitude modulation processes for long distance communication involved on/off keying of a radio carrier wave. The pattern or "code" of the on/off keying process determined the content of the information being transmitted. Linear or quasi-linear undulations are normally used to transmit the analog information present in speech and music. The radio carrier wave signal onto which the analog amplitude variations are to be impressed is expressed as:

$$e(t) = AE_c\cos(\omega_c t) \qquad [1]$$

where:

- $e(t)$ = Instantaneous amplitude of carrier wave as a function of time (t)
- A = A factor of amplitude modulation of the carrier wave
- ω_c = Angular frequency of carrier wave (radians/second)
- E_c = Peak amplitude of carrier wave

If A is a constant, the peak amplitude of the carrier wave is therefore constant and no modulation exists. Periodic modulation of the carrier wave exists if the magnitude of A is caused to vary with respect to time as, for instance, a sinusoidal wave:

$$A = 1 + (E_m/E_c)\cos(\omega_m t) \qquad [2]$$

where E_m/E_c is the ratio of modulation amplitude to carrier amplitude leading to:

$$e(t) = E_c\left[(1 + (E_m/E_c)\cos(\omega_m t)\cos(\omega_c t)\right] \qquad [3]$$

This is the well known basic equation for periodic (sinusoidal) amplitude modulation, and when all multiplications and a simple trigonometric identity are performed the result is:

$$e(t) = E_c\cos(\omega_c t) + (M/2)\cos(\omega_c t + \omega_m t) + (M/2)\cos(\omega_c t - \omega_m t) \qquad [4]$$

where: M = the amplitude modulation factor E_m/E_c

Eq. 4 can be represented graphically in three familiar ways: in the time domain representation shown in Fig. 1; in the frequency domain shown in Fig. 2; and as relative vectors shown in Fig. 3. The graphical representations shown are for a single-tone modulation index (M) of 0.7: i.e., the peak modulating voltage is 70% of the peak carrier wave voltage ($E_m/E_c = 0.7$). Fig. 2 shows the occupied bandwidth of an AM signal with single tone modulation. From this figure and its defining Eq. 4, it is clear that the bandwidth of an AM signal is equal to twice the highest modulating frequency when no system distortion is present. High quality music reproductions include frequency components as high as 15 kHz or higher and therefore the required theoretical bandwidth of a DSB-FC-AM signal capable of high quality music reproduction is at least 30 kHz. There are practical limits to the transmitter bandwidth which are related to the allocation requirements for stations on adjacent channels, however. Regulatory limits on transmitted bandwidths are discussed in later sections. Harmonic and intermodulation system distortion have the effect of widening the effective occupied bandwidth of the system. However, most modern transmitters have sufficiently low distortion characteristics that bandwidth stretching, due to system nonlinear distortions, is not normally a significant problem. The occupied bandwidth characteristics of an AM broadcast transmitter are discussed in more detail in the sections on "Factory Tests" and "Audio Processing and Preemphasis."

RADIO FREQUENCY

Power Amplifiers

The most important system component which is common to all amplitude modulation systems is the high-power final radio frequency (RF) power amplifier. High-power amplifiers that produce 0.25 kW to 50 kW of carrier power are common in AM broadcast transmitters in North America. Carrier power levels of one megawatt and higher are common in other parts of the world for medium wave broadcasting. The most common amplifiers used to meet the demands of high output power and high efficiency are the class-C, C/D, or D amplifiers, which may be either vacuum tube for large output powers from a single amplifier circuit or solid-state for large output powers derived from several combined lower power amplifier circuits. Class-B RF power amplifiers are still used occasionally at lower power levels and for driver stages of final class-C or D stages. Solid-state class-D amplifiers of up to five kilowatts are becoming more common as driver stages for final vacuum tube amplifiers and for the final power amplifier modules in transmitters of up to 50 kW carrier power. The most common major concerns for both manufacturers and users of modern AM broadcast transmitters are operating reliability and efficiency, both affecting operating cost. Therefore, the stages which consume the most power, the modulator and the final RF power amplifier stages, must be designed for the highest possible operating efficiency.

The basic tuned-anode vacuum tube amplifier is described in graphical form in Fig. 4. The vacuum tube can be either a triode, tetrode, or pentode. Tetrode final amplifiers are most common in modern high power transmitter designs. The RF excitation voltage is supplied to the grid of the power amplifier tube and the ratio of dc grid bias voltage to peak RF excitation voltage (shown sinusoidal in Fig. 4) determines the conduction angle (Θ_c) of anode current, given as:

$$\Theta_c = 2\arccos(E_{cc}/(E_g - E_{cc}) \qquad [5]$$

where the exciting grid signal (E_g) is sinusoidal as shown in Fig. 4A.

The shape of the anode current pulse is determined by the vacuum tube transfer characteristics and input wave shape. The pulse of current thus generated, Fig. 4C, is supplied by the DC power supply, E_{BB}, and passed through the resonant anode tank circuit shown in Fig. 4D. The resonant anode tank circuit is assumed to have sufficient operating Q to force anode voltage, e_p, to be essentially sinusoidal and of the same periodic frequency as the RF excitation voltage and resultant anode current pulse. The instantaneous anode dissipation, shown in Fig 4E, is the product of instantaneous tube anode voltage drop and anode current. The tube

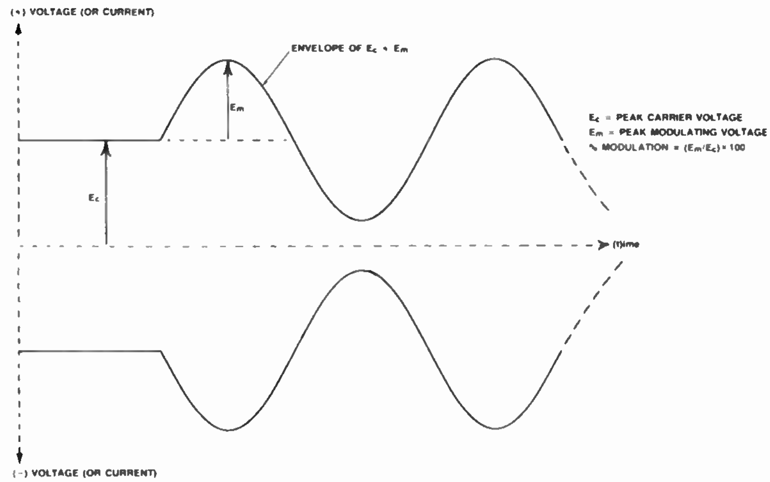

Figure 1. Time domain representation of a carrier wave signal amplitude modulated by a sinusoidal audio signal to a peak modulation depth of 70%.

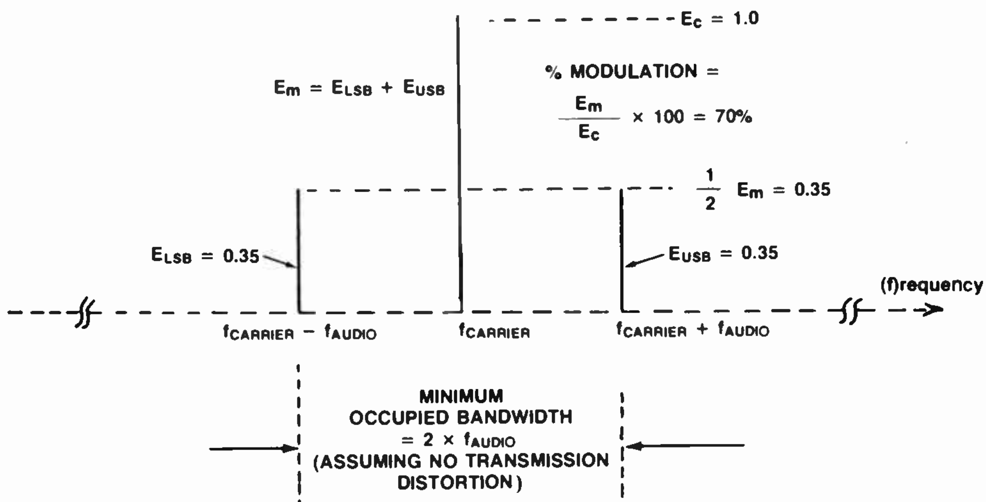

Figure 2. Frequency domain representation of an amplitude modulated signal showing the carrier wave signal and two resultant modulation sidebands at 70% modulation.

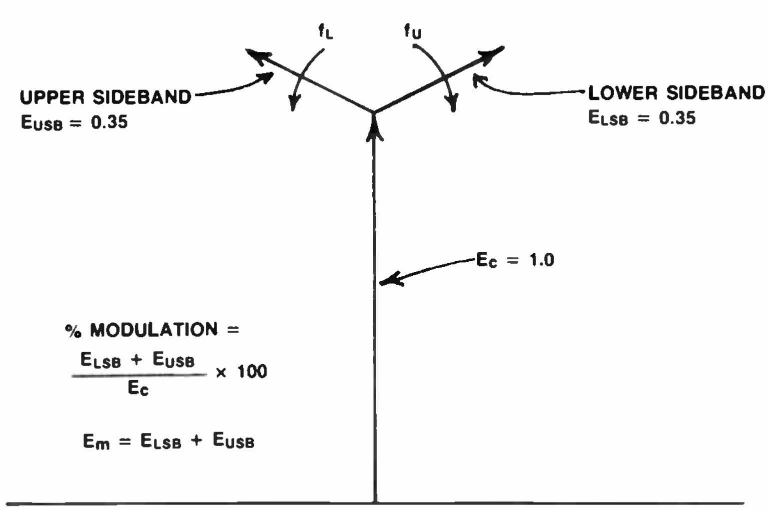

Figure 3. Vector representation of an amplitude modulation signal showing the carrier wave signal and two resultant modulation sidebands at 70% modulation.

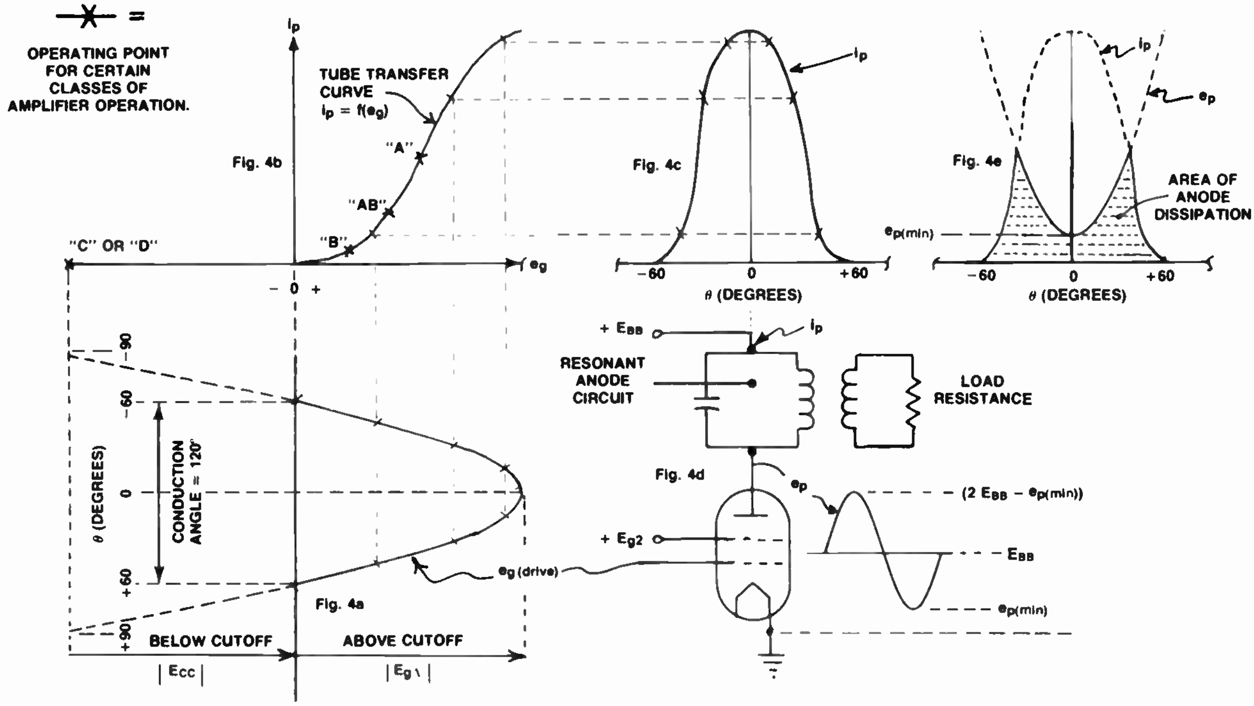

Figure 4. Classical vacuum tube class "C" amplifier with sinusoidal grid drive, 120° anode current conduction, and resonant anode load.

transfer characteristic is a variable dependent upon many tube factors, as well as maximum drive signal E_g. The exact shape and magnitude of the current waveform is normally obtained from a load-line plot on constant current characteristic tube curves supplied by the tube manufacturer. The resonant anode load impedance is chosen and adjusted to allow e_p(min) to be as low as possible without causing excessive screen grid (in the tetrode case) or control grid dissipation.

Some manufacturers increase anode efficiency beyond the limits for typical class-C amplifiers by using a circuit employing a third harmonic resonator between the output anode connection and the fundamental resonant circuit. In some cases, fifth harmonic resonators are also employed. This has the effect of squaring up the anode voltage waveform (e_p) thus causing the integral of the $e_p \times i_p$ product, or anode dissipation, to be smaller; resulting in lower anode dissipation for a given RF power output. An amplifier employing the third harmonic anode trap is commonly referred to as class-C-D: suggesting an efficiency rating somewhere between conventional class-C operation (nominal 120 degree conduction angle) and true class-D operation with rectangular anode or collector voltage waveforms. Anode efficiencies can be increased typically to values of 90% for transmitters up to approximately 10 kW carrier power and approximately 85% for transmitters higher than 10 kW carrier power by using the third harmonic trap technique. Table 1 shows a comparison of anode efficiency for six classes of high power tuned RF amplifiers.

DISCUSSION OF BASIC AM SYSTEMS

High Level Anode Modulation

The first practical method of generating the amplitude modulation signal was Heising constant current modulation,[4,5] a method of applying audio modulation to the anode supply voltage of a class-C RF amplifier. This general class of modulation is now known as high level anode (or plate) modulation. The Heising modulator was used at least as early as 1920 and was usually used to modulate a low-power RF amplifier or master oscillator stage, which was followed by several linear amplifier stages, until the desired power level was attained. In some cases the Heising modulator was used to modulate the final RF amplifier stage of lower power transmitters. The Heising shunt modulator operated in the class-A mode and therefore was low in operating efficiency. The early linear amplifiers were tuned class-B amplifiers operating with carrier level anode efficiencies of 30% maximum. Heising and similar systems of audio amplification were also used to modulate the grid bias level of RF amplifier stages in order to obtain the AM signal to be used for further linear amplification. Heising constant-current anode modulation was very popular in military and aviation radio sets used through the end of World War II.

Chireix "Outphasing" Modulation

Outphasing modulation was originally described in the literature by its inventor Henry Chireix in 1935.[6] It is a unique and ingenious method of obtaining an

AM signal by use of counter-phase modulation and vector addition of two separate radio frequency signals. It was marketed for many years by RCA under the trade name "Ampliphase," and many of those transmitters and others of European manufacturers are still on the air today at power levels of 100 kW and higher. This system of modulation is described graphically in Fig. 5. Two RF signals are derived from a common excitation source and then split into two separate channels. Each channel is shifted in phase, one positive and the other negative. The two channels are then each phase modulated by the modulating signal, again in opposing polarity. The two channels are amplified and then recombined in a vector-additive network which has the effect of producing the desired amplitude modulation. The main advantage, as with all systems previously discussed, is in operating efficiency. The two independent channels contain only phase modulated RF signals and, therefore, each can be amplified to the desired power levels in high efficiency class-C or D amplifiers. The actual modulation process takes place both at low level, in the phase modulators, and at high level, in a passive output network combiner.

There are two major disadvantages to this system of modulation. First, the efficiency of the output power amplifiers is not quite as high as the simple description above would imply, due to the fact that, at all instantaneous levels of modulation except one, the anode circuits must work into a reactive load. Secondly, output carrier power setting is sensitive to tuning of any stage in the chain; operators of early versions of this type of equipment soon learned of the potentially disastrous consequences of "trimming" a tuning control of some lower power stage. Later designs used broadband amplifying stages for the lower levels to circumvent the problem of tuning sensitivity.

A major disadvantage of the Chireix system in older transmitters was the generation of incidental phase modulation (IPM) in excessive amounts when the two low-level phase modulators were not well balanced in opposing PM characteristics. It was common for such an imbalance to exist, producing as much as 12° to 18° of peak IPM at either 100% modulation crest or trough. Modern solid-state circuitry using digital phase modulation techniques would completely remove this disadvantage (were the system still being commercially produced). This system ceased to be produced commercially when RCA discontinued AM transmitter manufacturing in the mid-1970s.

TABLE 1

Comparison of tuned RF amplifier efficiencies.

Amplifier Class	Conduction Angle (degrees)	Anode Efficiency (%)	Defined Conditions of Operation
A	360	30	$E_{b(min)} = 0.10 \times E_{BB}$
A-B	240	60	$E_{b(min)} = 0.10 \times E_{BB}$
B	200	67	$E_{b(min)} = 0.10 \times E_{BB}$
C	120	8	$E_{b(min)} = 0.05 \times E_{BB}$
C-D	120	90	$E_{b(min)} = 0.05 \times E_{BB}$
D	120	95	$E_{b(min)} = 0.05 \times E_{BB}$

Class-B High Level Anode Modulation

Historically, the most popular method of applying an audio modulating voltage to the anode circuit of a class-C RF power amplifier used a high-power, push-pull class-B audio amplifier. With the final RF power amplifier operating at approximately 80% anode effi-

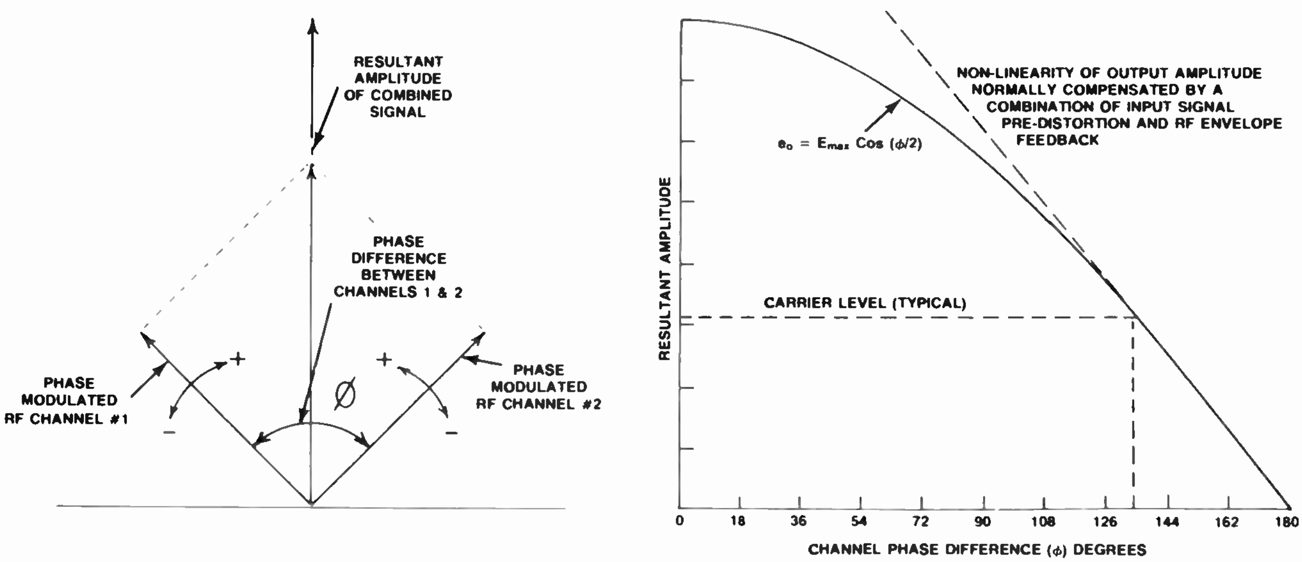

Figure 5. Principle of Chireix "outphasing modulation."

ciency and the class-B audio modulator total static currents approximately one-tenth that of an equivalent Heising modulator, total anode efficiencies at carrier level rose to approximately 72% compared to 37% for the Heising system and 30% for conventional linear amplification. A simplified drawing of a typical high level class-B anode modulation system is shown in Fig. 6. The vacuum tubes shown in Fig. 6 may be either triodes, tetrodes, or pentodes. The output circuit of the class-B modulator shows the output modulation transformer (MT), an audio coupling capacitor (C), and a dc shunt feed inductor (L).

This arrangement was used in all high level class-B high-power broadcast transmitters until about 1960, because of a transformer design constraint that would not economically allow unbalanced direct currents to magnetize the transformer core material without poor low frequency distortion. Advanced-technology core materials and careful magnetic transformer design allowed elimination of the coupling capacitor and the dc feed shunt inductor. Many of the more advanced modern AM broadcast transmitter designs still using high level class-B anode modulation have eliminated the extra C and L components from the modulator output circuitry, and the dc current to the modulated RF amplifier anode flows directly through the secondary of the output modulation transformer. This is necessary for optimum operation of modern AM stations. With the extra C and L components, the modulator output is effectively a three-pole, high-pass filter which causes low frequency transient distortion to be generated when driven with the complex waveforms that are produced by many modern and popular program audio processors. Eliminating the C and second L component causes the output modulator circuit to become a single-pole high-pass filter, greatly reducing low frequency transient distortion.

Another problem with transformer-coupled high-level class-B anode modulation is high frequency audio transient distortion. Stray internal winding capacitances and leakage inductances form multi-pole low pass filtering at the high frequency end of the audio spectrum. This equivalent multi-pole, low-pass filter generates transient overshoot distortion when driven by the processed complex program waveforms mentioned above. Transient overshoot up to 12% is typical for square-wave modulator input signals and results in a required modulation level reduction of the same 12% in order to maintain peak modulation levels within FCC allowed limits.

High frequency transient overshoot distortion can be effectively minimized by filtering the audio input to the transmitter with linear phase filters, resulting in somewhat lower high frequency audio response, by careful control of the modulation transformer equivalent circuit yielding more linear audio phase characteristics for the entire modulator circuitry, or by both methods. Balanced modulator negative feedback is used to reduce modulator nonlinear distortion and noise. Negative feedback, however, usually worsens high audio frequency transient distortion characteristics.

Doherty High-Efficiency Linear Amplifier for High-Power Facilities

The Doherty high-efficiency linear amplifier was first described in the technical literature in 1936 by its inventor, W.H. Doherty.[7] The Doherty high-efficiency

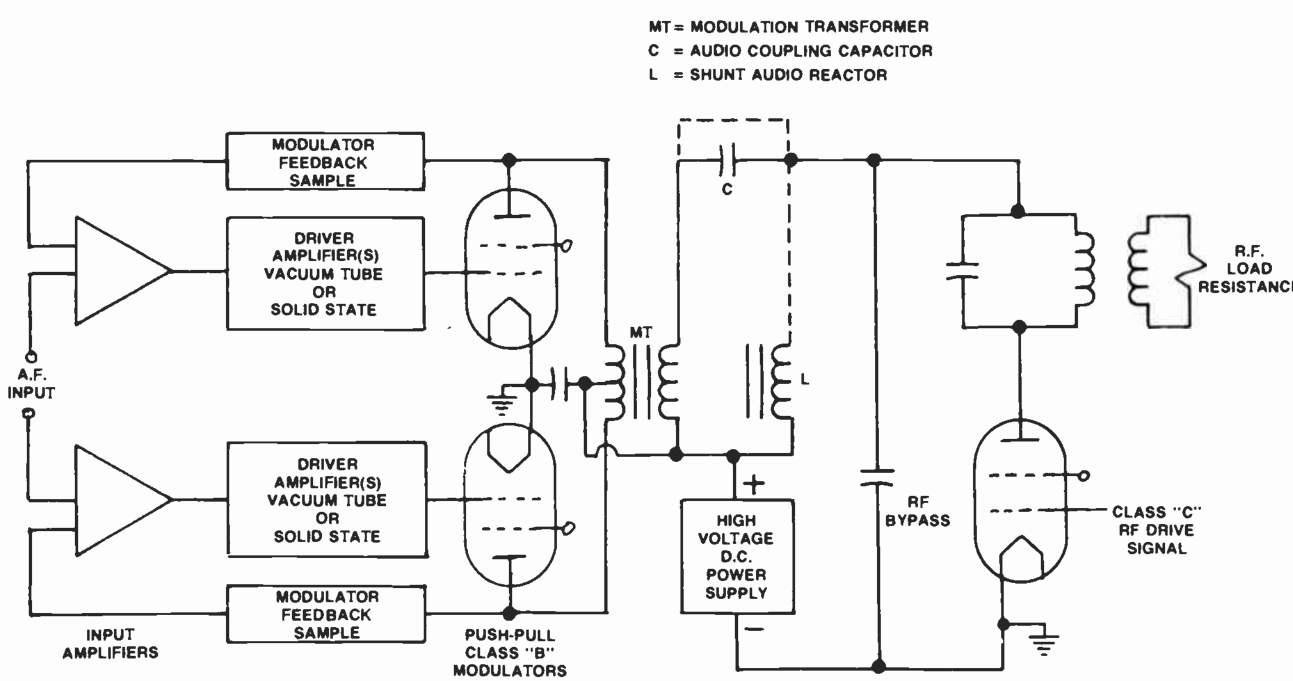

Figure 6. High level anode modulation employing transformer coupled push-pull class-B modulators.

linear amplification system has been used at power levels up to 500 kW carrier power, in both the original and in the patented Weldon[8] modified form, in many installations throughout the world on the medium wave broadcast and international short-wave broadcast bands, as well as on the long wave broadcast band in Europe. The Doherty linear amplifier is described graphically in Fig. 7. As with conventional linear amplifiers, the AM signal is generated at low levels and applied to the input of the final amplifier stage. The Doherty system employs two output amplifier stages, one defined as the carrier amplifier and the second as the peak amplifier.

The outputs of the two stages are combined in phase at the anode of the peak amplifier tube. At carrier level, the carrier tube is operated as a nearly saturated class-B amplifier and thus delivers almost all of the carrier power at class-B efficiencies, (approximately 70% anode efficiency). At carrier condition, the peak tube is biased and driven just above cutoff and therefore supplies a small amount (approx. 2% to 6%) of carrier power. The anodes of the two tubes are connected through a 90° impedance-inverting RF network. As the modulated signal increases in the positive direction to both peak and carrier tubes, the current supplied to the output load by the peak tube increases. The saturated voltage drop at the anode of the carrier tube remains constant over the entire positive modulation half-cycle, thus causing the current at the output of the inter-anode 90° network also to be constant during the same positive modulation half-cycle. The rising current from the peak tube anode has the effect of raising the impedance presented to the inter-anode network. Since the current from the network is constant, the net effect is an increase in output power from the carrier tube: i.e., $I^2 \times R_L$ increases because R_L increases.

At the 100% positive modulation crest, both tubes are producing exactly twice carrier power to the load, satisfying the requirement that peak envelope power (PEP) = $4 \times P_{carrier}$. During the negative half-cycle of modulation, the peak tube is cut off and the carrier tube behaves as a normal linear amplifier, allowing the envelope power output to drop linearly to zero at the 100% negative modulation trough. The anode efficiency of the Doherty high-efficiency linear amplifier at carrier level is more than twice the efficiency of conventional AM class-B linear amplifiers.

The Doherty linear amplifier also has two other important advantages in high power broadcast transmitters. First, and most important, the peak anode voltage at either tube is only about one-half that required for an equivalent carrier power high-level pulse-width modulation (PWM) or class-B anode modulated transmitter, thus allowing reliability and usable tube life to increase significantly. Secondly, no large modulation transformer or special filtering components are used in the final amplifier stages to cause transient overshoot distortion as previously discussed for class-B anode modulation or pulse-width anode modulation.

The main problems of the Doherty linear amplifier are nonlinear distortion and increased complexity of tuning. The major sources of nonlinear distortion are the nonlinearity of the carrier tube at or near the 100% negative modulation crest, and the nonlinearity of the peak tube at or near carrier level when it is just beginning to conduct. Both sources of distortion are effectively reduced by use of moderate amounts of overall envelope feedback. The tuning complexity problem is usually overcome by experienced and trained operators, by simplifying tuning procedures, and by built-in test equipment.

Pulse-Width High-Level Anode Modulation

Pulse-width modulation (PWM) of the dc anode voltage of a class-C RF amplifier was the first commercially successful attempt to improve significantly upon the efficiency of the popular high-level class-B modulation system by applying and improving basic PWM concepts described by Heising.[9] Since this first success, pulse-width modulation has become the method of high-level anode modulation preferred by many broadcast engineers, and is employed in broadcast transmitter designs by several manufacturers worldwide. The basic pulse-width modulation system and two ingenious improvements to the basic system are shown in Fig. 8. The circuit in Fig. 8A graphically describes the basic principle of PWM.

An inherent practical deficiency in the basic concept, Fig. 8A, is caused by the relatively high shunt circuit capacitance of the modulator tube filament transformer plus stray capacitances. Though special low-capacitance isolation transformers can be used to supply modulator filament and auxiliary power to minimize capacitive switching losses, typical realizable values of capacitance can cause excessive switching losses and audio distortion in lower-power transmitters.

For example, the switching losses at carrier level of a typical PW modulator for a 5 kW transmitter can be higher than the quiescent modulator losses of an equivalent power class-B modulator even when the stray modulator tube capacitances are as low as 100 pF. The power lost per modulator switching cycle is:

$$P_{modsw} = (CV^2/2) + P_{td} \qquad [6]$$

where:

- C = The shunt modulator filament transformer plus stray capacitance to ground
- V = The pulse switching voltage to ground at the cathode of the tube
- P_{td} = The saturated tube and diode losses during the respective on and off conduction states

Besides causing switching losses, this high stray capacitance to ground also causes modulator distortion at high negative modulation indices.[10] The circuit shown in Fig. 8B is one ingenious way to overcome the stray modulator capacitance problem. It is identical to the circuit in Fig. 8A, in principle, except that the high-voltage, pulse-modulated wave is at a point in the circuit where shunt capacitances to ground are inherently minimized. The circuit in Fig. 8C is basically

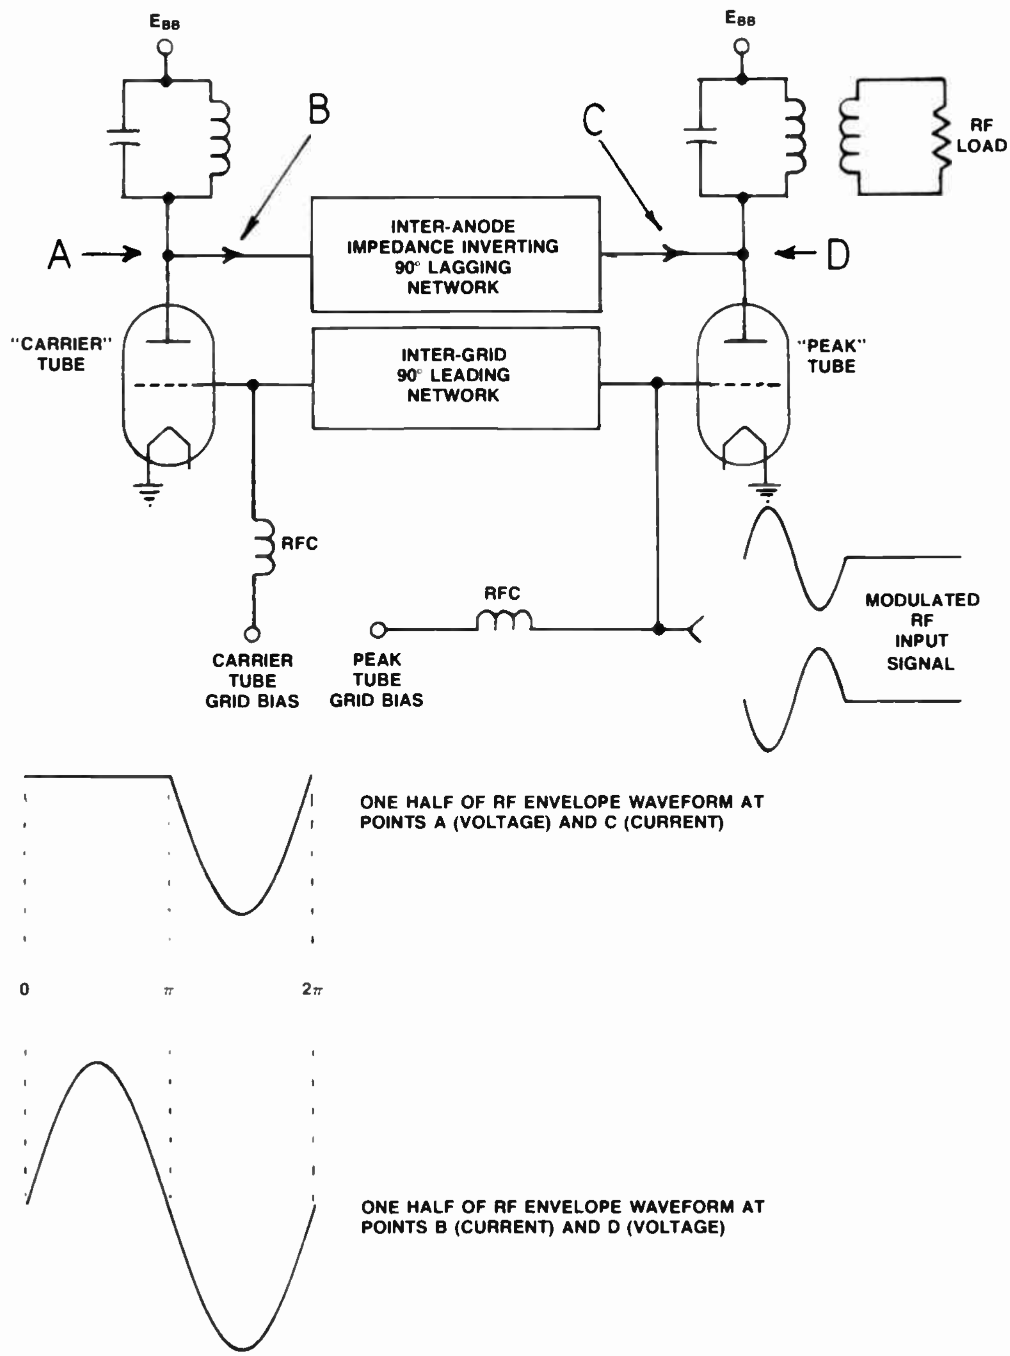

Figure 7. Doherty high efficiency linear amplifier for modulated waves.

the same as in 8B except that the system ground has been placed at another point in the circuit. PW modulator anode efficiencies approach 92% in some higher power transmitter designs yielding a combined modulator and carrier tube anode efficiency of approximately 74% at all levels of modulation.

An added efficiency advantage of PWM over high-level class-B anode modulation is that a PWM transmitter may have only two high power vacuum tubes, one modulator and one final RF amplifier, thus eliminating the filament heating power of one large vacuum tube required in push-pull modulator designs.

A significant disadvantage of PWM, as described in Figs. 8A and 8C, is that the cathode and grid circuits of the modulated RF amplifier are operated at high voltage levels off ground, adding complications to the circuitry that are avoided with the classical PWM circuit of Fig. 8A and conventional high-level class-B anode modulation. Another major disadvantage of PWM in any form is transient distortion caused by the phase nonlinearity of the multipole PWM filter (similar to that previously discussed for high-level class-B anode modulation). The switching frequency is typically 70 kHz for most transmitters manufactured in North America. This frequency is chosen to ease compliance with FCC regulations, which require that all spurious radiation more than 75 kHz removed from the carrier frequency be 80 dB or more below the carrier level.

In order to meet the spurious-output requirements of paragraph 73.44 of the FCC regulations, a very steep cutoff low-pass filter is required at the output of the PW modulator. Most manufacturers of PWM transmitters attempt to maintain linear phase characteristics in this filter to the highest audio frequency possible, but the laws of nature prevent required linear phase characteristics to the highest third audio harmonic from being achieved within the major attenuation constraints noted above. As a result, transient response to a square wave input can result in peak overshoot of approximately 6%. As with class-B modulation, this overshoot can be eliminated effectively by the use of linear phase (Bessel) filtering of the input modulation signal at the expense of a small reduction in modulation frequency response capability.

High-Efficiency Screen/Impedance Modulation

In 1938, Terman and Woodyard[11] described a modification to the basic Doherty high efficiency linear amplification system previously described. In the new system, the grid bias level of two tubes operating class-C is varied at the audio modulation rate, thus creating a higher efficiency system of amplitude modulation rather than amplification while still using the impedance inverting properties of the inter-anode network described by Doherty. The Terman-Woodyard system of modulation, however, was not extensively used in commercially successful high-power transmitter designs.

High efficiency screen/impedance modulation[12] is a method in which the audio modulating signal is applied to the screen grids of two tetrode vacuum tubes operating as class-C carrier and peak amplifiers. Invented by J.B. Sainton in 1965, the screen/impedance modulation system exhibits significant improvement because RF excitation voltages and audio modulating voltages are isolated from each other, thereby eliminating a troublesome source of tuning versus modulation interaction.

The screen/impedance modulation system is shown and described graphically in Fig. 9. The peak and carrier tubes are biased and driven in quadrature as class-C amplifiers from the continuous wave RF drive source. At carrier level, the screen voltage of the carrier tube is adjusted so that the carrier tube is near anode saturation and delivering approximately 96% of the carrier power. The screen voltage of the peak tube is adjusted so that the peak tube is just into conduction and supplying the remaining approximate 4% of carrier power. The combined anode efficiency at carrier level is better than 77% as shown in Eq. 7.

$$n_{at} = 1/(pc/n_{ac}) + (pp/n_{ap}) \qquad [7]$$

$$n_{at} = 1/(0.96/0.8) + (0.04/0.40) = 0.77$$

where:

- pc = Percent carrier power supplied by carrier tube (as a decimal)
- pp = Percent carrier power supplied by peak tube (as a decimal)
- n_{ac} = Carrier tube anode efficiency at carrier level (as a decimal)
- n_{ap} = Peak tube anode efficiency at carrier level (as a decimal)
- n_{at} = Total anode efficiency at carrier level (as a decimal)

Modulation of the RF carrier wave occurs when the screen voltage of the peak tube begins to rise during the positive modulation half-cycle, thus causing the peak tube to supply more RF current to the output load. This increase of current into the output network causes the resistance seen by the inter-anode network to increase and, due to the impedance inverting characteristic of the 90° inter-anode network, causes a proportional decrease in the load impedance presented to the carrier tube anode.

The carrier tube resonant anode voltage drop is fully saturated over the entire positive modulation half-cycle, and therefore is effectively a constant voltage source. The power output of the carrier tube thus increases during the positive modulation half-cycle, due to the modulated decreasing impedance at its anode until both peak and carrier tubes deliver twice carrier power at the 100% positive modulation crest. During the negative modulation half-cycle, the peak tube is held out of conduction while the carrier tube output voltage decreases linearly to zero output at the 100% negative modulation trough. Simple alterations to the inter-anode 90° network characteristic impedance gives the screen/impedance modulation system the capability of full FCC-allowed positive modulation (up to 125% peak) without added distortion.

The advantages of screen/impedance modulation are the same as mentioned for the Doherty linear amplifier except that screen/impedance modulation has higher efficiency at all depths of modulation, and is less critical to misadjustment of RF amplifier tuning. Screen/impedance modulation has been successfully used in medium-wave transmitters throughout the world at the two megawatt carrier power level and up to 250 kW in automatically-tuned transmitters for international shortwave broadcasting.

SOLID-STATE BROADCAST TRANSMITTERS

Solid-state technology came to high-power medium and shortwave AM broadcast transmitters about 1984. The new designs and products are proving themselves

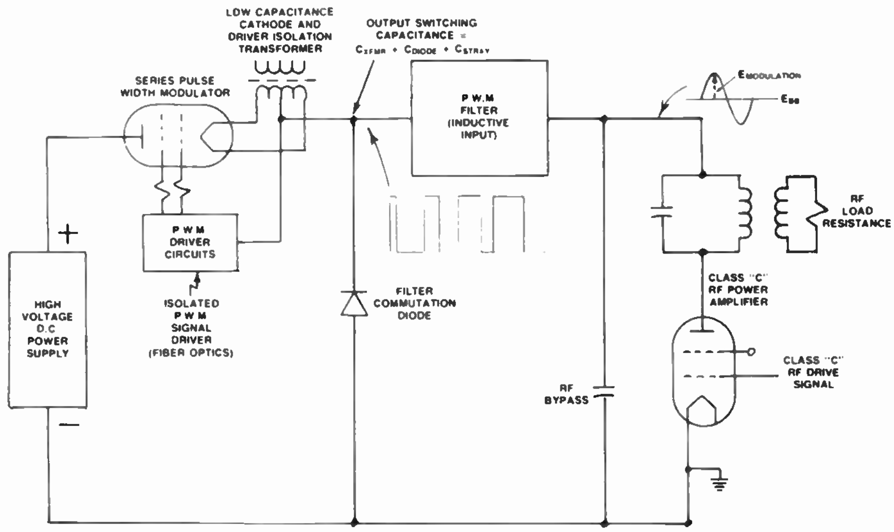

Figure 8A. Basic classical high level anode pulse-width modulation of a vacuum tube class "C" amplifier.

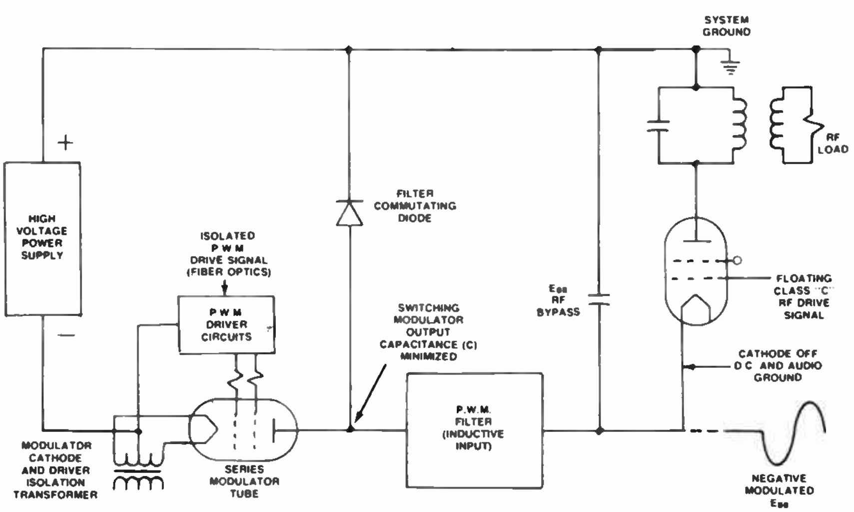

Figure 8B. Collins Radio/Continental Electronics patented modification to basic high level PWM System to minimize modulator lossed by minimizing switching modulator output capacitance.

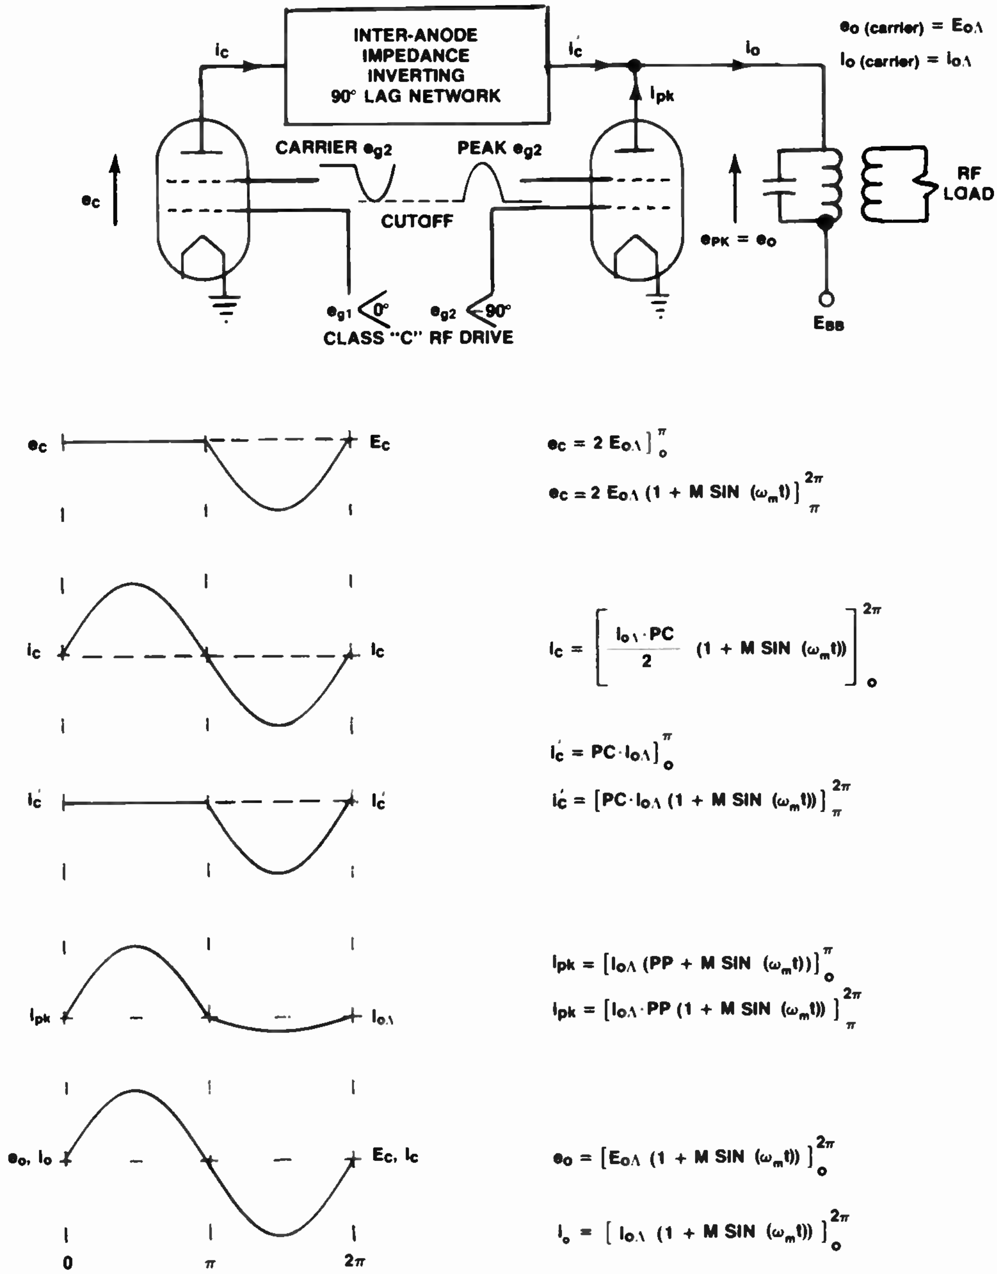

Figure 9 Principles of Sainton high efficiency screen/impedance modulation.

worthy in the harsh environment of high-power transient disturbances caused by gas arcs in associated vacuum tube circuitry and lightning strikes on antennas, power lines, and buildings. Products now available on the commercial market offer solid-state modulators for high-level anode modulation of a vacuum tube final RF amplifier up to 600 kW on medium wave and 500 kW for shortwave transmitters. The new all solid-state designs, up to 50 kW carrier power levels, are achieving great commercial success because of their higher operating efficiencies, reliability, size, weight, and superior modulation characteristics over competitive vacuum tube designs. Products and designs employing solid-state technology in the modulator circuitry for high-level anode modulation of power grid vacuum tubes are also enjoying great commercial success worldwide.

SOLID-STATE EQUIPMENT AND CIRCUITRY

Solid-state designs of AM broadcast transmitters basically fall into three categories: (1) solid-state modulator circuitry supplying the audio modulating power for high-level anode modulation of a power grid vacuum tube RF power amplifier, (2) solid-state, high-level collector modulation of solid-state RF power amplifiers, and (3) a design in which the amplitude modulation process is achieved by pseudo-digital pulse-code modulation taking place directly in the RF power amplifier stages.

The main advantage of solid-state circuitry is operating efficiency. It is still yet to be determined whether the reliability of solid-state designs is distinctly advantageous over vacuum-tube circuitry, but the efficiency advantages are clear and proven. The efficiency of a single power-grid vacuum-tube pulse-width modulator (including filament, control-grid, and screen-grid power losses), is approximately 90% maximum for a 50 kW transmitter. Pulse-step width modulator efficiency for a solid-state modulator at the same power level is approximately 95%.

When solid-state circuitry is also employed in the RF amplifier circuitry, the efficiency is even greater. The typical maximum anode efficiency of a power-grid vacuum-tube class-C amplifier is 84% (neglecting output network circuit losses). This can be improved to approximately 90% by anode-voltage wave shaping techniques, such as third and fifth harmonic traps in the output anode network. Therefore, the all-tube pulse-width modulated transmitter overall modulator/RFPA anode efficiency is 90% × 90%, or approximately 81%. Transmitter designs employing solid-state circuitry in the RF power amplifiers typically use class-D amplifier circuitry which achieve approximately 95% RF collector efficiency at medium wave frequencies. Therefore, an all solid-state pulse width modulated transmitter can have overall collector efficiency of 95% × 95% = approximately 90%, 9% greater than the all-tube transmitter. With energy costs at record high levels in all of the world and constantly rising, the efficiency of high-energy consuming products, such as broadcast transmitters, will continue to be of prime and ever-increasing importance.

Asea Brown Boveri (ABB) Pulse-Step Modulator

The Brown Boveri Corporation of Switzerland, who later merged with the Swedish electrical giant ASEA, was one of the first companies to market a workable very high-power solid-state modulator for use with their family of low frequencyh (LF), medium frequency (MF), and short wave (SW) transmitter products, from 100 kW to 600 kW of carrier power. The circuit employs several low voltage power supplies in series which are switched into operation in steps to provide the required anode modulation voltage, hence the term "step modulation." The concept was first employed in a 500 kW, shortwave transmitter design and later scaled down at LF, and MF, as well as other shortwave products of lower power levels to 100 kW, minimum. Typically the number of steps employed are approximately 28. Each "step" is pulse-width modulated to achieve the necessary total linearity required for broadcast transmitter modulation linearity characteristics. Each step represents approximately 1,000 volts in modulator output, yielding a total modulator output capability of approximately 28,000 volts at the 100% positive modulation crest.

The solid-state devices used to control the 1,000 volt steps are gate-turn-off (GTO) thyristors or SCRs. The transmitters were designed to comply with the CCIR international shortwave broadcast standard of 4.5 kHz audio bandwidth which is also compatible with the requirements for audio bandwidth of the European Broadcasting Union for Medium- and Long-Wave transmissions. Recently, ABB changed their high power switching devices from GTO Thyristors to IGBT (insulated gate bi-polar transistors) because of the latters superior high speed switching characteristics resulting in even higher modulator efficiency and modulation bandwidth capability.

To achieve high overall transmitter efficiency, ABB engineers concentrated not only on the solid-state modulator circuitry, but also on techniques to maximize the anode efficiency of the power-grid vacuum tube final RF power amplifier and associated circuitry. Working closely with the Power-Grid Vacuum Tube Division of ABB, they designed a tube with optimum circuit efficiency characteristics which operates with minimum grid drive power requirements an anode conduction angle of approximately 110° (rather than the more conventional 120° standard for class-C operation) which yields a total anode efficiency of approximately 87%, excluding circuit losses. Medium-wave transmitter designs by ABB, using pulse-step modulation, employ similar technologies with the addition of anode wave-shaping circuitry, resulting in anode efficiencies exceeding approximately 92%. Overall shortwave transmitter efficiency has been measured at greater than 76% on some international shortwave bands. Overall efficiency of ABB medium-wave transmitters has been measured at greater than 77%.

Continental Electronics Corporation (CEC) Pulse-Step Modulator

Continental Electronics Corporation introduced their own version of a high-power pulse-step modulator system in 1990. The system is similar to the ABB system described above in basic operating principle. The technique used to generate each step and the subsequent pulse-width modulation of each step is different than the system employed by ABB, but the net result is similar.

The CEC system for the basic step generation uses a modified flash A/D converter with an additional digital "ring" modulator system that electrically rotates the active steps equally among all available modules. This rotation provides equal power distribution among all system modules. Each step is pulse-width modulated by a linear mixing of a triangular "dither" signal to each A/D flash comparator.

The CEC system employs typically 48 discrete steps of approximately 1,500 volts each, and has been built for power levels of 100 kW, 250 kW, and 500 kW transmitters, both medium wave and shortwave. The CEC design employs high speed IGBT (insulated gate bi-polar transistors) producing typical modulator efficiencies of 95% or higher, overall transmitter efficiencies of greater that 72%, and modulation bandwidth capabilities exceeding 10 kHz.

Nautel Corporation—AMPFET Transmitters

The Nautel Corporation of Nova Scotia, Canada was one of the first to introduce all solid-state transmitter designs on the commercial broadcast market. Initially available for only 1 kW, 5 kW, and 10 kW carrier powers, they have since added capability up to 50 kW.

The Nautel design employs modules of approximately two kilowatts, each, with class-D RF power amplifiers using pulse-width modulation of the class-D amplifier collector voltage. Each module contains its own RF power amplifier (RFPA) and pulse-width modulator and a number of modules, depending on the power level, that are combined in an RF-combining network to achieve the desired carrier-power level. The collector efficiency of each class-D RFPA is approximately 95%, and the efficiency of the combining networks is greater than 99%, yielding a total RF system efficiency of approximately 94%. The efficiency of the pulse-width modulators are approximately 95%, resulting in an overall collector efficiency of better than 89%. Nautel engineers then carefully selected and designed the remaining transmitter components to require no more than approximately 10% of nominal carrier power for all auxiliary transmitter functions, such as control circuitry, exciter and driver circuitry, cooling equipment, etc., thus achieving an overall transmitter efficiency of greater than 80%.

The basic circuit of the Nautel design is shown in Fig. 10.

Polyphase Pulse-Width Modulation

In the late 1960s, Harris developed pulse duration modulation (PDM), a technique that offers improved efficiency and audio quality while eliminating some large and costly components from the transmitter. In the original configuration, audio information to be transmitted is sampled at a nominal 75 kHz rate. This creates a 75 kHz pulse train with its pulse width rate-of-change being equal to the audio frequency. Studies have determined that the time duration of the sample pulse is not critical. The sample rate is based on an upper frequency of 15 kHz sampled at five times that frequency to ensure broadcast-quality bandwidth and distortion. In practice, most transmitters manufactured for use in North America employ a switching frequency of approximately 70 kHz, to simplify compliance with the FCC requirement for suppression of spurious emissions beyond 75 kHz from the carrier frequency.

The technique of polyphase pulse-width modulation (PPDM) was a further development to overcome the switching transition losses of the higher sampling frequency. Fig. 11 shows the relations of the four-phase system operating at a fundamental rate of 60 kHz. The effective sample rate is four times that or 240 kHz.

When extracting the long and short term DC average information from an encoded single-phase PDM signal, a sharp filter roll off characteristic is required. Such a characteristic is shown by the solid line curve in Fig. 12. This sharp attenuation characteristic generates overshoot due to the inherent group delay characteristic of the sharp roll off filter. The effective 240 kHz sampling rate of the Harris four-phase sampling system, however, allows some improvements in filter design that significantly reduce overshoots.

The resultant 240 kHz four-phase switching frequency being farther removed from the audio baseband than the 75 kHz single-phase PDM sampling rate has facilitated the design of a phase linear PDM filter. This new Harris PPDM filter reduces the group delay just mentioned. The resulting softer roll-off characteristic is depicted by the dotted line response curve of Fig. 12. Reference to Fig. 13 shows the relative distortion amplitudes and spectra of 75 kHz and effective 240 kHz sampling rates. Inspection of this figure shows the added advantage of less distortion energy present in the demodulated audio baseband, which is due to the effective sampling rate being farther removed from that baseband than previously.

Attenuation of 60 kHz energy occurs within the PDM filter in two ways: the normal filter attenuation mechanism, as well as a capacitive coupling technique. The capacitors C1, C2, C3, and C4 emanating from each of the PDM filters in Fig. 14 tie together at a common terminal. This configuration in effect connects the 60 kHz energy present in the individual filters to a common summation point. As the spectral energy created by the sampling process creates energies that are 180° out of phase with each other, and assuming that a balanced amplitude among sampling phases exists, the capacitive coupling of 60 kHz energies will result in a high degree of cancellation.

The output of the PDM filter is a combination of long-term and short-term average information. Transmitter output power is determined by the long-term average voltage; modulation power is determined by the short-term average voltage.

Harris Broadcast Division, DX Series Pulse-Code Modulation

One of the newer improvements to medium-wave AM broadcast transmitters employs direct digital techniques to generate the amplitude modulated wave. The technique has no "modulator" as such and the complete AM wave, carrier and modulation sidebands, are produced by direct digital pulse-code control of several low-power solid-state RF amplifier modules.

Invented by Hilmer Swanson of Harris Broadcast Division, the DX system is employed in transmitters ranging in power from five to 50 kW for the domestic U.S. market, and has been sold at 100 kW power levels for the CCIR Region 2 and 3 markets in which carrier powers up to one and two megawatts are not uncommon.

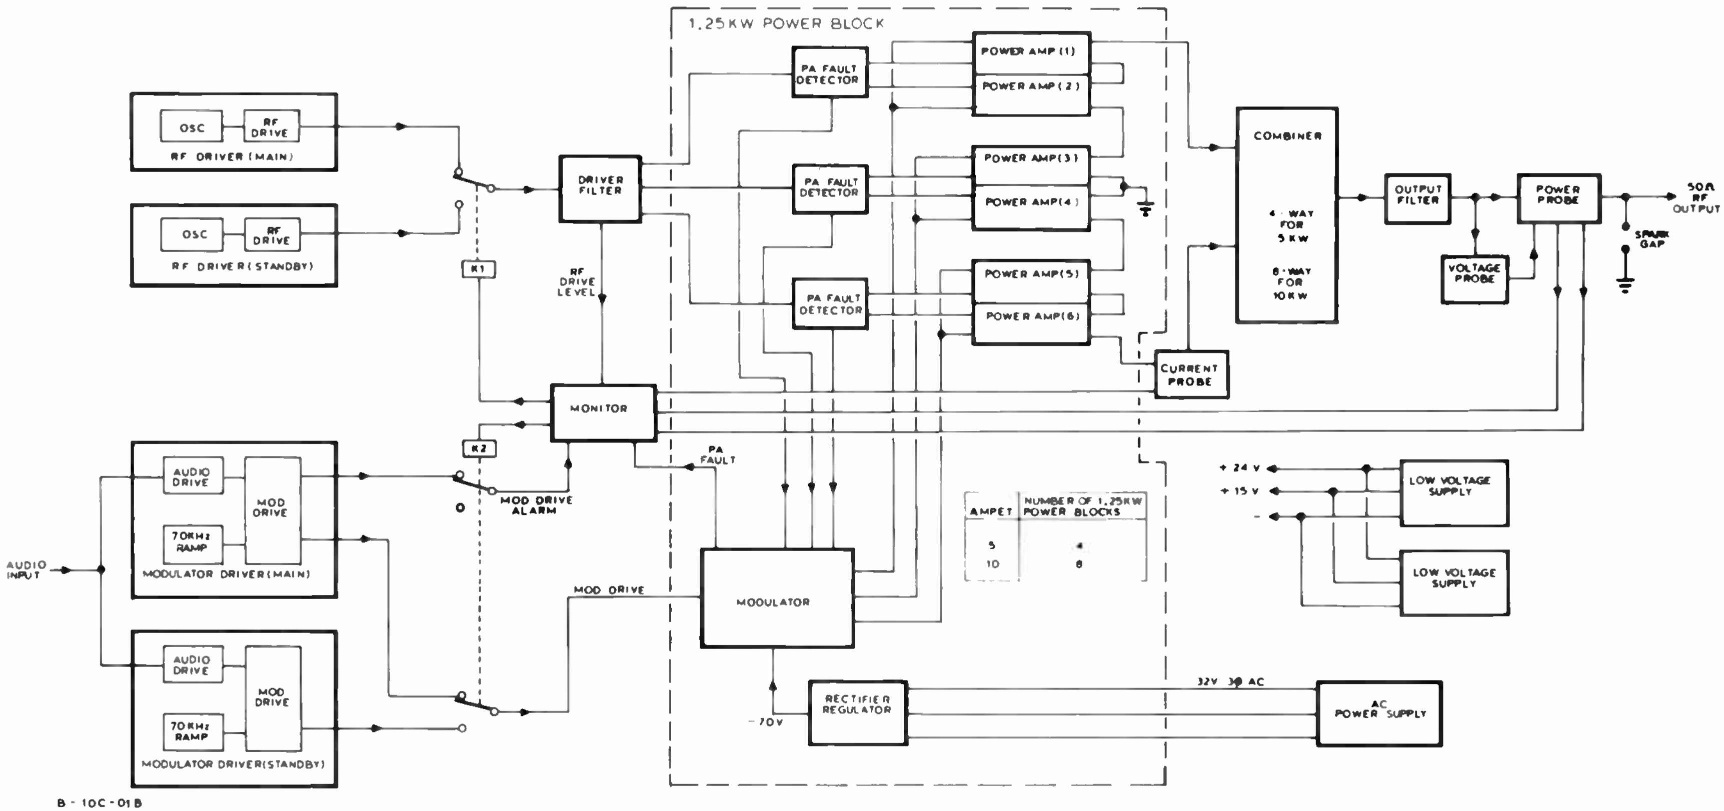

Figure 10. Block diagram, Nautel Model AMPFET 5 and AMPFET 10, 5 & 10 kW AM broadcast transmitters.

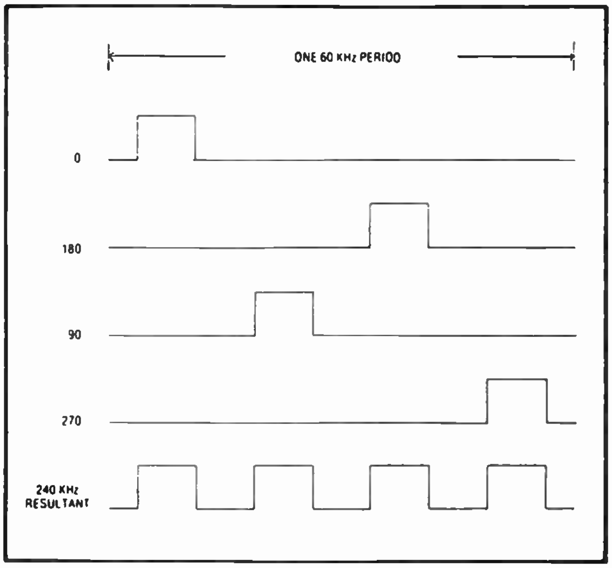

Figure 11. Effective 240 kHz sampling rate.

The system has many inherent advantages over conventional AM modulation systems:

1. It is solid-state and employs no separate modulation of the final RF amplifiers; i.e., the amplitude modulated wave is achieved directly digitally by selecting series-connected RF output modules.
2. Having no audio modulator, it is capable of high quality modulated wave characteristics with lower modulation noise, distortion, and transient modulation characteristics.
3. Being basically a digital system, it is capable of receiving digital audio input directly from any variety of digital audio sources.

The Harris DX system is shown in Fig. 15. The incoming analog signal is converted to digital code by conventional sample-and-hold and pulse-code-modulation (PCM) techniques and circuitry. The top six (most significant) bits of a twelve-bit analog-to-digital PCM system are converted into 64 equal steps. The top 22 steps are not used, leaving 42 equal steps which control 42 equal-output series RF amplifier modules. This is equivalent to keeping the lower 5.4 of the 6 top bits of the PCM digital code; i.e., $2^{5.4} \approx 42$. The bottom 6 (least significant) bits are then used to control six half-step RF amplifiers; i.e., amplifiers with outputs of ½, ¼, ⅛, 1/16, 1/32, and 1/64 of the major 42 equal step amplifiers. In effect, this creates a digital reconstruction of the analog input waveform of 2709 discrete steps; i.e., $(42 + 1) \times 63 = 2709$. This is roughly equivalent to a pulse-code-modulation system with a total resolution of 11.4 bits; i.e., $2^{11.4} \approx 2702$.

Such a PCM system[Panter13] yields a theoretical harmonic distortion value of approximately 0.03% and audio noise of less than −70 dB referred to 100% modulation. Typical measured values of total harmonic distortion (THD) are approximately 10 to 30 times this theoretical figure due to the practical difficulty in achieving balanced output contribution from all of the series output modules. However, even these levels of

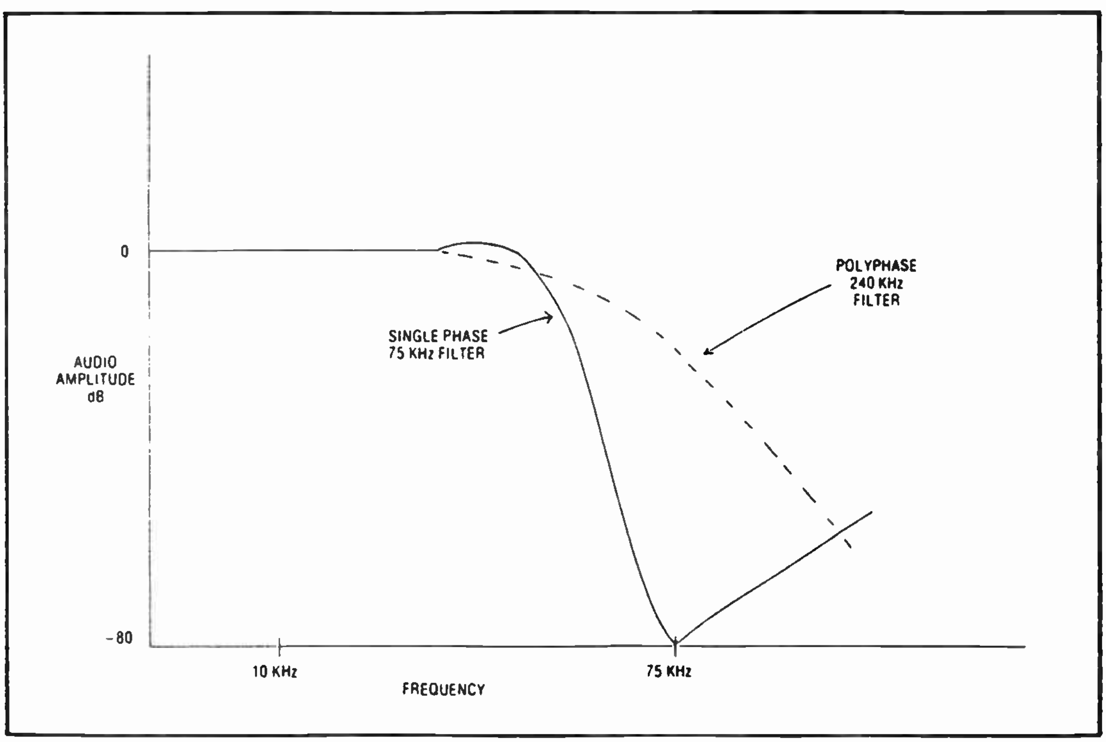

Figure 12. Comparative PDM filter responses.

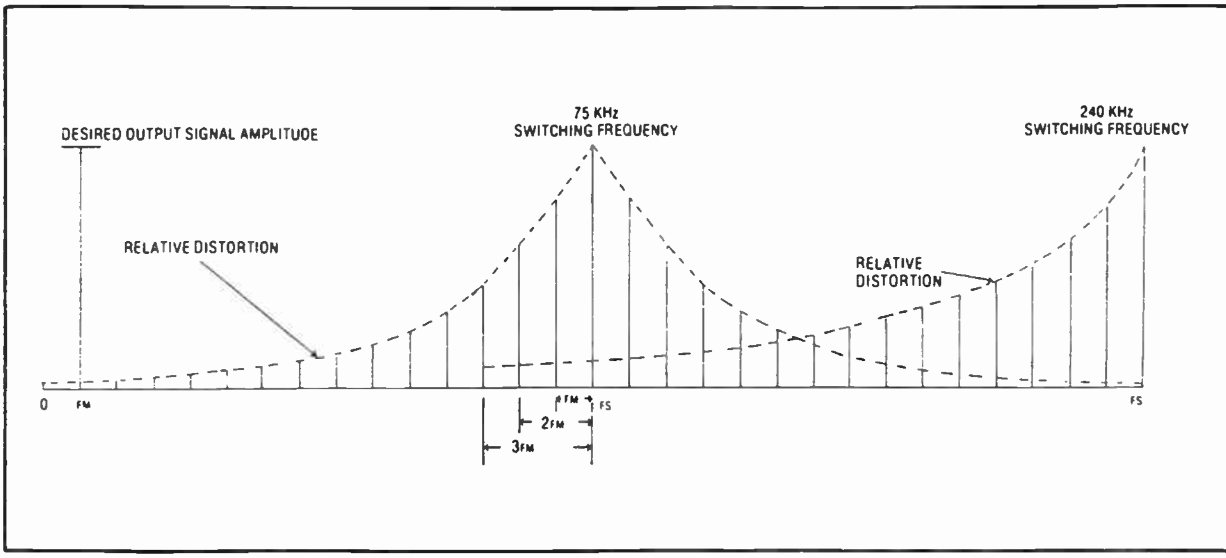

Figure 13. Switching modulator spectrum.

harmonic distortion (less than 1% maximum) are well below accepted norms for modern high-power AM broadcast transmitters. Typical values of measured audio noise are very close to the theoretical maximum of −70 dB referred to 100% tone modulation at full carrier power.

Each high-power amplifier module is a solid-state amplifier operating in the class-D mode, having approximately 95% power efficiency, including output circuit losses. Since there are no additional modulator losses (because the modulation process takes place in the RF circuitry itself, as described above) the auxiliary

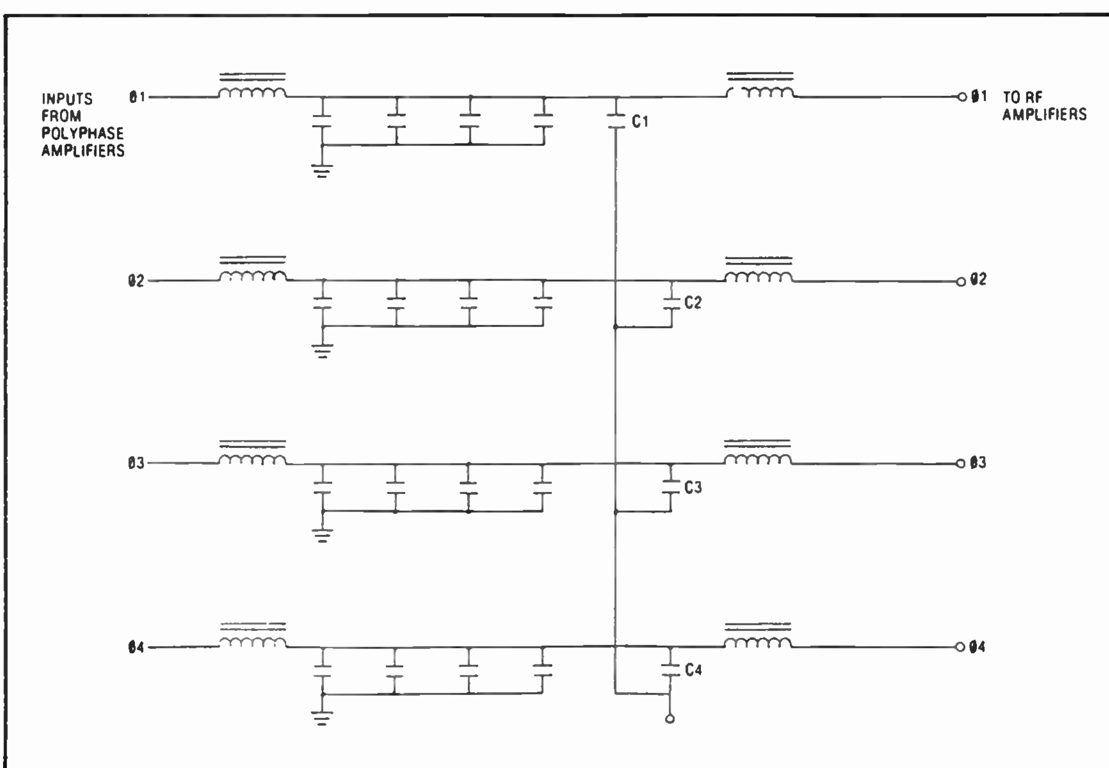

Figure 14. Polyphase PDM filter.

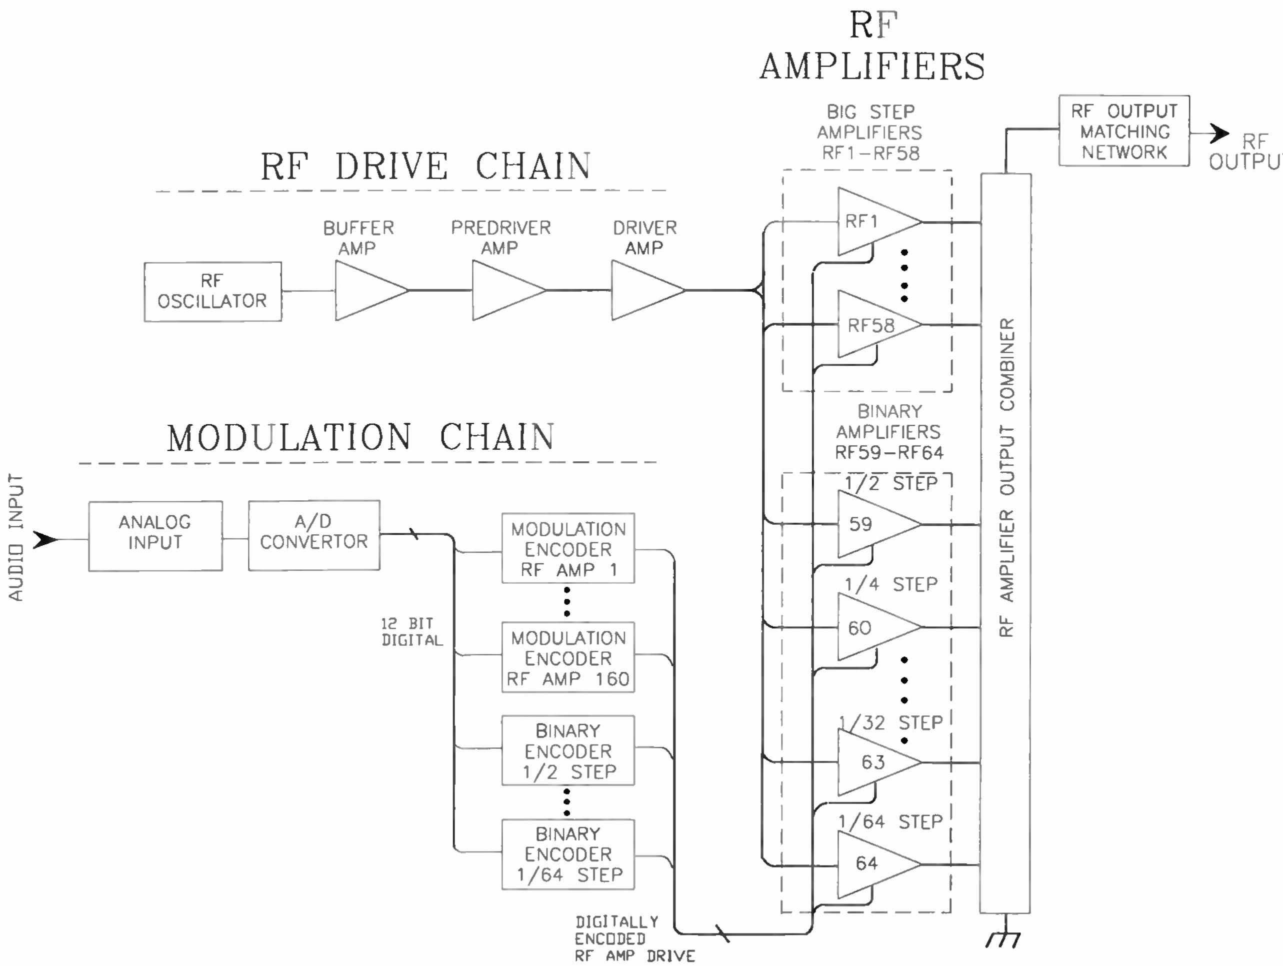

Figure 15. Harris DX system.

circuits for cooling, control, excitation, and drive represent the only other input power requirements. The total auxiliary input power of a 50 kW transmitter is approximately 5 kW. This means that the total input power of a 50 kW transmitter at carrier-only power (no modulation) is approximately: 50/0.95 + 5 = 57.63 kW, yielding an overall efficiency of approximately (50/57.63) x 100% = 86.76%. Harris Broadcast Division claims 87% or greater overall efficiency for all their DX series transmitters greater than 5 kW carrier power.

Kahn Power-Side System

"Power-side" refers to an asymmetric modulation system wherein the power in one sideband is three times that in the other, and the other sideband is reduced to maintain the maximum envelope modulation of +125%. All preemphasis is removed from the stronger sideband and concentrated in the weaker sideband. Since the strong sideband is free of preemphasis, listeners with continuously-tunable receivers or digitally-tuned radios with less than 3 kHz steps may *sideband tune*.

The advantages of sideband tuning is that, by tuning for the loudest signal, the listener may tune away from adjacent-channel interference. Also, the receiver's IF passband is centered more closely on the stronger sideband than on the carrier, increasing the apparent fidelity of the receiver. Furthermore, the proper tuning range for a power-side signal is less sensitive, allowing over five times the normal angular displacement of tuning. All types of receivers, including 10 kHz step digital receivers, should benefit from this asymmetry under adverse conditions such as selective fading, distorted antenna nulls, distortion from reradiation from buildings and power lines, and so-called *carrier-beat co-channel* interference.

TRANSMITTER CIRCUITRY

Detailed transmitter circuit design is as varied as the individual designers. There is, however, some basic circuitry common to all transmitter types and models will be briefly discussed in this section.

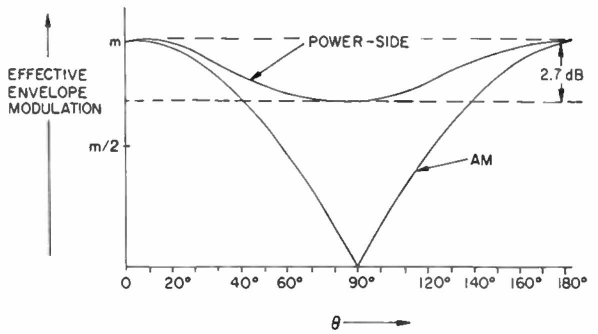

Figure 16. Envelope modulation of Kahn Power-Side compared to conventional AM.

Carrier Frequency Generator/Exciter

The stable frequency source for virtually all AM transmitters has been the quartz crystal oscillator. The quartz crystals used in older model transmitters were large cuts of natural quartz, vacuum-sealed in glass envelopes, similar to small-power vacuum tube envelopes, and occasionally mounted in temperature-controlled ovens to obtain the required FCC carrier frequency stability. In modern designs the quartz crystals are enclosed in small, hermetically sealed metal cans made popular and proven reliable by the military and commercial communications equipment industries. These lack special temperature controlled circuitry. Modern quartz crystal manufacturing technology and solid-state oscillator designs allow these types of small metal-sealed units to maintain adequately the FCC's current requirement of ±20 Hz carrier frequency tolerance. Stability of the quartz oscillator circuits is normally adequate over the full lifetime of the equipment. Should frequency adjustment ever be required to bring a unit back inside the FCC limits, mechanically stable adjustment components, usually a glass or ceramic piston-type of capacitor, are provided for use by a qualified station engineer using calibrated frequency measuring equipment. (FCC Rules Sections 73.1540 and 73.1545.)

Exciters for all proposed AM-stereo systems provide the carrier frequency excitation for the transmitter as well as the stereo generating circuitry. Some manufacturers of AM-stereo exciters generate the desired carrier signal with frequency synthesizer techniques. This method is generally equal to or better than the discrete quartz oscillator method with regard to frequency tolerance, but can produce higher phase modulation noise if the circuits are improperly designed or adjusted.

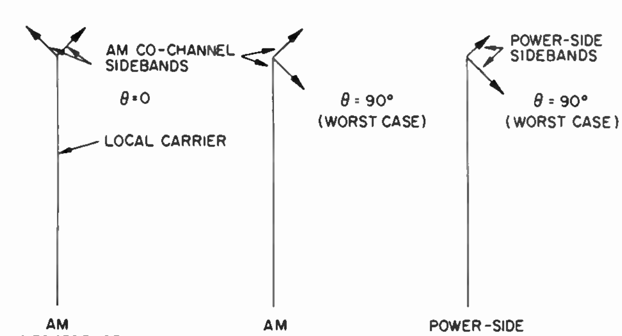

Figure 17. Interference phase relations of Kahn Power-Side and conventional AM.

RF Power Amplifiers

As discussed in earlier sections, all modern AM broadcast transmitters using power-grid vacuum tube final RF amplifiers employ class-C amplification. Some employ designs using third and fifth harmonic trap circuitry yielding quasi-class-D operation for improved efficiency. All solid-state transmitters currently available in the North American Market use class-D RF final power amplification.

RF Output Networks

The purpose of the RF output network is to match the impedance of the load (the common-point impedance of one or more antenna matching and combining networks) to the impedance required by the final RF power amplifier tube(s) or transistor(s) in order to produce the desired carrier and sideband power. The output network circuit is also designed to provide the attenuation characteristics necessary to meet FCC requirements for spurious and harmonic output. There are many techniques to accomplish these basic tasks. One simple and effective method is shown in Fig. 18. The terminating load impedance for the network shown in Fig. 18 is defined by the Smith chart representation of Fig. 19, which is a typical common point impedance characteristic of a multi-tower AM broadcast directional antenna array.

Fig. 20 shows the impedance-versus-frequency characteristics at the input of the network (at the anode of the final RF amplifier tube). The shape of the impedance curve in Fig. 20 differs significantly from the shape of the terminating impedance curve shown in Fig. 19 due to the narrowing of bandwidth caused by the output matching network. The voltage standing wave ratio (VSWR) (normalized to the resistive carrier impedance) at ±10 kHz is about 1.2 in both Figs. 19 and 20, but at ±50 kHz the VSWR at the input to the network has increased from about 2.4 to approximately 3.0. The shape of the impedance-versus-frequency curve at the anode(s) of the RF output amplifier tube(s) or transistor collector(s) greatly affects the high audio frequency performance characteristics of the transmitter, such as frequency response and harmonic distortion.[14] The shape of the impedance versus frequency curve should be symmetrical about the resistive axis of the Smith Chart and should yield lowest practical VSWR values at the highest expected fundamental sideband frequencies.

Fig. 21 shows the result of an attempt to lessen the magnitude of the mismatch at the input to the matching network by the addition of the dotted components

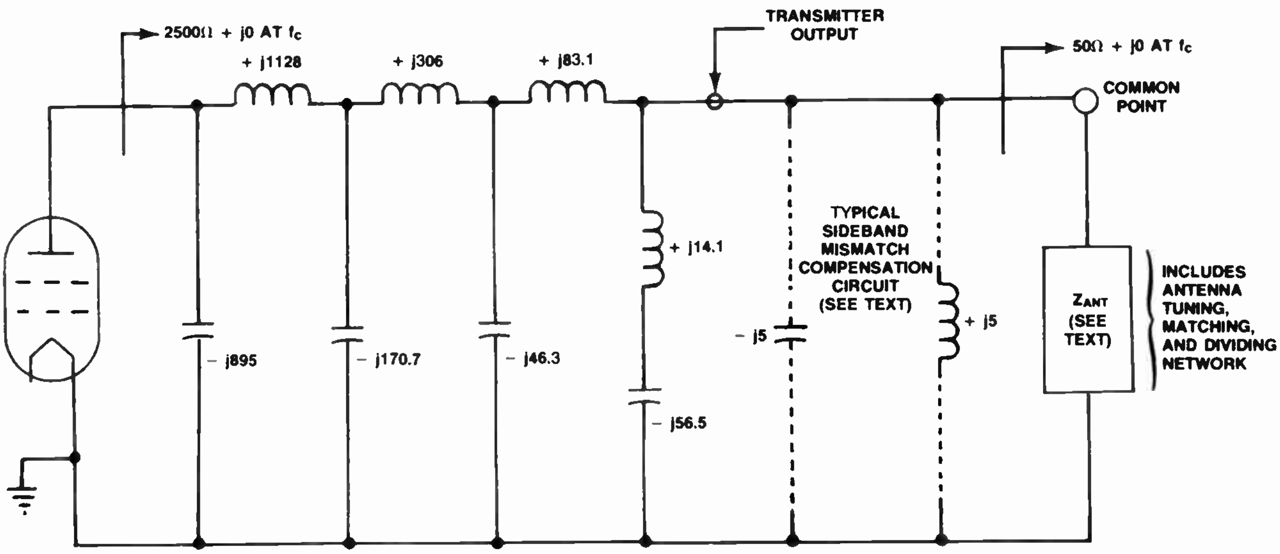

Figure 18. Typical output matching network yielding 80 dB or better harmonic attenuation and a compensated symmetrical sideband load at the anode(s) of the RF output amplifier.

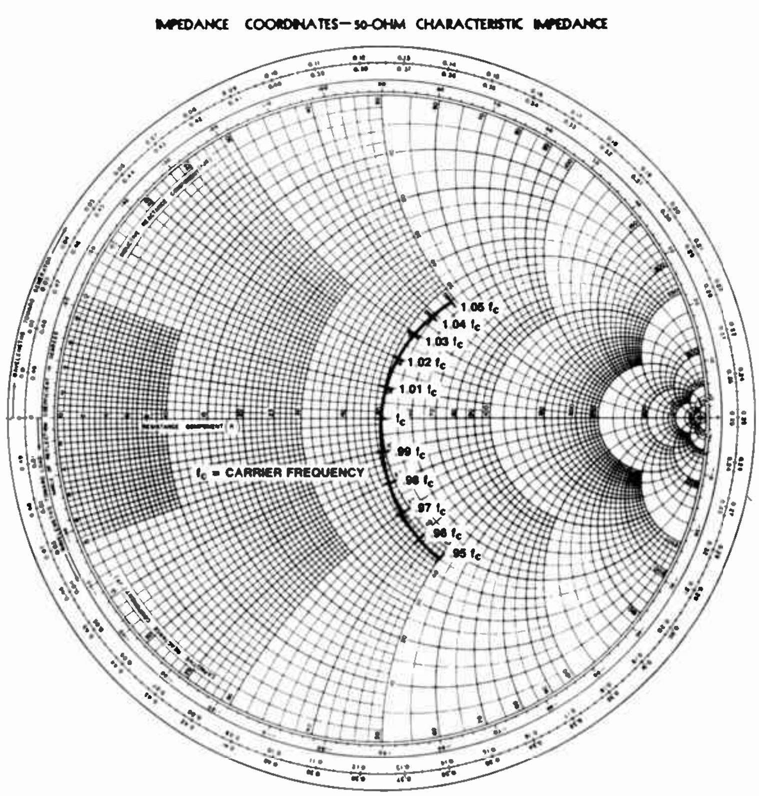

Figure 19. Typical impedance versus frequency characteristic of antenna common point.

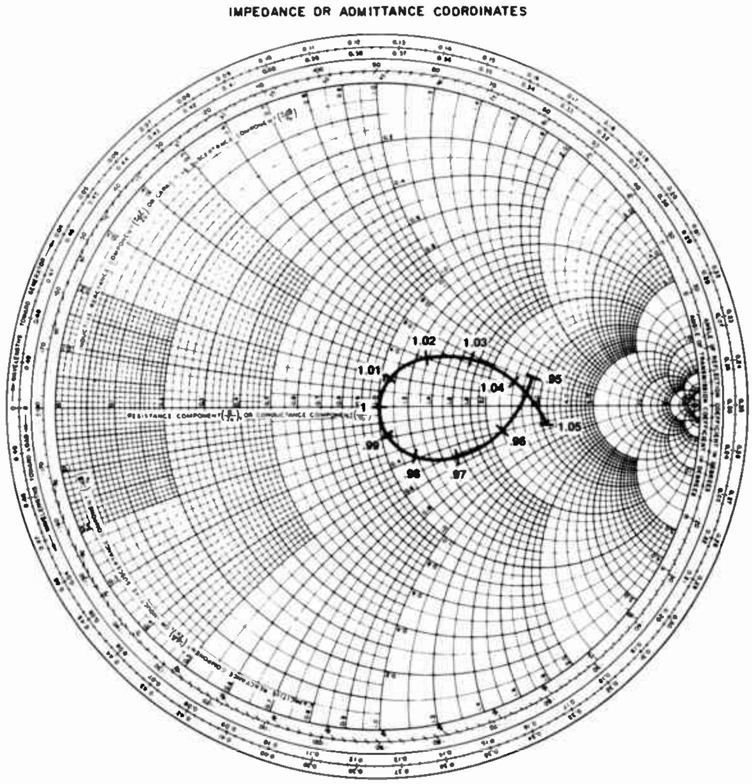

Figure 20. Impedance versus frequency characteristic at anode of final RF power amplifier.

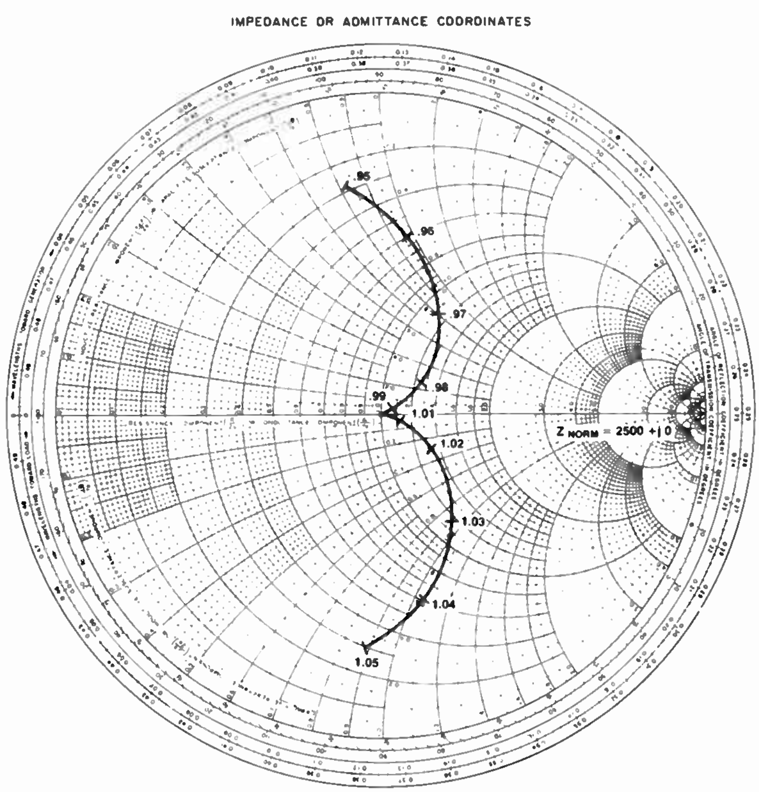

Figure 21. Impedance versus frequency characteristic at output anode with sideband mismatch corrective network added.

shown in Fig. 18. The result is a significant reduction in tube anode load mismatch at sideband frequencies of ±10 kHz; from about 1.2 VSWR in Fig. 20 to approximately 1.1 VSWR in Fig. 21. The reduction of mismatch at ±10 kHz, however, comes at the expense of an increasing mismatch at sideband frequencies greater than ±30 kHz. The increasing mismatch at higher sideband frequencies is normally not a problem and often tends to improve transmitter harmonic distortion performance, acting as an output bandpass filter to higher-order harmonics. There is, theoretically, no limit to the amount of sideband mismatch correction that can be achieved with more complex network circuitry.

The most important criterion is symmetry about the Smith Chart resistive axis. Station engineers or their engineering consultants should work with the transmitter manufacturers and antenna system designers to determine and achieve the desired impedance-versus-frequency curve at the output RF amplifier tubes anode connection. The example given above for load sideband mismatch correction is for illustrative purposes only. It is quite common for the complex impedance at the sideband frequencies to present a more severe mismatch at the antenna common point than that shown in Fig. 19. More severe mismatch and impedance asymmetry requires more complex sideband-mismatch corrective networking.

Transmitter Control and Monitoring

AM broadcast transmitter control circuitry is normally very basic and uncomplicated. It is now common to find transmitter control performed with discrete digital IC logic circuitry instead of simple relay control logic. Some manufacturers are incorporating microprocessor technology in their latest equipment designs to replace discrete digital logic circuitry. The aim of manufacturers is normally to provide the operating engineers and technicians with the most basic, reliable, and easy-to-maintain and troubleshoot transmitter possible. Experience has shown that well-designed relay control logic, discrete digital IC logic, and microprocessor-based logic are all about equal in terms of reliability and ability to perform the required transmitter control functions.

Future microprocessor-based transmitter control logic promises: (1) to provide self- and remote-assisted diagnostics of transmitter problems and remote interrogation of transmitter operating parameters; (2) to alter the basic characteristics of a transmitter control system through software control; and (3) to allow the basic transmitter design to be more easily customized to individual users' operating requirements. Because of the high voltage and high current faults that can exist in any high-power transmitter component, extra care must be taken by designers and manufacturers to prevent the potential destructive energy in these faults from affecting the performance and operation of the relatively delicate solid-state control logic circuitry.

High speed vacuum contactors and solid-state regulator/controllers are used in modern designs to control the high voltages and currents encountered in all levels of high power AM transmitters, which previously had been controlled by slower, though equally reliable, air-magnetic contactors and relays.

Remote control systems are commercially available that will allow remote control into almost any transmitter, old or new. These systems, like the basic transmitter control system, use relay, discrete digital IC, microprocessor-based logic circuitry, or combinations of these, depending on the manufacturer of the control equipment and the complexity of the remote control functions desired. Many transmitter equipment manufacturers also provide limited built-in remote control functions and circuitry for their products.

The FCC requires manufacturers of AM broadcast transmitters to provide certain basic monitoring functions for proof of performance parameters. These requirements are contained in the FCC Rules Section 73.1215.

High-Voltage Power Supplies

High-voltage power supplies in AM broadcast transmitters must provide acceptable performance in two basic areas: (1) power supply ripple, which affects transmitter hum and noise output, and (2) dynamic regulation, which affects low frequency modulation transient response. It is typical for transmitters of five kilowatts carrier power and lower to operate from single-phase ac power sources, usually 240 volts in North America. Transmitters with carrier power ratings of 10 kW operate with single-phase or three-phase power source, depending upon the manufacturer of the transmitter. Transmitters with carrier power ratings of greater than 10 kW operate only from three-phase power source, usually 480 volts for power levels up to 100 kW and 4,160 volts or 11,000 volts in North America for higher carrier power levels.

Three-phase power has the advantage of being easier to filter and usually provides better dynamic regulation of critical modulator voltages than single-phase supplies. Single-phase power is more readily available, which is the only reason why it is used at the lower transmitter power levels, because installation cost would be disproportionately increased were three-phase power required. Single-phase rectifier power supply systems generally require inductance-capacitance (L/C) filtering to provide low ripple output for low transmitter hum and noise specifications. However, L/C filtering creates power supply resonances in the audible to sub-audible range of modulating frequencies and therefore is a source of poor dynamic power supply regulation when the modulator circuitry is excited by vowel sounds or musical percussion sounds. It has been common since about 1970 for higher-power transmitters to use special high voltage supply transformers to generate a six-phase ac supply from the basic three-phase power source. The six-phase supply, when full wave rectified, yields a 12 pulse rectified dc waveform that has both lower ripple content and a higher ripple frequency than conventional three-phase full wave rectification. As a result, the output of the rectifier can be sufficiently filtered with no additional filter inductors, thus improving low audio modulating frequency dynamic power supply regulation and hence, low frequency transient distortion.

TRANSMITTER PERFORMANCE MEASUREMENTS

AM transmitter performance parameters should be measured on a periodic basis in order to assure that certain minimum broadcast quality standards are provided to the listening public. Excluding the performance standards for AM stereo, these are listed below. Some are specifically required by the FCC Rules, while others are merely a matter of good engineering practice.

- Operating power [Section 73.51]
- Carrier output power delivered to the antenna system [Section 73.54]
- Modulation capability
- Total audio frequency distortion
- System frequency response
- Carrier-amplitude regulation (carrier shift)
- Hum and noise output level
- Carrier frequency tolerance [Section 73.1545(a)]

All audio measurements should be made from a demodulated voltage or current sample at the antenna system common point.

Output power measurement (the measurement of transmitter power output by the direct method described in Sections 73.51 and 73.1215) is subject to more than 13% error if the measurement inaccuracies allowed by the FCC are taken to the limit. For example, assume that a common point impedance of 50 ohms resistive can be measured to within 2% accuracy with a RF impedance bridge (a realistic tolerance). Further, assume a direct-reading RF ammeter having a full scale reading of 100 amperes and an FCC allowed tolerance of ±2% of full scale is used and indicates 33.33 amperes of common point current, just meeting the minimum FCC accuracy and indication requirements in Sections 73.1215(b)(2) and (3). Under these conditions, the actual power delivered to the antenna is between the limits of (35.33 × 35.33 × 51) = 63.65 kW, as a maximum, and (31.33 × 31.33 × 49) = 48.10 kW, as a minimum; yielding a total measurement error of approximately +14, −13%. Using an RF ammeter with a 50 ampere full scale reading, the same FCC allowed inaccuracies, and the same meter indications as above, would result in power output measurement errors of approximately ±8%.

FACTORY TESTS

When buying an AM broadcast transmitter it is advisable to ask manufactures for specific, detailed test and performance data at the start of the investigation. Before a final decision is made, detailed tests should be made at the manufacturers factory under strict control of an experienced engineer or engineering consultant. Most manufacturers of AM broadcast equipment welcome this kind of intelligent approach. Hints on what kind of tests and a discussion on the details of each test are given below.

Audio Frequency Response

AM transmitter frequency response characteristics, referred to a reference frequency of either 400 Hz or 1,000 Hz, typically is well within ±1 dB from 50 to 10,000 Hz at any depth of modulation, exclusive of antenna system characteristics which can and often does have a deleterious effect on many audio performance characteristics. Practically all mass production AM receivers made in any country have (IF) intermediate frequency and audio amplifier bandpass characteristics that limit receiver −3 dB high-end audio frequency response to between approximately 2500 Hz and 5000 Hz, with 2500 Hz the more common of the two figures. Typical low end −3 dB frequency response of consumer AM radios is between 100 Hz and 300 Hz, with approximately 200 Hz a common value.

Audio Harmonic and Intermodulation Distortion

AM broadcast transmitters typically produce less than 2% total harmonic distortion (THD), up to 90% modulation at any frequency of modulation between 50 Hz and 10,000 Hz for monophonic transmission. Most of the modern all solid-state digital systems produces typical audio distortion of less than 1% THD.

Intermodulation distortion (IMD) has been known for years and has been documented in technical audio journals to be more disturbing than harmonic distortion, though both are important. The CCIR method of IMD measurement is preferred for radio broadcast transmitters. With this method, two equal audio tones separated by 170 Hz are fed to the transmitter, and the peak modulation level is adjusted to between 85 and 95% modulation. The level of odd and even-order products are measured using an audio-wave or spectrum analyzer connected to the test output terminals of a high quality modulation monitor.

Two IMD measurements should be taken, one with the two tones near mid-audio band (for example 400 Hz and 570 Hz) and one with the two tones near the upper audio end (for example 7,000 Hz and 7,170 Hz). High quality broadcast transmitters should produce IMD products more than 30 dB below the level of either of the two modulating tones. The RSS value of all IM products, relative to the level of either modulating tone, should also be less than 7% at 90% peak modulation levels.

Residual AM Hum and Noise

AM noise of 60 dB below the 400 Hz/100% modulation level can be achieved by most current production AM broadcast transmitters. The bandwidth of noise measuring equipment should be 20 kHz. Typical modulation monitor demodulated audio bandwidth is approximately 25 kHz to accommodate FCC bandwidth requirements.

Residual PM Hum and Noise

Residual phase modulation (PM) noise is normally not a problem for modern AM broadcast transmitters designed for monophonic broadcasting. Quartz crystal oscillator circuits and even moderately-careful RF component mechanical designs produce quite acceptable phase noise characteristics. However, for AM-stereo applications, where a frequency synthesizer may be used for RF signal generation, is it wise to test the purity of the synthesizer circuitry. Excessive residual PM noise can convert to AM noise over certain nighttime propagation paths and appear to distant listeners as objectionable AM hum and noise.

An acceptable value of PM noise is −25 dB RMS relative to one radian peak, measured in a 15 kHz bandwidth, for monophonic, medium wave band AM transmission. Transmitters with quartz crystal oscillator exciters typically exceed this recommendation by 25 dB or more. Transmitters used for international short wave broadcasting (4 MHz to 26 MHz) require PM noise levels of approximately −45 dB relative to a one radian peak because of more severe sky wave PM to AM conversion at higher frequencies.

Incidental Phase Modulation (IPM)

Like residual PM, IPM is more important in stations using or planning to use AM stereo transmission. IPM is defined as the peak phase deviation of the carrier frequency (in radians) resulting from amplitude modulation. IPM values of several radians were common in the very early days of broadcasting. Typical values of IPM for modern transmitters that have not been specifically designed or adjusted to minimize IPM range from about 0.1 to 0.5 radians peak (approximately 6° to 30°). A maximum acceptable value of IPM required for present or future AM stereo operation is generally considered to be approximately 0.03 peak radians with a desired value of better than 0.012 peak radians. State-of-the-art modulation meters such as the Hewlett Packard model HP-8901B and other similar instruments are preferred for accurate PM and IPM

Carrier Amplitude Regulation (Carrier Shift)

Carrier-level shift in a given transmitter has more importance to overall transmitter performance than many broadcast engineers realize. Large values of negative carrier shift can have as much effect on effective transmitted sideband power as poor transient overshoot distortion. The term carrier shift may be somewhat confusing, especially to newcomers in radio broadcasting who often equate the terminology with frequency shift instead of level or amplitude shift; hence, the new terminology of carrier amplitude regulation. The CCIR refers to the same characteristic as carrier-level shift, which appeals to many engineers because of its closer adherence to the original terminology, but without the ambiguities. Carrier-level shift is the effective shift in apparent carrier-level due to the amplitude modulation process.

Carrier-level shift can be caused either by poor power supply regulation or by modulation even-order harmonic distortion (which generates a dc offset component in the modulated RF envelope) or by both. Carrier-level shift can be either positive or negative, although it is usually negative. This is because power supply regulation is most often the major source of carrier-level shift and power supply regulation is most generally negative in sign (lower voltage output at higher current loads). Poor power supply regulation is not always caused by the transmitter power circuitry; it can also be, and often is, caused by poor supply-line voltage regulation or, more generally, a combination of the two.

Another common misconception regarding carrier-level shift is that the defined level shift is direct shift in carrier power. Actually, carrier-level shift is defined as the shift in effective carrier *voltage or current* due to modulation. This means that a carrier-level shift of −5% is equivalent to a carrier power shift of approximately −10% i.e.,

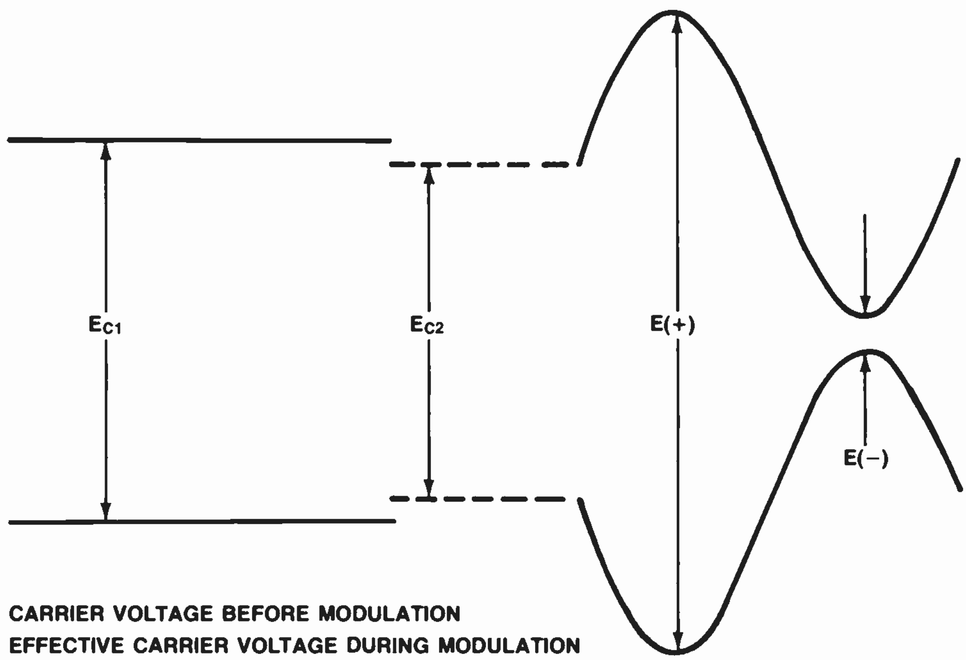
$$P_{carrier\,(mod)} = \text{Pcarrier} \times (1 - 0.05)^2$$
$$= 0.9025 \times \text{Pcarrier}$$

Transmitters having no carrier-level shift produce an average output power of 1.5 times the carrier power level with 100% sinusoidal tone modulation. Transmitters that exhibit 5% carrier level shift produce an average output power only 1.35 times the carrier level at the same conditions of symmetrical sinusoidal tone modulation. A broadcast station engineer or engineering consultant should completely understand these and other equally important transmitter characteristics in order to make an intelligent buying decision based upon measurable and proven technical merit. Fig. 22 gives a graphical representation of carrier-level shift.

Audio Phase Linearity

Proper attention is given to phase linearity by most station engineers and engineering consultants. Station managers and engineers are usually concerned about the "sound" of their stations. Loudness, or perceived loudness, is a common criteria of quality in many stations with diverse programming formats. However, it is not uncommon for station engineers to spend more time researching the merits of program processing equipment than the one characteristic in their transmitter purchase that could partially neutralize any advantage from a program processor. That characteristic is audio phase linearity.

Audio phase nonlinearity and its major detrimental result, transient overshoot have been discussed in previous sections of this chapter. Modern programming philosophy and program processors have made trans-



E_{C1} = CARRIER VOLTAGE BEFORE MODULATION
E_{C2} = EFFECTIVE CARRIER VOLTAGE DURING MODULATION

$$\text{CARRIER LEVEL SHIFT (CS)} = \frac{\dfrac{E(+) + E(-)}{2}}{E_{C1}}$$

$$\text{\% MODULATION} = \frac{E(+) - E(-)}{E(+) + E(-)} \times 100$$

Figure 22. Graphical representation of carrier level shift and formulas for calculation of carrier level shift and % modulation.

mitter audio phase linearity characteristics an important performance criteria.

In the late 1960s, the FCC authorized 125% positive program modulation, allowing AM transmissions to accommodate certain naturally-occurring asymmetries in voice and music, thus achieving a gain of 2 dB of real loudness or actual program side-band power (20 log(1.25) = 2 dB). As stated earlier, some AM broadcast transmitters in present use exhibit as much as 12% overshoot of a square wave input due to phase nonlinearity. This has the effect of taking away one of those two dB (20 log(1/1.12) = −1 dB).

A simple way to determine the effects of phase nonlinearity is to require the transmitter manufacturer to demonstrate rectangular-wave modulation characteristics of the transmitter. When such a test is performed, the overshoot will be directly visible and measurable on the oscillographic display of the output envelope. The station engineer should also investigate the effects that antenna system phase nonlinearity may have on the total system transmission transient characteristics.

Occupied Bandwidth

Occupied bandwidth of an AM broadcast transmitter can best be measured with a band-limited, colored Gaussian noise source (similar to pink noise used in certain acoustical tests) to provide a continuous wideband modulating signal. Pink noise has equal energy-bandwidth ratio (equal energy per octave, per third octave, per tenth octave, etc.). White noise has equal energy per bandwidth (equal energy per Hz). Both noise signals can have a gaussian or pseudo-gaussian probability density function which closely resembles that of voice and music. Fig. 23 shows a block diagram of the test procedure. The reader is also referred to CCIR recommendation 559–1 (Vol X, Part 1, Geneva, 1982).

The measurement of occupied bandwidth is a dynamic test which effectively summarizes two important transmitter static parameters, audio nonlinear distortions (which are the source of IMD and THD) and incidental phase modulation (IPM).

Harmonic and Spurious Output

Harmonic and spurious output of an AM broadcast transmitter or transmission system can only be measured effectively in two ways:

1. Use a sample of the transmitter RF output when operating into a dummy load with a known or accurately-measurable impedance characteristic

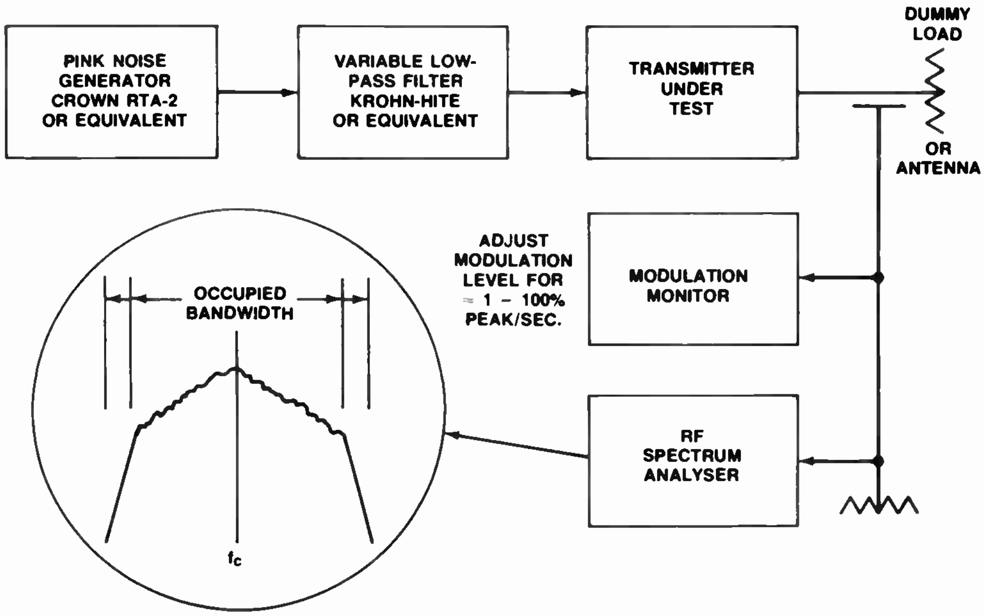


Figure 23. Block diagram test procedure for determining transmitter occupied bandwidth.

out to approximately the tenth RF harmonic. Then, with a calibrated measuring system, take measurements and compute the output power of each harmonic according to the formula:

$$P_n = V_n^2 \times R_{pn} \qquad [8]$$

where:

P_n = The power at the nth harmonic
V_n = The corrected measured voltage of the nth harmonic at the calibrated impedance point
R_{pn} = The parallel resistive component of the load impedance at the nth harmonic

2. Measure the actual power radiated from the antenna system at each harmonic frequency or suspected spurious output frequency using standard field intensity measurement techniques. This is the most meaningful of the two techniques because the measurement is made under actual conditions of operation with all systems interconnected. It is the transmitter manufacturer's and user's joint responsibility to correct any actual interference problems to other broadcast or nonbroadcast communication services, even when the interfering signal meets the standard FCC requirements (FCC Rules Section 73.44.c).

Carrier Output Power

The most accurate method of measuring the RF output power of a transmitter is by the calorimetric method, which uses the very accurately known and measurable physical and thermal characteristics of water or other liquids. This measurement is usually done only in a transmitter manufacturer's factory because the capital investment required to purchase and maintain calibration of this kind of infrequently-used equipment is usually not justified for AM broadcasting operations.

Water is known to have a thermal capacity very close to 4.186 Joules per degree C per gram weight at a mean temperature of 60°C. A Joule is equal to one watt-second. Therefore, the capacity of water to absorb power is 69.8 watts per degree C per liter of water flow per minute, or

Power (kW) = Flow (lpm) × DT°C × 0.0698 for water flow measured in liters per minute (lpm)

OR

Power (kW) = Flow (gpm) × DT°C × 0.2641 for water flow measure in U.S. gallons per minute (gpm)

The flow of water can be measured with an accuracy of approximately ±1%, by even the most common methods. Differential temperature measurement accuracy of approximately ±0.1°C is commonly practical, which, for temperature differentials of 20°C, is equivalent to ±0.5% accuracy. Using calorimetric measurement techniques, the output power of AM transmitters can be measured with total accuracies better than ±2%. The RF output amplifier efficiency factor F (referred to in the FCC Rules Section 73.51(e)(1) can then be determined for future operating and proof-of-performance reference. However, even with this method of determining the factor F, an accuracy of less than ±2% cannot be maintained over the life of the equipment. FCC-required transmitter voltage and current meters have a ±2% accuracy, in addition to the multiplied power accuracy of approximately ±4%. When accuracy levels are combined, this yields a total uncertainty of ±6% for the factor F. Still, this is considerably better than the accuracies obtainable by the direct measurement technique.

Operating Efficiency and Input Power

Measurement of transmitter input power should be done under actual or simulated operating conditions. This requires program or simulated program modulation during the power input measurement. The preferred method of measuring ac input power uses a standard rotating-disk watt-hour meter. The accuracy of these familiar meters is typically better than 0.5%, better than four times the accuracy of any other conventional direct ac power measurement technique, and they can be obtained with accuracies better than 0.1%. The watt-hour metering system should be connected in the main power feed line to the transmitter.

Sinusoidal test signals, useful for other tests of transmitter performance, are not recommended for power consumption tests because of the distinctly opposite statistical characteristics of sinusoidal signals and typical voice and music program material and the effect this difference has on actual operating power consumption measurements. This difference between periodic sinusoidal signals and mathematically random types of signals such as human voice and/or music has been known for decades. The effect this difference produces in AM broadcast transmitter power consumption and operating efficiency measurements, however, was first documented in 1980, by investigators in Europe[15] and was later verified and further explained by investigators in the U.S.[16,17] and other countries.

The critical difference between sinusoidal signals and typical program types of signals is explained in Fig. 24, which shows the amplitude-density characteristics of a sinusoidal waveform (U-shaped curve) and an amplitude density characteristic of typical broadcast program modulation (pyramid curve). The totally different shapes of the two curves in Fig. 24 cause the measured transmitter efficiency at identical RMS modulation levels to be quite different. The pyramid shaped curve in Fig. 24 was generated in 1984 from measurements taken off the air of five differently-formatted FM radio stations located in Dallas, Texas. Data was taken continuously for 24 hours for each station and averaged for presentation as shown in Fig. 24. FM stations were used because of their consistent day/night signal levels, symmetrical modulation characteristics (for easier comparison to the sine wave), and omni-directional emission pattern. Some transmitters,

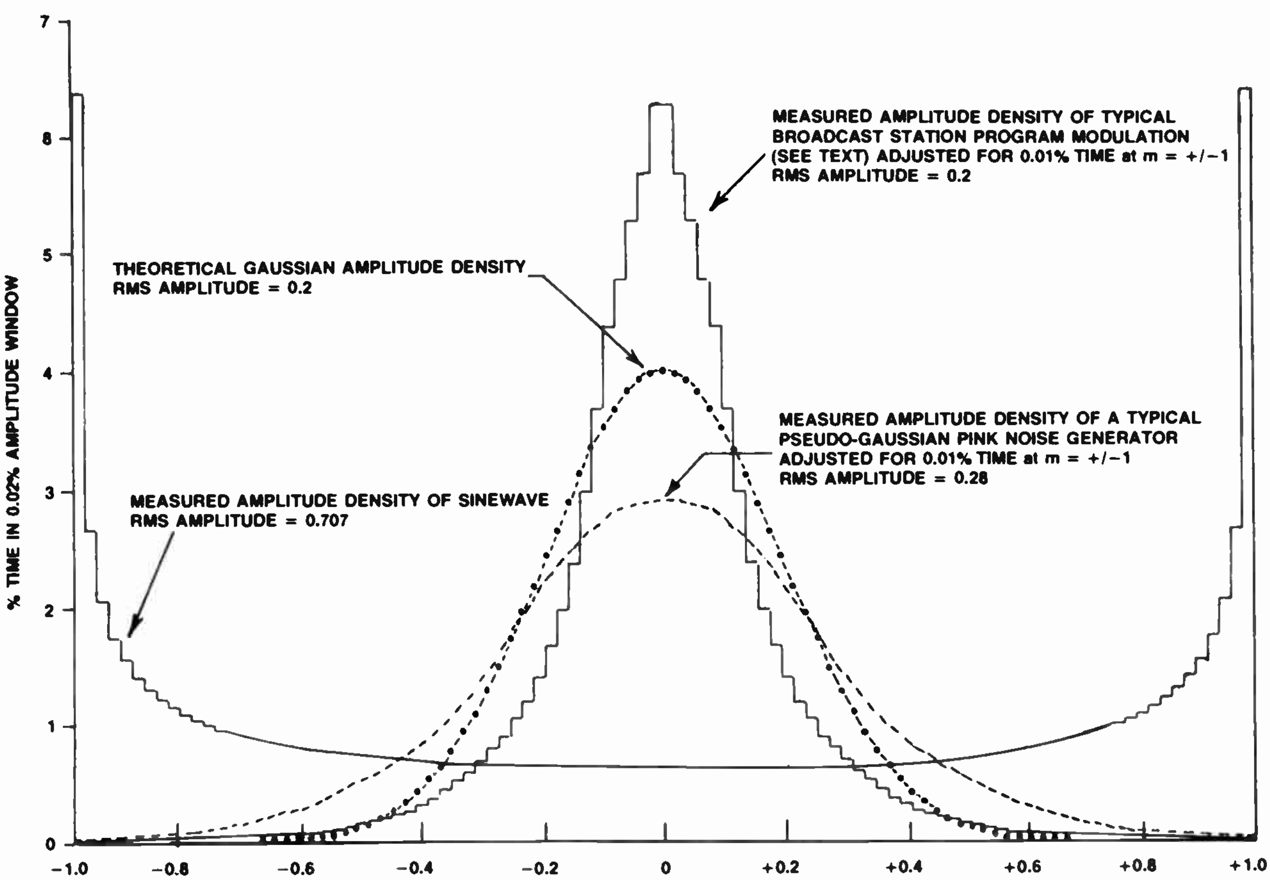

Figure 24. Amplitude density of sinusoidal test signals and typical program or noise test signals. Program or noise test signals recommended for transmitter efficiency measurements (see text).

or, more correctly, modulation systems, are more efficient with program modulation than with equivalent RMS sinusoidal test signals while others have poorer efficiency with program modulation.

Modulation systems or techniques that yield higher carrier efficiencies also yield higher program efficiencies (lower program power consumption than with an equivalent RMS sinusoidal modulation test signal). It is obvious that the program input power consumption test is the one most meaningful to broadcasters who broadcast programs, rather than sinusoidal tones. In this discussion, the terms "program efficiency" and "program input power consumption" have generally been given equal value. It is correct to equate these parameters for transmitter comparisons if it is assumed or defined that average transmitter output power is constant for a defined program input. Such an assumption is correct, except that transmitters with excessive transient overshoot will have correspondingly less average modulated RF power output for given peak levels of processed program modulation.

Experimental methods have been devised to measure average long-term transmitter output power (RF kilowatt-hour output).[18] With such equipment it would be convenient to compute accurately actual program efficiency knowing both kilowatt-hours input and kilowatt-hours output. Until such equipment becomes commercially available, however, only the transmitter-energy input can be measured accurately with single-phase and multi-phase kilowatt-hour instruments.

Fig. 24 also shows a third curve (dashed curve) which is the amplitude density function of a popular pink noise generator. It is recommended that either a pink noise signal with amplitude density characteristics similar to the curve in Fig. 24 or a recording of actual program modulation be used as a program source for these tests. Program processing equipment, if used, and peak modulation levels should be adjusted to normal station operating procedures. Transmitter input power measurements are then taken during a 30 minute (minimum) segment of the program material. Refer to FCC Rules Section 73.1570(a) and (b) for modulation setup procedures.

The average input power determined by this method will be very close to the transmitter power consumption of the transmitter during its operating life and therefore can be used to predict accurately actual operating energy costs. This is the only method that will provide accurate energy consumption forecasts.

IMPORTANT AM-STEREO TRANSMITTER CHARACTERISTICS

Incidental Phase Modulation

Some AM-stereo systems use a form of phase modulation for encoding the stereo signal on the AM carrier. For this reason, the most important transmitter characteristic affecting AM-stereo operation is incidental phase modulation (IPM), which has been discussed previously. Excessive IPM can affect stereo separation, monophonic distortion, and the occupied bandwidth of a stereo transmission; with the most significant of the three being monophonic distortion.

There are many potential sources, but the most common is incorrect neutralization of either a final modulated RF amplifier or a lower-power driver stage. The solution is, of course, better neutralization of the offending amplifier. This is easier said than done in most cases. Since the inception of AM-stereo broadcasting, manufacturers of transmitters have paid more attention to IPM and in most cases have reduced it to acceptable levels for AM-stereo operation.

For especially difficult problems, field engineers from the factory must make special on-site adjustment of transmitters which are particularly susceptible to excessive IPM. Several engineering consulting firms have developed special knowledge in the AM-stereo field and have collected data on many transmitters in current use (some of which have been out of production for several years). Such a firm should be contacted to solve particularly difficult neutralization problems.

Phase Noise

Residual phase-modulated noise cannot normally be detected by a standard AM broadcast receiver employing envelope detection, but stereophonic AM receivers are sensitive to PM noise. PM to AM conversion can occur on the medium wave band over multi-ionospheric "hops" (nighttime skywave propagation) and can then be detected by receivers employing standard envelope detection.

Phase-modulated noise in modern transmitters is virtually nonexistent due to the use of high-quality quartz crystal oscillator and synthesizer circuitry. Phase noise modulation of 0.6° (0.01 radians) average is fully acceptable for monophonic AM broadcasting. Phase noise modulation of approximately 0.2° (0.0032 radians) average is usually considered acceptable for AM stereophonic broadcasting. As with measurements of IPM, an HP-8901, (or equivalent), *modulation analyzer* is recommended for phase noise modulation measurements.

Stereophonic Phase/Gain Equalization

Standard production exciters for AM stereo systems may incorporate circuitry designed to match approximately the phase and gain characteristics of the normal monophonic transmitter transmission path to the transmission path for the encoded stereo signal. Transmitters which have excessive in-band nonlinear phase characteristics may require special "out-boarded" phase/gain equalization networks to achieve optimum stereo performance.

INTERNATIONAL SHORTWAVE BROADCAST TRANSMITTERS

Shortwave Transmitters

Shortwave broadcast transmitters are similar in many respects to medium wave transmitters and very different in others. The similarities are in methods of modulation, control, and monitoring. The differences are, generally, that shortwave transmitters are higher in power, more complex in tuning, and are more difficult to operate and maintain than medium wave "standard" broadcast transmitters. Although there are numerous exceptions, the general rule is that the minimum usable carrier power level on shortwave is 50 kW, and the maximum economical carrier power level from a single transmitter is 250 kW to 500 kW.

It is not unusual for a shortwave transmitter to operate on five to ten separate frequencies in one broadcast day. Schedules of the prestigious broadcasting organizations are very tight, necessitating built-in automatic frequency-changing circuitry which allows the transmitter to tune to several programmed frequencies in 10 to 30 seconds, with minimum operator intervention. The trend in shortwave transmitter operation is toward unattended or minimum attended sites, with program and frequency changes done either by remote or computer control or by both.

Single-Sideband Operation on the International Shortwave Bands

The International Telecommunications Union (ITU) and its radio broadcasting special committee, the International Radio Consultative Committee (CCIR) encourage the adoption of a form of single-sideband (SSB) as the standard modulation system for international shortwave broadcasting. This is due to the ever-increasing congestion in the shortwave broadcast bands, the competitive increases in transmitter power levels (which contributes to congestion), and appreciation of the increased efficiency of SSB transmission. A World Administrative Radio Conference Committee, meeting in Geneva in January and February 1984, adopted a detailed 20-year plan for conversion to SSB on the international shortwave broadcast bands. The committee report addressed necessary changes in both transmitter and receiver technologies. These changes can double the available channel space and improve reception quality in the current international broadcast bands.

AUDIO PREEMPHASIS

In the 1980s, transmitter and audio processor equipment manufacturers, broadcasters, and receiver manufacturers came together in a forum called the National Radio Systems Committee (NRSC), jointly sponsored by the National Association of Broadcasters (NAB) and the Electronic Industries Association (EIA). Out of this forum came definition and formal recognition of certain system inconsistencies that were impeding the growth of AM broadcasting.

The major such inconsistency in AM broadcasting had been known for some time. The offending parameter could be called transmitter/receiver interface. Because of the nature of nighttime skywave propagation on the medium-wave AM band, and the adjacent (and sometimes next-adjacent and even next-next-adjacent) channel interference created by this propagation, manufacturers had severely restricted the intermediate frequency (IF) and audio bandwidth of receivers produced for the AM band. The bandwidth restriction was often severe; −20 dB to −30 dB frequency response at 5 kHz was not unusual. Yet, stations continued to transmit wideband audio (out to at least 10 kHz and often 15 kHz) in an effort to provide the highest quality signal possible.

The committee addressed this transmitter/receiver interface mismatch and produced a recommended standard which restricted transmitted bandwidth to 10 kHz hoping this would encourage receiver manufacturers to widen the IF and audio-frequency response of the receivers correspondingly.

The solution was the only one that could be made in light of the present congestion in North America on the AM band. The standard that the committee proposed was based on the compliance of a majority of North American broadcasters and manufacturers of AM receivers for the North American market. More than 1000 private AM broadcasters in the U.S. and Canada participated, prompting the FCC to make the NRSC standard a requirement by all U.S. AM broadcast stations. The FCC requirement took effect on June 30, 1990. The standard recommends an AM preemphasis curve is to be used in audio processing equipment or in the transmitter itself. The curve is called a "Modified 75 micro-second AM Preemphasis Standard Curve." It exhibits approximately 1 dB boost at 1 kHz and approximately 10 dB boost at 10 kHz, followed or accompanied by a single pole low-pass filter with a break frequency of 8.7 kHz to reduce the peak boost at high frequencies. The matching deemphasis curve in the receiver can be achieved in the IF and audio stages.

The recommendation by the NRSC and following supportive action by the FCC is at least an important

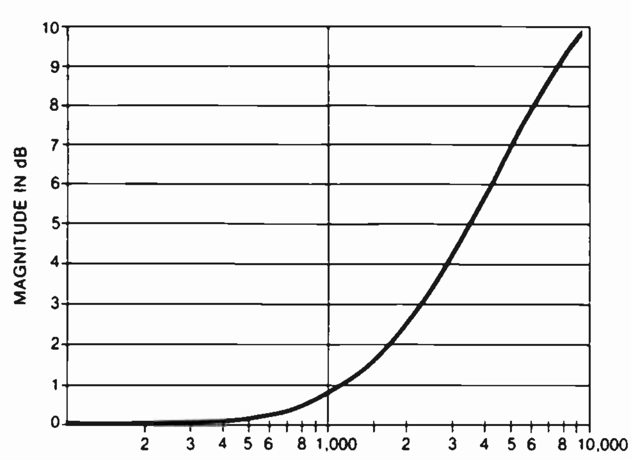

Figure 25. Modified 75 micro-second AM standard preemphasis curve.

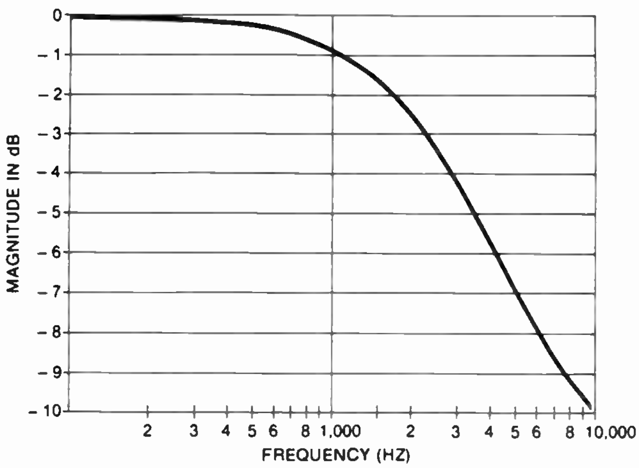

Figure 26. Modified 75 micro-second AM standard deemphasis curve.

first step in achieving improved bandwidth on the North American AM broadcast band. The issue of high audio-frequency preemphasis is not without some controversy. Some broadcast engineers believe the standard is good in concept but does not go far enough, that high-frequency boost should be limited to somewhat lower than 10 kHz to further reduce or possibly even eliminate adjacent channel interference. The European Broadcasting Union (EBU), in conjunction with the CCIR, recommends moderate high-frequency preemphasis to 4.5 kHz (European AM channels are spaced at 9 kHz intervals), followed by a sharp-cutoff low-pass filter at frequencies above 4.5 kHz. An identical standard of 4.5 kHz maximum sideband width is also recommended by the CCIR for shortwave broadcasting where the channel spacing is 5 kHz.

The NRSC also generated a second standard pertaining to measurement of actual occupied bandwidth of a licensed AM broadcast station. The FCC has ordered that all U.S. AM broadcast stations comply with this second new standard, NRSC-2, by June 30, 1994.

The full text of NRSC standards 1 and 2 follow as Appendix A and B.

§ 1. SCOPE

The National Radio Systems Committee (NRSC) is a joint Committee composed of all interested parties including representatives of AM broadcast stations, AM receiver manufacturers, and broadcast equipment manufacturers. This document describes an interim[1] voluntary national standard that specifies the preemphasis of AM broadcasts, the deemphasis of AM receivers, and the audio bandwidth of AM stations prior to modulation. The standard applies to AM monophonic and AM stereo L+R transmissions, and to dual bandwidth and single bandwidth AM receivers. Compliance with the standard is strictly voluntary. To the NRSC's knowledge, no industry group or entity is or will be adversely affected by issuance of this document. Every effort has been made to inform and accommodate any and all interested parties. The NRSC believes that implementation of the standard will reduce AM interference, increase useful AM service areas, and encourage the production of higher fidelity AM receivers.

A five year review provision is established.

§ 2. INTRODUCTION

On September 5, 1985, the NRSC adopted a resolution to study proposals to standardize AM transmission preemphasis and AM receiver deemphasis with the objective of establishing an industry-wide AM preemphasis/deemphasis voluntary standard. After twelve months of study, on September 10, 1986 the NRSC released a draft voluntary standard that proposed a specific AM preemphasis/deemphasis curve as well as a 10 kHz standard AM bandwidth. The bandwidth specification evolved from NRSC deliberation on the causes and cures of AM interference, and ways to technically encourage the production of higher fidelity AM receivers. After a three month public comment period, the NRSC, on January 10, 1987, formally adopted this standard and authorized its publication by the National Association of Broadcasters and the Electronics Industries Association.

The purpose of the NRSC voluntary standard is to create a transmission/reception system where (1) AM broadcast stations will know, with certainty, the likely audio response characteristics of AM receivers, and (2) AM receiver manufacturers will know, with certainty, the likely audio response characteristics of AM broadcasts. A "matching" of preemphasis and deemphasis is expected to improve the consumer's overall satisfaction with the technical quality of listening to AM radio. The NRSC believes that the public interest is served by establishing a compatible transmission/reception system and the accompanying improvement of AM broadcasts and AM receivers.

This document also describes a specification for the maximum audio bandwidth transmitted by AM broadcast stations. Implementation of a bandwidth specification will reduce second-adjacent channel interference and thereby lead to (1) a significant reduction of second-adjacent channel interference as perceived on "wideband" AM receivers; (2) a corresponding increase in the interference-free service areas of AM stations; and (3) an incentive for the further building of dual bandwidth AM "wideband" receivers.[2] Analysis by a subgroup of the NRSC has shown that there would be little if any detrimental effect on today's "narrowband" AM receivers upon the implementation of this voluntary standard.

§ 3. BASIC DEFINITIONS

A. Preemphasis. The boosting of high audio frequencies prior to modulation and transmission.

B. Deemphasis. The attenuation of high audio frequencies during the process of reception and demodulation.

C. "Narrow" receivers. A subjective term to describe receivers with typical combined RF, IF and AF response characteristics of -10 dB at 4.2 kHz, -20 dB at 6.0 kHz. Response characteristics of narrow AM receivers are known to vary widely.

D. "Wideband" receivers. A subjective term to describe receivers with typical combined RF, IF, and AF response of -6 dB

1.The standard is described as "interim" until it is submitted and approved by the American National Standards Institute.

2.First Adjacent channel interference considerations may continue to discourage the building of single bandwidth "wideband" receivers; however, the extent and nature of this form of interference has not been fully studied by the NRSC.

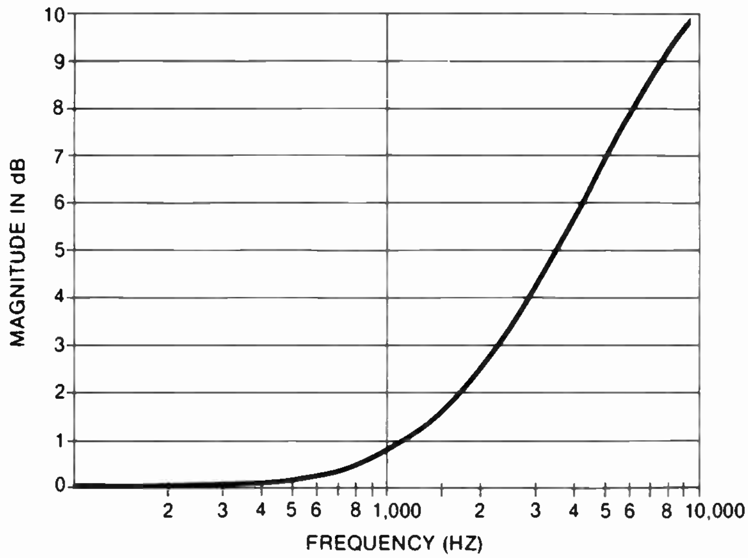

Figure 1. Modified 75μs AM Standard Preemphasis Curve

Technical Information

Frequency	Magnitude (dB)	Phase (deg)	Group Delay (sec)	Frequency	Magnitude (dB)	Phase (deg	Group Delay (sec)

4500	6.37	37.4	7.8900E-007				

at 6 kHz, -10 dB at 8 kHz. Response characteristics of wide AM receivers are known to vary widely.

E. "Excessive" Preemphasis. Preemphasis that produces no discernable benefit when received by a "narrow" receiver but increases interference to adjacent channel AM stations.

§ 4. AM TRANSMISSION PREEMPHASIS

§ 4.1. In General. AM preemphasis is the boosting of high audio frequencies prior to modulation and transmission. Today, most AM stations use preemphasis to varying extents. This preemphasis is employed in an attempt to compensate for the "narrow" response of most AM receivers. If AM preemphasis is not controlled, one station may interfere with AM receivers listening to neighboring stations located on adjacent AM channels. Whether such interference is objectionable will depend on (1) the response characteristics of the AM receiver, (2) the amount and nature of transmission preemphasis, (3) the extent to which the AM station is employing compression/ limiting techniques, and (4) whether the AM transmission system is bandlimited in the audio processor, transmitter or antenna.

Preemphasis is useful for improvement of the AM transmission-reception system audio response only to a limited extent for receivers using IF transformers. Many receivers using ceramic filters with narrow response characteristics can not be improved by use of excessive preemphasis. These receivers can not "hear" the transmission of preemphasized high audio frequencies. But excessive preemphasis will foster adjacent channel interference and cause wideband radios to sound shrill or strident.

§ 4.2. Description of the Modified 75 uS Preemphasis Curve. Each AM broadcast station shall broadcast with audio preemphasis as close as possible (within the capabilities of the station's transmission system) to the recommended standard, without exceeding it. The curve applies for audio frequencies up to 10 kHz.

The NRSC proposed standard AM transmission preemphasis curve is shown in Figure 1. The curve describes the recommended net transmission system static audio response of an AM station.

The recommended preemphasis curve is a single zero curve with a break frequency at 2122 Hz. It is similar to the 75 uS curve used for FM broadcasting. To reduce the peak boost at high frequencies, a single pole with a break frequency of 8700 Hz is employed. NRSC analysis has shown that the proposed curve is compatible with most existing AM receivers.

§ 4.3. Methods for Determining Performance. The NRSC AM preemphasis curve is a static curve, and cannot be measured dynamically. NRSC studies have shown that the dynamic and non-linear functions performed by most AM station audio processors will modify any given preemphasis curve. In addition, it is the audio response of the entire AM transmission system that indicates performance in accordance with the standard. For these reasons, measuring a station's preemphasis curve for the purpose of determining compliance with the NRSC standard shall be performed in accord with the following specifications:

§ 4.3.1. Use of Audio Tones. Compliance with the curve shall be measured by sweeping the station's transmission system with audio tones. The dynamic functions of the AM station's processor, but not the frequency shaping circuits, must be disabled (i.e., in "proof" mode).

§ 4.3.2. Location of Measurement. The net transmission system audio response is best measured by detecting the over-the-air signal. This will ensure that the AM transmitter and antenna combination is faithfully reproducing the preemphasized audio.[3] Alternatively, if the transmitter and antenna combination is reasonably broadband, performance can be determined by static measurement of the audio signal prior to modulation.

§ 5. AM RECEIVER DEEMPHASIS

§ 5.1. In General. Receiver deemphasis results from the selectivity

---

3.However, the deemphasis characteristics of the device used to demodulate the AM transmission must be accounted for. Additionally, some AM stations with transmitter or antenna problems may not be able to pass preemphasized audio without introducing "splatter" interference and/or overmodulation. If a particular AM station transmission system cannot "handle" the NRSC recommended curve, it is suggested that a lower amount of preemphasis be used until the system problems are corrected to allow the NRSC curve to be faithfully implemented.

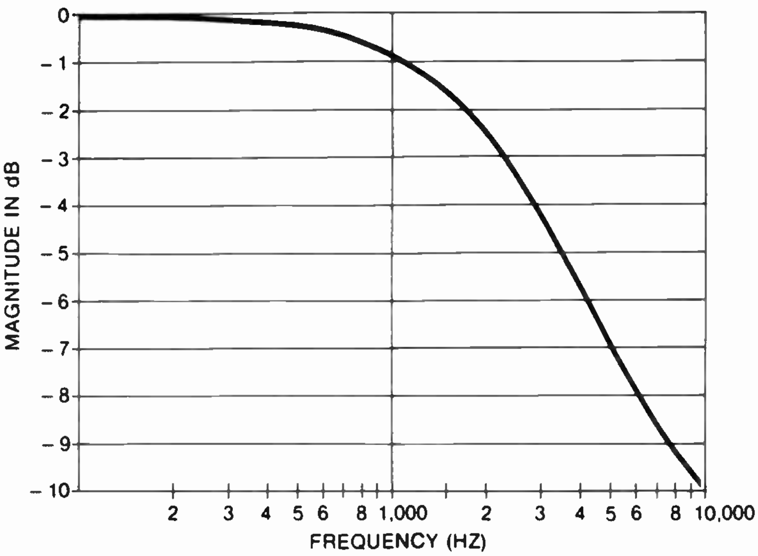

Figure 2. Modified 75μs AM Standard Deemphasis Curve

characteristics of a receiver's RF and IF stages and the response characteristics of the receiver AF section. A standard deemphasis curve permits AM stations to know, with certainty, the likely overall response characteristics of AM receivers.

§ 5.2. Description of the Standard Deemphasis Curve. AM receivers shall complement the recommended transmission preemphasis characteristic described in § 4 by incorporating a net receiver system audio response described in Figure 2. (The net system audio response of an AM receiver is the combined RF, IF, and AF audio response.) The NRSC deemphasis curve is characterized by a single pole at 2122 Hz and a single zero at 8700 Hz. It is the precise complement of the preemphasis standard described in § 4. The preemphasis/deemphasis voluntary standards apply only for audio frequencies below 10 kHz; the implementation of preemphasis/deemphasis standards produces a transmission/reception system that is essentially flat to nearly 10 kHz and limited only by the AM receiver's choice of bandwidth.

§ 5.3. Methods for Determining Performance. The deemphasis characteristic shall be determined by measuring the overall frequency response in accordance with International Electrotechnical Commission ("IEC") Publication 315.3, Clause 11.2:

(1) The receiver is brought under standard measuring conditions and the reference audio-frequency output voltage is noted. The modulation frequency is then varied and the output voltage at each frequency is noted and expressed in decibels relative to the reference voltage.

The modulation depth is adjusted at each frequency in accordance with the preemphasis characteristic of AM broadcast transmission. To avoid overmodulation at some frequencies it may be necessary to use a modulation factor of less than 30% at some frequencies.

(2) If overloading of the AF section of the receiver occurs, either the volume control attenuation should be increased or the modulation factor reduced, and a corresponding factor applied to the results.

(3) The measurements may be repeated with other values of RF input signal level and frequency.

The frequency response shall be measured for both monophonic and stereophonic reception, in accordance with the definition of the particular AM stereo system. For dual bandwidth receivers, the frequency response shall be measured in both bandwidth positions.

Results may be presented graphically, with modulation frequency plotted logarithmically as abscissa and the output in decibels as ordinate.

The frequency response can be stated as follows:

Selectivity	Frequency Response
Narrowband	50 Hz to 5000 Hz +/- X dB
Wideband or Stereo	50 Hz to 10,000 Hz +/- X dB

(Where X is the maximum deviation from the recommended frequency response, and 5000 Hz and 10,000 Hz are example frequency specifications.) The deviation X shall be of as low a value as practical. If a notch filter is used while the AM receiver is under test, the stated frequency response should be modified accordingly. Suggested modifications include (1) adding an appropriate footnote to the frequency response specification; and/or (2) lowering the upper limit value to the above "wideband" audio response specification.

§ 5.4. Notch Filters. A notch filter is a very selective filter that attenuates the spectrally pure carriers of first adjacent channel AM stations. Although an optional enhancement to an AM receiver, using notch filters is recommended. If used, the notch filter should (1) have as high a "Q" as is practical, (2) adequately suppress the interfering carriers, and (3) not unduly degrade the desired bandwidth performance of the AM receiver.

§ 6. 10 KHZ BANDWIDTH FOR AM TRANSMISSION

§ 6.1 In General. Each AM broadcast station shall modulate its transmitter with an audio bandwidth described by the specification in Figure 3. Appropriate and carefully designed audio low-pass filters as the final filtering prior to modulation can be used to implement this specification. The purpose of the bandwidth specification is to remove interference by controlling the occupied RF bandwidth of AM stations.[4]

§ 6.2. Description of the Standard. The audio bandwidth transmission standard is specified in Figure 3. The audio

4.It should be noted that the operation of non-linear AM Stereo systems theoretically may produce phase modulation components outside the desired RF bandwidth. The NRSC will examine this phenomena with the goal of determining whether such components exist and, if they do exist, whether they are objectionable. For a discussion of the detrimental effect of high audio frequencies on occupied RF bandwidth, see Klein, Modulation, Overmodulation, and Occupied Bandwidth: Recommendations for the AM Broadcast Industry, Proceedings of the 1987 NAB Engineering Conference, Dallas, Texas (April, 1987).

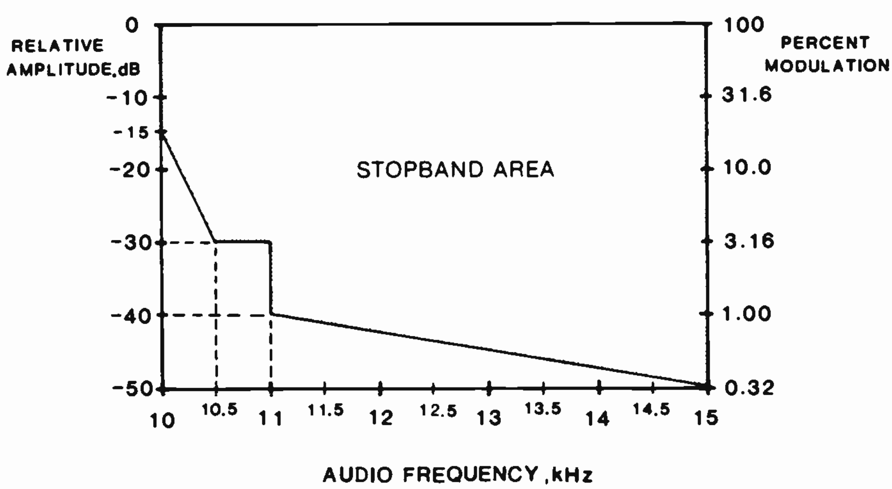

Figure 3. NRSC Stopband Specification
(Audio Envelope Input Spectrum To AM Transmitter)

envelope input spectrum to the AM transmitter shall be -15 dB at 10 kHz, smoothly decreasing to -30 dB at 10.5 kHz, then remaining at -30 dB from 10.5 kHz until 11.0 kHz. At 11.0 kHz, the audio bandwidth shall be -40 dB, smoothly decreasing to -50 dB at 15 kHz. Above 15 kHz, the audio bandwidth shall remain at least -50 dB. The reference level is 1 dB above a 200 Hz sine wave at 90% negative modulation. See Figure 3.

§ 6.3. Method for Determining Performance. An AM station is determined to be in compliance with the NRSC bandwidth characteristic by measurement of the station's audio bandwidth in accordance with the following parameters:

§ 6.3.1. Location of Measurement. Audio bandwidth measurements shall be obtained at the audio input terminals to the AM transmitter. For AM Stereo stations, audio bandwidth shall be measured at the L+R audio input terminals to the RF modulator. Note that the NRSC bandwidth standard characterizes an audio bandwidth that represents station program material that has been modified by possibly non-linear circuits in the station's audio processor. For this reason, the NRSC recommends use of a test signal that adequately characterizes typical audio program material, rather than relying on static audio test tones. However, it may still be useful to measure bandwidth statically at the time that AM preemphasis is measured.

§ 6.3.2. Use of Standard Test Signal. Audio bandwidth shall be measured using a test signal consisting of USASI (United States of America Standards Institute) noise that is pulsed by a frequency of 2.5 Hz at a duty cycle of 12.5%. See Figure 4. USASI noise is intended to simulate the long-term average spectra of typical audio program material. Pulsing of the noise is intended to simulate audio transients found in audio program material. USASI noise is a white noise source[5] (i.e. noise with equal energy at all frequencies) that is filtered by (1) a 100 Hz, 6 dB per octave high-pass network and (2) a 320 Hz, 6 dB per octave low-pass network. See Figure 4. A pulsed USASI noise generator is shown in Figures 5 and 6. Using the attenuator pad, the ratio of peak-to-average amplitude shall be 20 dB at the audio output of the pulser. The station's audio processor must be in normal operating mode.

§ 6.3.3. Use of Standard Measurement Devices. A suitable swept-frequency or FFT (Fast Fourier Transform) spectrum analyzer shall be used to measure compliance with the NRSC bandwidth specification.

(a) Spectrum Analyzer Setup. When a swept-frequency audio spectrum analyzer is used to measure compliance with the NRSC bandwidth specification, the analyzer's setup shall consist of:

a. 300 Hz resolution bandwidth.[6]
b. 2 kHz/horizontal division.
c. 10 dB/vertical division.
d. Reference: 1 dB above 200 Hz (sine wave) 90% negative modulation.
e. Display: maximum peak hold (or equivalent function).

The analyzer's operating span and sensitivity are adjusted as necessary to determine compliance.

(b) Fast Fourier Transform Analyzer. When a FFT analyzer is used to measure compliance with the NRSC bandwidth specification, the analyzer's setup shall consist of:

a. Reference: 1 dB above 200 Hz (sine wave) 90% negative modulation.
b. Window: Hanning.
c. Horiz. span: 20 kHz.
d. Dynamic range: 80 dB or available range.
e. Display: Maximum peak hold (or equivalent function).

5.Acceptable white noise sources include GenRad Models 1382 and 1390B; Bruel & Kjaer Model 1405; and National Semiconductor IC No. MM 5837N.

6.Note: if the audio bandwidth under test fails to meet the NRSC specification when a 300 Hz resolution bandwidth is employed, a narrower resolution bandwidth, such as 100 Hz, may be used to determine compliance; however, the sweep rate and the video bandwidth of the analyzer must be adjusted according to the manufacturer's instructions in order to assure accurate representation of the resolution bandwidth employed. If in doubt, check with the analyzer operating manual or the manufacturer. Further Note: the NRSC may suggest a different or more precise measurement standard as the industry gains experience. Spectrum analyzers that are capable of 300 Hz resolution bandwidths at audio frequencies include, but are not limited to, Tektronix Models 5L4N and 7L5; Hewlett-Packard Models 3580A, 3582A, 3585A, 8553A or B, 8566A or B, 8568A or B, 71100A; Marconi Models 2370, 2382; Rhode/Schwarz/Polarad Model CSA-240M; and a Techron Model TEF System 12.

§ 7. FIVE YEAR REVIEW PROVISION

It is the goal of the NRSC to increase the fidelity of the AM transmission and reception system from its present state to a quality level that approaches the quality available via FM broadcasting. Towards this end, the voluntary standards described in this document shall be in effect for five (5) years from the effective date of this standard. During the interim five year period, this voluntary standard will be reviewed at least once a year to determine whether the fidelity goals of the NRSC are being realized.

§ 8. EFFECTIVE DATES

These dates serve only as objectives. AM Broadcast stations and AM receiver manufacturers are expected to make a good faith effort to implement the NRSC standard.

A. AM Broadcast Stations. The effective date of this standard is January 10, 1987.

B. AM Receiver Manufacturers. The effective date of this standard is January 10, 1988.

EMISSION LIMITATION FOR AM BROADCAST TRANSMISSION (NRSC Voluntary Standard No. NRSC-2)

§ 1. Scope.

The National Radio Systems Committee (NRSC) is a joint committee composed of all interested parties including representatives of AM broadcast stations, AM receiver manufacturers, and broadcast equipment suppliers. This document describes an interim[1] voluntary national standard that specifies radio-frequency spectrum occupancy for AM broadcast stations. The standard applies to both AM monophonic and AM stereo transmissions. Compliance with the standard is strictly voluntary. To the NRSC's knowledge, no industry group or entity is or will be adversely affected by issuance of this document. Every effort has been made to inform and accommodate any and all interested parties. The NRSC believes that implementation of this standard will lead to reduced AM interference, thus providing increased service for all AM stations and an increase in quality of service to present and future AM listeners.

§ 2. Introduction.

On January 10, 1987, the NRSC authorized the National Association of Broadcasters and the Electronic Industries Association to publish an interim voluntary national standard specifying AM preemphasis, AM deemphasis and a 10 kHz AM audio bandwidth (Standard No. NRSC-1). The NRSC-1 audio standard applies to the audio signals that are intended to modulate the AM transmitter. Its purpose is to reduce second-adjacent channel interference by band limiting AM stations to a nominal

[1]The standard is described as "interim" until the test methods contained within the document can be fully verified through field tests. In addition, field test data of "splatter monitor" technology will be evaluated to determine the correlation between results obtained with such devices and the methods described within this document (see § 5.).

20 kHz occupied radio-frequency (RF) bandwidth (twice the 10 kHz audio bandwidth presented to the transmitter's modulation circuits). Implementation of the NRSC-1 audio standard alone largely achieves this purpose. However, there remain characteristics of the AM transmission process that may cause the RF occupied bandwidth to exceed a nominal 20 kHz. This document accommodates these transmission characteristics. It is in two Sections. Section 3 is a voluntary standard maximum RF occupied bandwidth of AM broadcast transmissions. Section 4 consists of a voluntary RF occupied bandwidth testing and control standard designed to insure repeatability and consistency of RF occupied bandwidth test measurements.

§ 3. RF Maximum Occupied Bandwidth Specification.

§ 3.1. Purpose. The purpose of an RF maximum occupied bandwidth specification is to control modulation products, desired or undesired, that fall outside the specified RF occupied bandwidth.

§ 3.2. Maximum Occupied Bandwidth. The maximum occupied RF bandwidth voluntary standard represents the maximum peak output of a swept-frequency spectrum analyzer IF over a minimum ten minute period.[2] The specification encompasses all spectral components caused by direct programming and all ancillary or data communications. AM broadcast stations shall occupy spectrum according to the following maximum specifications:

(see next page)

[2]It is recognized that the output of the spectrum analyzer depends on the shape of the analyzer's IF filters.

Table 1

Frequency Band Relative to Carrier (+/- kHz)	Attenuation Relative to Carrier (dB)
0 to 10	0
10 to 20	greater than -25[3]
20 to 30	greater than -35
30 to 60	greater than -(5 + 1 dB/kHz) from carrier[4]
60 to 75	-65[4]
above 75	-80[4]

(See Figures 1 and 1A (solid line) attached).

§ 3.3. Measurement Procedure.

§ 3.3.1. Use of Ordinary Program Material. Measurements of AM station spectrum occupancy shall be conducted using ordinary program material. All audio processing used in the AM station shall be in normal operating modes. The audio signal input to the AM transmitter shall conform to the NRSC audio standard adopted January 10, 1987.

§ 3.3.1.1. Use of Audio Tones. Sweeping a transmission system with audio tones is a widely accepted and respected method for gauging spectrum occupancy and for troubleshooting and adjusting AM transmission systems. The NRSC endorses audio tones for these purposes, but urges caution in the use and selection of audio tones particularly with AM stereo transmission.[5] It should be noted, however, that it is

---

[3]Note: the slope of occupied bandwidth in the transition region between 10 and 11 kHz is expected to parallel the NRSC-1 audio standard. Accordingly, attenuation levels in the region shall be 6 dB greater than described in the audio standard to adjust for carrier level reference.

[4]For carrier power levels between 50 and 5000 Watts, the maximum limit shall be $-(43 + 10 \log P_W)$ dB (where P_W is the carrier power in Watts) or as indicated in Table 1 and/or the attached Figure 1, whichever is lesser attenuation. For carrier power levels below 50 Watts, a -60 dBC maximum limit shall be used.

[5]The manufacturer of the particular AM stereo system employed should be consulted for the appropriate tone frequencies/modulation levels for "worst-case" condition testing.

difficult to infer the dynamic response of a transmission system while observing it in a steady-state condition.

§ 3.3.2. Use of Spectrum Analyzer. A suitable swept-frequency RF spectrum analyzer shall be used to measure compliance with the NRSC RF occupied bandwidth specification. The analyzer shall measure the over-the-air RF spectrum occupancy as perceived in the far field (i.e., at least 10 wavelengths from the antenna center). Some caution should be used in measuring spectrum occupancy with directional antennas.[6]

The analyzer's setup shall consist of:

a. 300 Hz resolution bandwidth.
b. 5, 10, or 20 kHz/horizontal division (as appropriate).
c. 10 dB/vertical division.
d. Reference: carrier peak.
e. Peak Hold: 10 minute duration minimum.
f. No Video Filter.

§ 4. RF Occupied Bandwidth Testing and Control Standard.

§ 4.1. Purpose. The NRSC recognizes that for the purposes of troubleshooting, design, and adjustment it may be desirable to use an occupied bandwidth emission standard that is coupled to a standard test signal and measurement procedure. This second measurement technique can also be utilized by transmitter manufacturers and broadcasters to provide results that may be directly correlated with each other. For these purposes, the NRSC proposes the following interim voluntary national test and control standard:

§ 4.2. Maximum Occupied Bandwidth. The RF occupied bandwidth test and control standard is a stored peak specification. With the standard test signals and measurement procedures specified below, AM stations shall occupy a maximum RF bandwidth that conforms to the following maximum specifications:

---

[6] *See* Klein, *Modulation, Overmodulation, and Occupied Bandwidth: Recommendations for the AM Broadcast Industry* (NAB, September 11, 1986) at 18-23.

Table 2

Frequency Band Relative to Carrier (+/- kHz)	Attenuation Relative to Carrier (dB)
0 to 10	0
10 to 13.5	Minimum is defined by a line with endpoints found at -25 dB/10 kHz and -35 dB/13.5 kHz[7]
13.5 to 54.5	Minimum is defined by a line with endpoints found at -35 dB/13.5 kHz and -65 dB/54.5 kHz[8]
54.5 to 75	-65[8]
above 75	-80[8]

(See Figures 1 and 1A (dotted line) attached).

§ 4.3. Measurement Procedure.

§ 4.3.1. Standard Noise Test. Measurements of AM station spectrum occupancy shall be conducted using a standard noise test signal described in the January 10, 1987 NRSC audio standard.[9] All audio processing employed in the AM station or test configuration shall be in a normal operating mode. The audio signal input to the AM transmitter shall conform to the NRSC audio standard adopted January 10, 1987.

§ 4.3.1.1. Monophonic conditions. The noise source is unmodified.

§ 4.3.1.2. Stereophonic conditions. Two independent but equivalently designed USASI-weighted noise sources are employed. Pulsing of the sources is controlled by a single control signal. The pulsed output of one noise generator is defined as L+R (mono, sum information) where the other is attenuated by 3 dB to

[7]See footnote 3.

[8]For carrier power levels between 50 and 5000 Watts, the maximum limit shall be $-(43 + 10 \log P_W)$ dB (where P_W is the carrier power in Watts) or as indicated in Table 2 and/or the attached Figure 1, whichever is lesser attenuation. For carrier power levels below 50 Watts, a -60 dBC maximum limit shall be used.

[9]*See National Radio Systems Committee, Interim Voluntary National Standard (NRSC-1)*, § 6.3.2 and Figures 4, 5, and 6 (January 10, 1987).

provide L-R (stereo, difference information). The signals are then matrixed to provide left and right channel information to be applied to the audio input terminals of the stereophonic audio processor employed.[10] See Figure 2 (attached).

§ 4.3.2. Use of Spectrum Analyzer. A suitable swept-frequency RF spectrum analyzer shall be used to measure compliance with the NRSC RF occupied bandwidth testing and control standard. The analyzer's setup shall consist of:

a. 300 Hz resolution bandwidth.
b. 5, 10, or 20 kHz/horizontal division (as appropriate).
c. 10 dB/vertical division.
d. Reference: carrier peak.
e. Peak Hold: 10 minute duration minimum.
f. No video filter.

§ 5. Splatter Monitor. It is understood that the NRSC does not anticipate a Spectrum Analyzer will be available for mask standard measurements in most AM radio stations. However, the current development of a low cost "splatter monitor" device may allow economical continuous monitoring of compliance with RF mask characteristics.

Such a device accommodates the following factors: (1) NRSC deemphasis, and (2) amplitude detection of in-phase and quadrature signal components found in the defined stopband region.

As these devices are evaluated and correlated with current spectrum analysis measurement techniques, a determination shall be made by the NRSC with respect to possible modification of RF mask compliance measurement methods.

§ 6. **Effective Date. June 1, 1988.**

§§§§

[10]The signal provided by the audio processor to the transmitter left and right audio input terminals shall not exceed single channel modulation limits as dictated by the constraints of the particular stereo system employed.

3.2
AM Stereo Broadcasting

Edward J. Anthony
Broadcast Electronics, Inc., Quincy, Illinois

INTRODUCTION

The acceptance and implementation of AM stereo broadcasting in the United States has been a slow and difficult transition. Beginning with the now famous FCC marketplace decision in 1981, the field of prospective AM stereo system proponents has been reduced from five (Belar, Harris, Kahn Communications, Magnavox, and Motorola) to two, namely the Kahn Independent Sideband System (ISB) and the Motorola C-QUAM System.

Recent years have shown a quiet growth in AM stereo conversion, with less controversy than was experienced in the early and mid-1980s. The broadcaster's interest has turned more toward proper installation and maintenance of AM stereo than on which system to use. Both remaining methods of stereo transmission have proven to be effective, and it is not in the scope of this chapter to discuss the relative merits of one system over the other. A separate discussion of the C-QUAM and ISB systems may be found in Appendices A and B.

The proper operation of stereo transmission for AM is relatively more difficult than its FM counterpart. Anyone familiar with installing AM stereo will attest to this. It is intended, therefore, to discuss the more practical aspects of AM stereo preparation, installation, and maintenance to aid the AM broadcaster in achieving a high quality stereo transmission.

STATION PREPARATION FOR AM STEREO

Depending on the particular station, part or perhaps all areas of the operation will be affected during the AM stereo installation process. It is best to consider each section of the transmission path separately, so as to make a more thorough and logical conversion.

The Audio Chain

Unless the current AM studio is outfitted with stereo equipment, it will be necessary to install new stereo sources such as cart machines, CD players, consoles, and other distribution facilities. If good engineering practices are employed during the installation and layout phases, this portion of the process should pose no major hurdles.

One area to be concerned about, however, is to insure proper audio phase and amplitude matching of both channels throughout the facility. Without adequate tracking between left and right channels, proper monophonic frequency response and stereo imaging will not be maintained.

Fig. 1 shows the resulting loss in monophonic frequency response due to improper phase relationship between the two audio channels. Another consequence of poor channel matching is a rapid degradation in L+R (monophonic) to L−R (stereo), and L−R to L+R crosstalk. This parameter typically degrades with frequency, reducing high frequency monophonic coverage and altering the high frequency stereo image.

Fig. 2 graphically shows the degree of amplitude and phase matching required to obtain an arbitrary amount of crosstalk. For instance, a 0.1 dB amplitude error combined with 1 degree of phase mismatch will limit L+R to L−R and L−R to L+R crosstalk to about 40 dB. As we shall see later, this relationship holds true for stereo separation during transmitter equalization.

AM Stereo Processing

Due to the nature of AM stereo transmission, the audio paths are different than its FM multiplex counterpart. Rather than operating in a discrete left and right channel mode, AM stereo transmission necessitates the use of matrix mode for transmission, since the amplitude modulation information comes from the combination of L+R (monophonic) audio and the

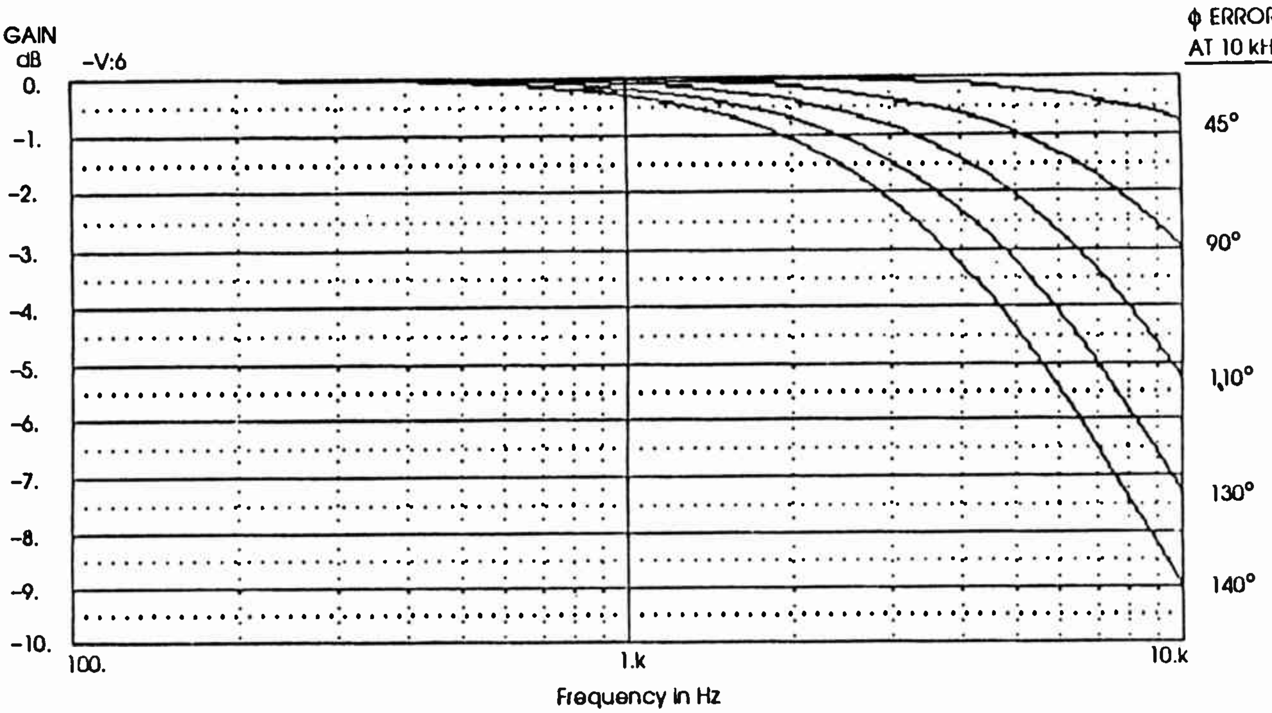

Figure 1. Loss in monaural frequency response due to phase errors.

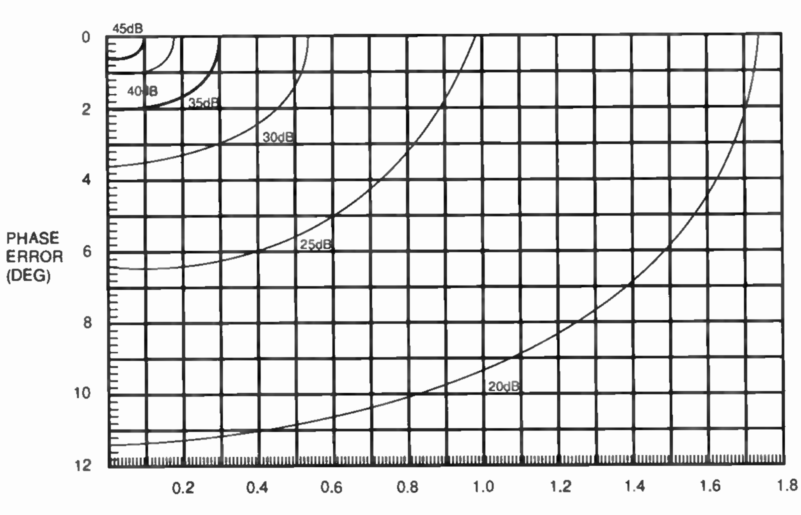
RF carrier employs some form of phase modulation representative of the L − R (stereo) information. Unlike composite FM stereo, these paths are independent of each other and may also be processed independently. In fact, since the two audio paths are combined in matrix form before the actual modulation occurs, processing for AM stereo is most effective if it is also done in matrix form.

Fig. 3 is a representation of a common and very effective tool used in AM stereo installation and maintenance: the X − Y or Lissajous pattern of a two channel oscilloscope. Standard operation is with the X input driven by the left channel, and the Y input driven by the right. This will produce a straight line display of 45° angle in the first and third quadrants for total L + R modulation, and a straight line display of 45° in the second and fourth quadrants for total L − R information.

If conventional left and right channel processing is used, the limiting must be done symmetrically, and at



General Equation:

$$\text{Separation }(A,\theta) = \left[\frac{(\cos\theta + A)^2 + (\sin\theta)^2}{(\cos\theta - A)^2 + (\sin\theta)^2}\right]$$

Where: $A = \frac{L-R}{L+R}$ Amplitude ratio

$\theta = \frac{L-R}{L+R}$ Phase error in degrees

Figure 2. Crosstalk (separation) vs. amplitude and phase errors in a matrix system.

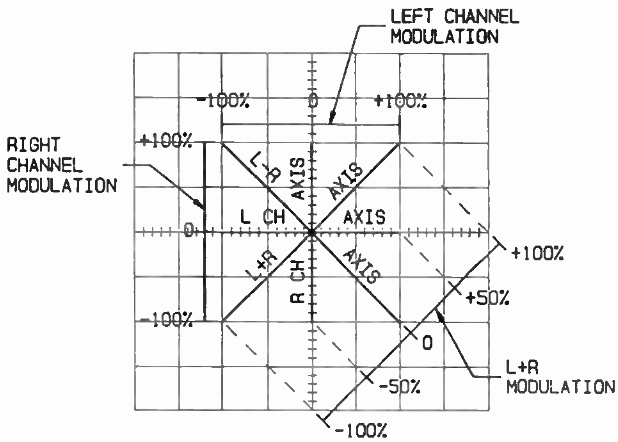


Figure 3. Conventional "X-Y" oscilloscope display.

a level equivalent to 50% L + R and L − R modulation if only one channel were being applied. In this manner, proper 100% limiting will occur when L = R for the envelope (amplitude) modulation, and when L = (− R) for the phase modulation. However, under single channel conditions, there is a 6 dB loss in both monaural loudness and coverage. This undesired effect can be improved if the processing is done in matrix form.

Fig. 4 shows the classic diamond shape produced by full matrix stereo processing. With this method, left and right channels are increased under single channel conditions, and under heavy stereo conditions, to maintain full envelope modulation. This mode of operation is called full monaural support matrix stereo limiting.

Unfortunately, instead of the 6 dB loss in monaural loudness associated with the conventional processing method, the full matrix method results in a 6 dB *increase* in stereo single channel loudness. However, this has been found to be less objectionable than the alternative, and combined with the infrequent nature of single channel conditions, is a more desirable side effect for AM stereo.

There is still one aspect of full monaural support matrix stereo limiting which makes it unacceptable. The unique decoder requirements necessary for the C-QUAM AM stereo system necessitate that the left and right channels be limited to − 75%, where − 100% is equivalent to full envelope modulation caused by a single channel input. In addition, the Kahn ISB system has nonlinear effects caused by single channel modulation greater than 75%. Therefore, all professional AM stereo matrix processors include a single channel limiter to prevent these problems. The new operational area is shown in Fig. 5. Notice the protection areas which have been included to prevent nonlinear stereo operation. This style of AM stereo processing has been referred to as **modified** monaural support matrix stereo limiting.

Proper alignment and operation of any matrix AM stereo processor requires a thorough understanding of these departures from conventional FM stereo processing, as well as the practical limitations imposed by current AM stereo hardware designs. Without a proper grasp on these concepts, the processing can do more harm than good, and has often been the source of great frustration during installation and maintenance.[1]

Studio-to-Transmitter Link

Many AM stations operate studios at locations other than that of the transmitter. Therefore, there must be some form of studio-to-transmitter link to carry the audio information to the transmission facility. Traditionally, this has taken one of two forms: equalized phone lines, or a microwave radio link.

Stereo transmission requires a second link to be installed, and if not done carefully, can be a serious limitation to proper stereo operation.

Phone Lines

Installing a second phone line is often the first choice for many AM stations, especially if they are currently

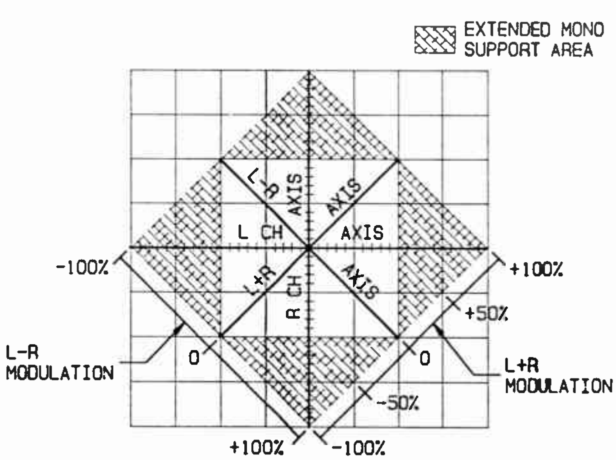

Figure 4. Full matrix stereo processing.

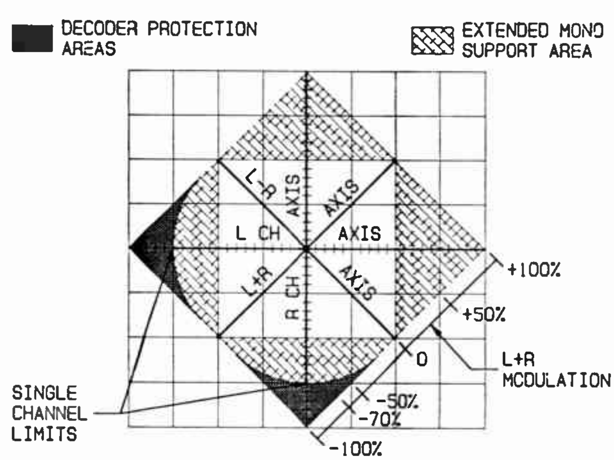

Figure 5. Modified matrix stereo processing.

using one. Two of the more common complaints with this approach are the increase in monthly fees associated with the second line, and the troublesome problem of maintaining the amplitude and phase matching between the two lines.

Equalized phone lines typically have complex filters and frequency shaping equalizers associated with them. This makes them difficult to match, and also prone to drift with time and temperature. The complexity of the circuits can also increase the total possible phase shift, making complete monophonic cancellation, or combing, a problem under extreme conditions. This same phenomenon will also cause complete mono to stereo image rotation, which will cause unexpected stereo imaging and excessive phase modulation.

Unfortunately, these paths are not under the direct control of the station, and one is often left to the mercy of the local telephone company for support.

Radio Links

Installing a new radio link is generally considered a more favorable alternative, providing the frequency allocation is available. It also relieves the monthly financial burden associated with rented phone lines. However, discrete left and right STL transmission can suffer some of the same problems with amplitude and phase matching, but usually not to the same degree as phone lines. The STL transmitters and receivers will have audio, RF and IF filters, and depending on the design, construction and alignment, may not be well matched. It is best to consult the manufacturer to get an assurance that the two systems will track adequately.

There is a third approach which has been used in some locations with great success. An FM stereo generator can be used to create a baseband composite FM stereo signal which can then be transmitted on a single wideband STL link. The signal is then decoded back to left and right at the transmitter location using a high-quality stereo decoder. This approach can be more expensive than discrete radio links, but results in a very high quality, reliable, and stable way to provide the two channels to the transmitter.

Stereo Synthesizers

A final alternative which will be mentioned involves the use of a stereo synthesizer at the transmitter location. This is perhaps the least expensive way to add stereo, since it requires no studio or STL modifications. Rather, a stereo synthesizer is placed at the transmitter to provide a pseudostereo image. This approach will still require the use of a matrix audio processor at the transmitter location, and the user runs the risk of monaural coverage problems due to combing if too much stereo synthesis is employed. However, it is mentioned here as a low cost way to get started in AM stereo.

Transmitter Preparation

Now that the studios are stereo ready, and the two channels are present at the transmitter site, the real job of installing AM stereo begins. Depending on the age and model of the current transmitter, preparing it to accept AM stereo can range from minor to the nearly impossible.

Unfortunately, there are no absolutely defined procedures for making a transmitter stereo-ready. It is highly recommended that a competent and reliable broadcast consultant be used to prepare the transmission chain. A reputable consultant with AM stereo installation experience can save time, trouble, and in the long run, money, since he will know what is required for your unique set of circumstances and can implement them correctly.

In general, the work which will be required can be broken down into a few basic categories.

General Maintenance

The first step to high-quality AM stereo is to have high-quality AM monaural. Many AM transmitters have been neglected for years. A monaural proof of performance will show if the system is up to specifications. If not, it needs to be fixed so that it produces a decent proof. This is definitely money well spent, since it will improve your on air sound to all listeners, both monaural and stereo. It will also make the stereo installation easier, since there will be enough other problems to compensate for without the added burden of poor monaural performance.

Factory Modification Kits

Most manufacturers of AM transmitters will provide support to help upgrade their transmitters for AM stereo. Past experience has shown them where the stereo problems will be for any given model. In addition, some manufacturers have standard modification kits available, with instructions, to prepare the transmitter for stereo.

IPM Reduction

Incidental phase modulation, or IPM, is broadly defined as any undesired angular phase shift of the RF carrier. It can be further broken down into two subcategories: IPM caused by power supply ripple (or induced magnetic fields), and IPM caused by envelope modulation.

The first form of IPM most often results from insufficient power supply bypassing. Before the advent of AM stereo, transmitter manufacturers were not concerned about IPM, since it was not decoded by conventional envelope detectors and generally did not effect the AM signal. It was simply not worth the additional cost to provide the extra bypassing.

Its main effect is to limit the decoded L − R signal-to-noise ratio (SNR), and is often the dominant stereo noise component. Any improvement in this area will improve the decoded stereo signal-to-noise ratio. It should be possible to reduce this form of IPM to −45 to −55 dB below 100% L − R modulation.

The second form of IPM is much more troublesome to reduce, and more detrimental to quality AM stereo. This mode of IPM is caused by amplitude modulation of the carrier, and can be caused by several mechanisms. For tube type transmitters, it is often the result of poor neutralization of the final PA stage, and can result in equivalent L − R modulation levels in excess of 25%.

The interelectrode capacitances found in vacuum tubes can cause instabilities. In particular, the plate to grid feedback capacitance provides a path for positive feedback. Fig. 6 shows the static interelectrode capacitances found in a tetrode. The C_{g-c} and C_{g-p} are the two capacitances of importance for proper neutralization. The intent of neutralization is to cancel the C_{g-p}, so as to minimize its effect, both on stability and on IPM. The most popular method of neutralization is the capacitance bridge. Fig. 7 shows a simplified tetrode configuration employing classic bridge neutralization. C_{g-p} and C_{g-c} are the grid-to-plate and grid-to-cathode interelectrode capacitances, respectively. C is comprised of any input capacitance, including stray capacitance, and is required for complete neutralization of C_{g-c}. C_n is the neutralization capacitance required to balance C_{g-p}. For proper balance (proper neutralization), the capacitor ratios must satisfy the following relationship:

$$\frac{C_n}{C} = \frac{C_{g-p}}{C_{g-c}}$$

With proper neutralization, IPM levels should be able to be reduced, typically, to −35 to −45 dB below 100% L − R modulation.[2,3]

For the solid-state transmitter, IPM is most often caused by the nonlinear output capacitance of the solid-state device. The value of this capacitance is a function of the applied collector or drain voltage. Since most solid-state transmitters use high level modulation,

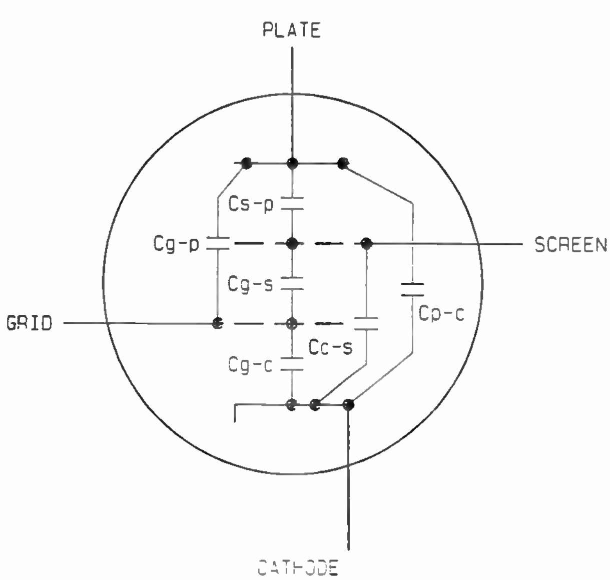

Figure 6. Static interelectrode capacitances of a tetrode tube.

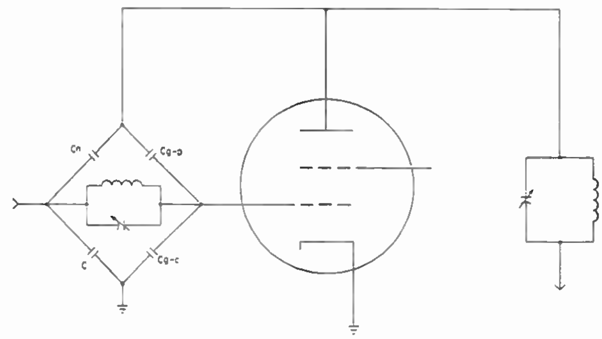

Figure 7. Bridge neutralization.

this voltage varies at the audio rate, which will effect the RF phase angle.

Fortunately, most solid-state transmitters are relatively recent designs, and steps have been taken to reduce this effect to an acceptable level. Many new transmitters are shipped stereo-ready, requiring no additional effort to reduce IPM.

Tuned Circuits

Some older transmitters used narrow bandwidth tuned RF circuits as input, interstage, and output coupling networks. As we shall see later, proper stereo operation requires that the amplitude and phase relationship of the L + R (envelope) information match that of the L − R (phase modulated) information. These narrowband tuned networks have three undesired effects. First, they introduce a nonuniform time delay to the RF carrier, resulting in complex phase equalization problems. Second, they result in L − R high frequency response problems, further aggravating the equalization requirements. Finally, the narrowband nature of the network alters the sideband structure of the phase modulation, resulting in increased distortion.

It is a fairly common practice to increase the bandwidths of these circuits to improve the stereo signal. A word of warning, however: reducing the Q of a tuned stage will result in a decrease in voltage at the output of the network. Care must be taken to insure the resulting signal is adequate to drive the following stage. It is wise to consult the factory or a knowledgeable consultant before attempting this modification.

Antenna and Phasor Alignment

All AM stereo transmissions are sensitive to amplitude and phase nonlinearities to one degree or another. For best performance, the antenna system should be as broadband as possible, and as symmetrical as possible. The C-QUAM system especially requires good transmission bandwidth and phase linearity.

If required, a consultant should be retained to broadband the antenna system and insure its fitness for AM stereo transmission.

Monaural Proof-of-Performance

One final step should be carried out before the actual stereo conversion begins. A complete monaural proof-of-performance should be done to insure the system is ready to accept stereo, and as a record to compare final monaural performance after installation.

STEREO EXCITER INSTALLATION

With a properly operating monaural transmission chain in place, the actual transmitter conversion to AM stereo may begin. Mount the AM stereo exciter close enough to the transmitter to allow proper interconnection. A general rule is the RF interconnection cable should be no more than 30 feet from the transmitter.

RF Interfacing

Picking the RF Insertion Point

Since AM stereo transmission uses some form of phase modulation of the RF carrier, the AM stereo exciter will have a phase-modulated RF output which will replace the transmitter's internal RF oscillator. The rated output power varies from exciter to exciter, from a few watts up to ten watts.

It will be necessary to pick a suitable RF insertion point to break the internal RF chain and replace it with the RF from the exciter. Stereo-ready transmitters will be outfitted with a BNC connector, usually requiring a transistor-transistor logic (TTL) level (5 volts, peak-to-peak) signal for proper operation. Other transmitters require modification to provide a way into the RF sections.

If the particular type of transmitter uses narrow tuned RF stages, it is a good idea to pick the farthest point in the transmitter which the exciter can still provide adequate RF drive.

Many transmitters can accept a TTL level signal but are not outfitted with the necessary interface. Fig. 8 shows a general purpose interfacing network which may be used in these transmitters.

Providing the Proper Termination

The RF output of an AM stereo exciter is designed to operate in a 50 ohm system. This is required due to the extended distances from the RF source and the transmitter. For proper operation, the transmitter end of the 50 ohm coax *must* be terminated with 50 ohms to prevent reflections on the line. This is especially important if the RF output is a square wave, which it is most likely to be. Improper termination will cause reflections on the line, which can cause excessive ringing and, for TTL inputs, improper logic operation. If the ringing is excessive, it is possible to damage the input stage due to excessive voltages. For TTL compatible input levels, a ¼-watt resistor is adequate, provided that the input to the transmitter is AC coupled, then DC restored (Fig. 8). If higher power levels are required, select the proper resistor power rating based on the following formulas:

$$P_{diss} = \frac{(V_{rms})^2}{50} \text{ (for sine wave input)}$$

$$P_{diss} = \frac{(V_{peak})^2}{50} \text{ (for square wave input)}$$

Internal RF Oscillator

Since the transmitter's original RF oscillator has been replaced by the AM stereo exciter, some possible problems may need to be dealt with. First, there may be some coupling between the original oscillator and the new RF signal. This coupling manifests itself most often in the form of a beat frequency equal to the difference in the two oscillators frequency calibration.

The most common cure is to simply remove the original crystal from the transmitter, or disabling the power supply to the oscillator. This will prevent beat frequencies, and is minor enough modification to allow quick replacement should the original oscillator be needed in an emergency.

If the old oscillator should be required due to a failure in the AM stereo exciter, it would be nice to be able to quickly switch back to the original oscillator and return to the air, in monaural, until the problem can be resolved. This can be done fairly easily with a relay. Fig. 9 shows one possible implementation of an RF switching circuit. Notice the extra relay contact used to remove the power from the original oscillator during normal stereo operation. Again, this eliminates the possibility of beat frequencies.

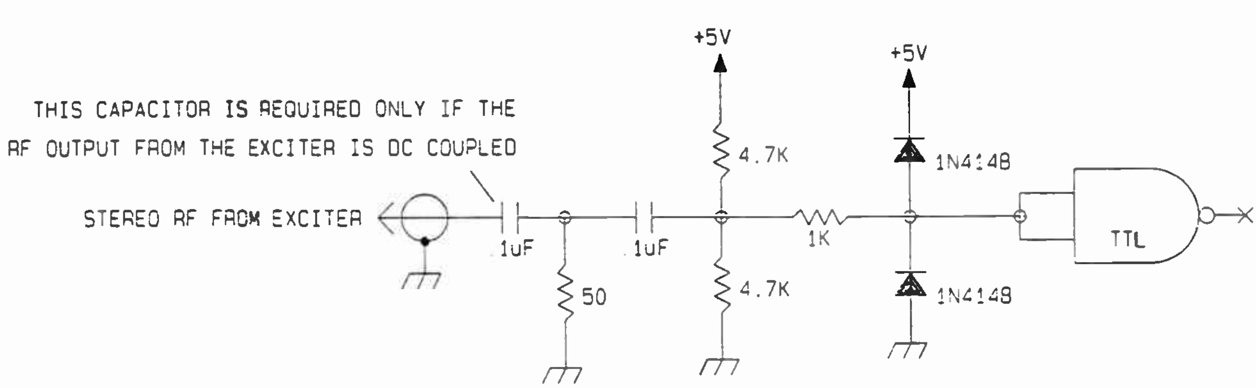

Figure 8. TTL RF interfacing.

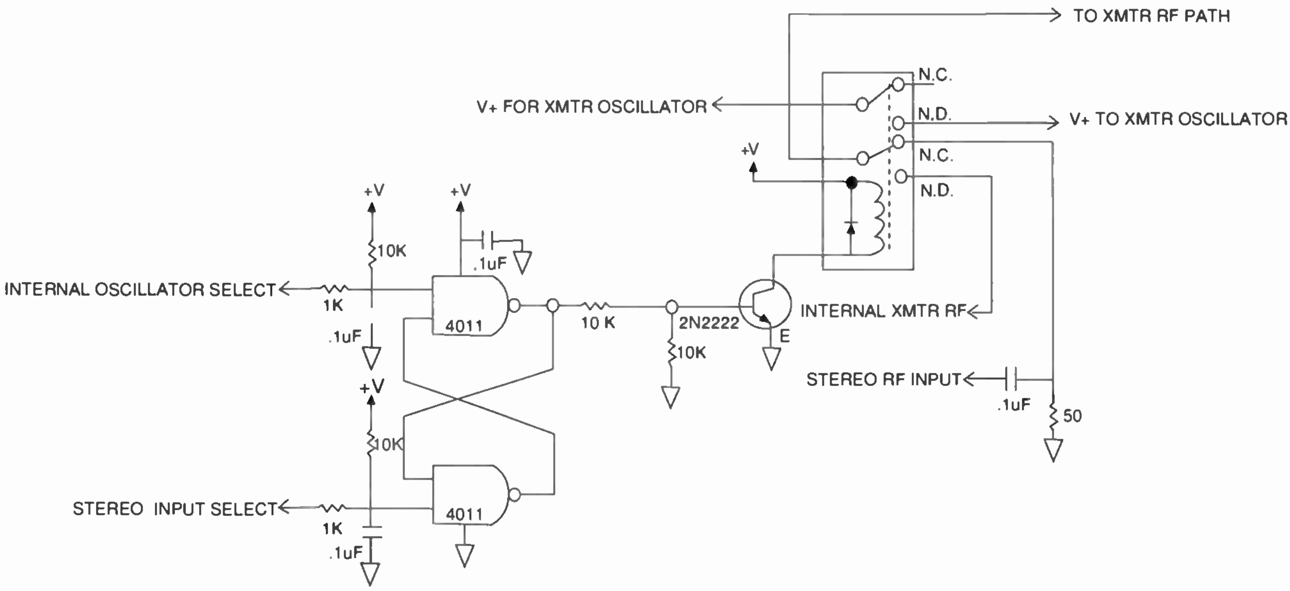

Figure 9. Mono/stereo emergency switching.

Audio Interfacing

The left and right channels must be connected to the exciter, and the levels set according to the manufacturers recommendations. The existing monaural input to the transmitter should be replaced by the monaural output from the AM stereo exciter. All audio connections should be made using a high quality shielded cable, such as Belden 8451. This is important to prevent RF pickup on the cable. To prevent ground loops, ground the shield at only one end.

AM STEREO EQUALIZATION

Now that all the necessary pieces are in place, the final part of the AM stereo installation can begin. Since half of the stereo information is contained in the monaural (L + R) connection to the transmitter, and the other half is in the form of phase-modulated RF (L − R), they must arrive at the modulator portion of the transmitter at the same time. This is required so that proper left and right channels may be recovered in the receiver after dematrixing. The amount of amplitude and phase (delay) matching required at the transmitter's modulator to produce a given amount of stereo separation after dematrixing can be seen by referring back to Fig. 2.

Without proper audio equalization, both stereo separation and distortion would suffer. Unfortunately, the amount of delay and amplitude equalization required for one type of transmitter is different from any other. In addition, the circuits in the transmitter which cause the problems are generally complex, so the best that any AM stereo exciter equalizer can do is to approximate the response shape. The effectiveness of the equalizer is dependant on the type of transmitter and the complexity of the antenna pattern at any given station.

For these reasons it is clear to see why there are no firm rules to follow during equalization. It is often a trial and error routine, especially at the higher audio frequencies where the response shape is most complex. If an AM stereo exciter were designed specifically for one brand of transmitter, it would be possible to equalize the two paths almost perfectly, but since it is a generic conversion tool, it can, at best, only come close.

Types of Equalization

There are three different equalization sections in an AM stereo exciter. Each is intended to fix a particular frequency range. Some installations require all three, others only two, and very rarely, only one will be needed.

Group Delay

The first section which is almost universally required is commonly labeled the group delay equalizer. Its purpose is to provide a constant time delay to either the L + R or L − R paths, depending on which one arrives at the modulator first. It is primarily used to equalize the low to mid frequencies (up to a few kilohertz). If the response shape of the offending path in the transmitter is low pass (or band pass for the RF path), the time delay for the lower frequencies will be constant, so the alternate path can include this equalizer to compensate adequately.

A common example would be any AM transmitter employing pulse width modulation (PWM), in which case the L + R path would include a PWM low-pass filter in the modulator just ahead of the RF amplifier. The L + R audio will have significantly more delay than the L − R (RF phase modulation) path. In this case, the group delay equalizer would be added to the L − R path to slow it down so that it arrives at the RF amplifier at the same time the L + R signal does.

On the other hand, some transmitters will have more low/mid-frequency delay in the L − R path due to several RF interstage band-pass filters. In this instance, the group delay equalizer would be added to the L + R path to compensate.

Low-Frequency Equalization

The second type of equalizer found in the exciter is the least often used section. It is only necessary if the low-frequency response of the L + R path is nonuniform. This is found primarily in older plate modulated transmitters where the reactance of the plate transformer causes phase, and to a lesser degree, amplitude nonlinearities.

Some transmitters will also include an active audio high-pass filter in the monaural input. This can also be effectively corrected by the low-frequency equalizer.

High-Frequency Equalization

The third audio equalizer is designed to approximately complement the complex high frequency response shape of most AM transmitters. The amount and shape of high frequency correction varies greatly from transmitter to transmitter, which makes this section the most difficult adjustment of the installation process.

Since this section is only meant to approximate the high-frequency amplitude and delay characteristics, it will not correct at all frequencies. It is not uncommon to be caught in a seemingly endless loop of adjusting for one frequency, only to find out you have made another frequency worse. The key to a successful installation is the ability to recognize a good overall compromise, and once you have, to quit. This is one area where a good engineering consultant with AM stereo installation practice will be helpful.

Fig. 10 shows the various equalization adjustments found on one C-QUAM AM stereo exciter. Notice the additional set of equalization labelled "Night." This is useful for stations utilizing a different transmitter, antenna pattern, or both for part of the broadcast day.

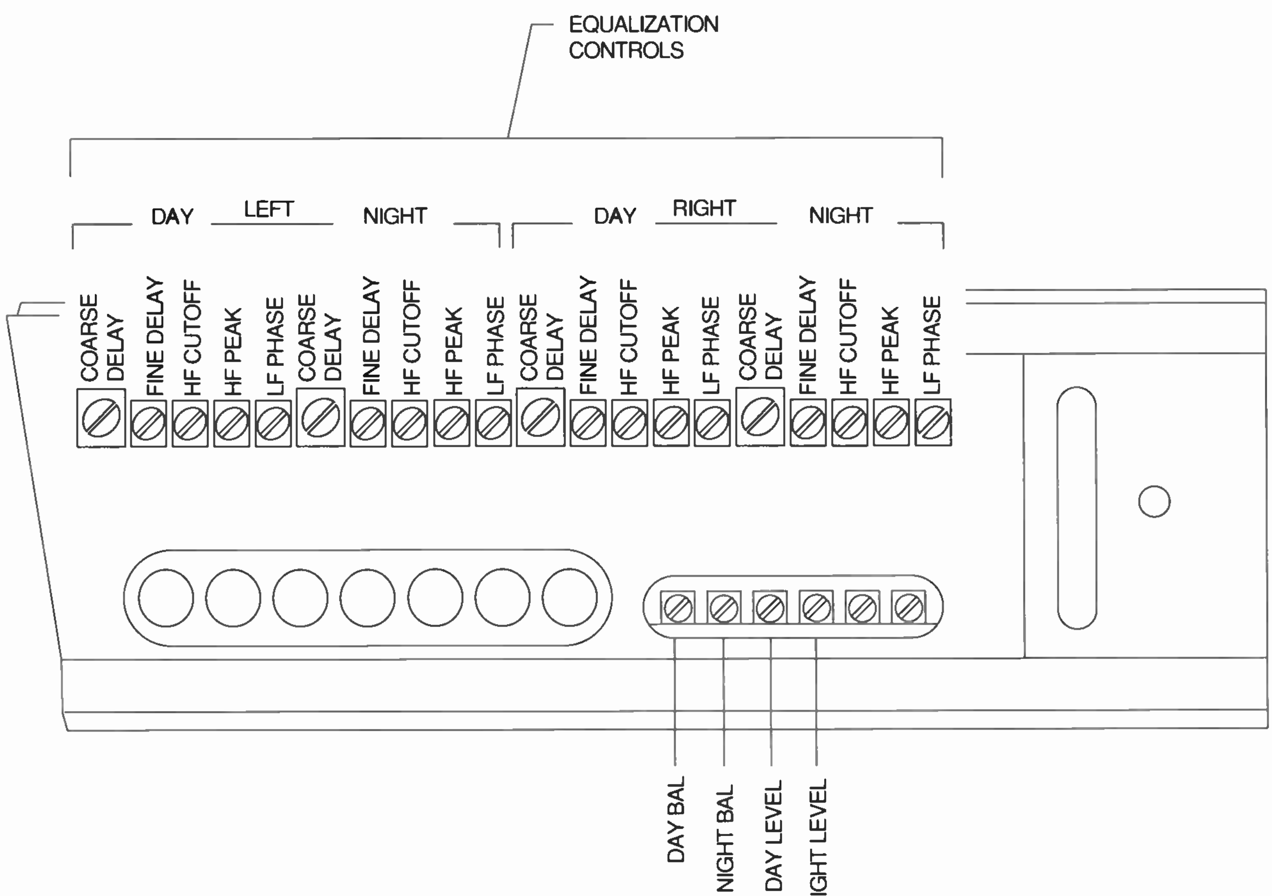

Figure 10. Broadcast Electronics Model AX-10 stereo equalization.

It can also be used to equalize an emergency backup transmitter.

Equalization Path Selection

The proper alignment of the three equalization sections is the key to high-quality AM stereo. However, before they can be adjusted, they must be inserted into either the L + R path or the L − R path, depending on where they are needed.

For someone with an intimate knowledge of the design of a particular transmitter, it may be possible to know for sure which path needs which equalizer. However, it is also possible that unique antenna characteristics could change what would be necessary into a 50 ohm resistive load. What results is a "try it and see" method. It may be necessary to change paths during the installation procedure as other equalizer sections are included. This will happen when, for instance, the inclusion of the high-frequency equalizer in series with the group delay equalizer actually forces the constant delay to be added to the other path to compensate for low- and mid-frequency delay found in the high-frequency equalization.

Fig. 11 shows one method of selecting the proper path for any equalizer. This matrix switch is a flexible patch bay approach to inserting equalizers in series or parallel into either the L + R or L − R paths.

Equalization Procedure

Fig. 12 outlines a typical test setup required for AM stereo equalization. Test equipment required for an adequate installation can be as simple as a low distortion audio oscillator/analyzer, an AM stereo modulation monitor, and a dual trace oscilloscope with X − Y capability. In addition, a spectrum analyzer capable of resolving audio sidebands at the AM band frequencies can be very useful, but is not mandatory.

The X-Y Oscilloscope

The fundamental problem in AM stereo is determining the type and path of equalization required. In

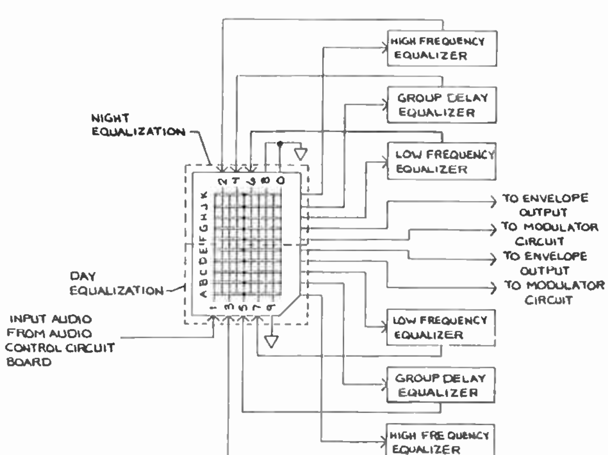

Figure 11. Broadcast Electronics Model AX-10 matrix switch.

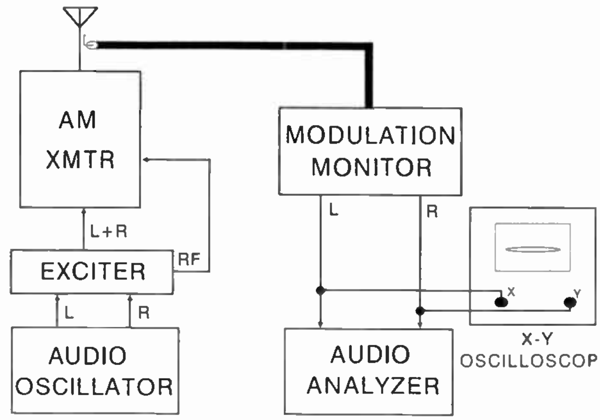

Figure 12. Stereo equalization test setup.

addition, it is necessary to determine if the system requires phase or amplitude equalization. A dual trace oscilloscope operating in the X − Y or Lissajous pattern mode is capable of resolving between amplitude and phase errors (or a combination thereof), as well as showing a multitude of additional information such as harmonic distortion, IPM, negative limiting, modulation compression, and so on. To the trained eye, it is one of the most useful tools in AM stereo installation. Without this tool, it would be almost impossible to equalize the system.

AM Stereo Modulation Monitor

The final performance results of a stereo installation will only be as good as the equipment used to measure them. One of the most critical pieces of test equipment for proper installation, and just as important, routine maintenance, is the AM stereo modulation monitor. It should be a high quality piece of test equipment, and simple to use.

Fig. 13 is a picture of one commercially available monitor that incorporates a high-quality C-QUAM decoder for high-performance stereo decoding. In addition, the use of an RF AGC insures constant decoder performance over fluctuations in RF input level. Front panel audio monitoring connectors and autoranging meters simplify the job of installation and maintenance.

An Equalization Example

AM stereo exciters will have similar equalization adjustments, but may be labelled differently. The *day* adjustments are used, however, the *night* procedure is identical.

The first adjustment to be made is to set the exciter's L + R, or envelope, level to get the correct amplitude modulation for a corresponding L = R input. This is, at this stage, only a coarse adjustment. It can be done at any convenient modulation percentage. For instance, input 1 kHz L = R to the exciter such that the L + R meter on the exciter reads 80%. Then adjust the envelope output level of the exciter until the transmitter is modulating 80% as measured on the modulation monitor.

Figure 13. Broadcast Electronics Model AS-10 C-Quam AM stereo modulation monitor.

Next, apply a 1 kHz tone to the input of the left-channel only, at a level equivalent to 50% amplitude modulation. The oscilloscope should show a horizontal line (assuming the 'X' input is the left channel). Most likely, it will be neither exactly on the X axis, nor a perfectly straight line. Fig. 14A shows a typical display. If a display similar to Fig. 14B is seen, the polarity of the L + R connection to the transmitter is wrong. This can easily be fixed by reversing the plus and minus terminals at the transmitter input. Fig. 14B actually shows the high second-harmonic distortion produced when the polarities of the amplitude modulation and phase modulation are not correct.

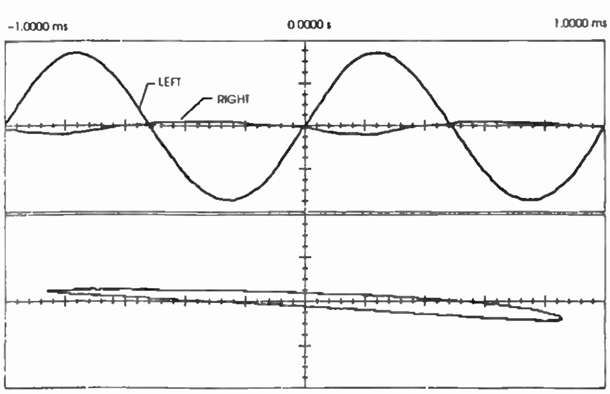

Figure 14A. Typical left channel only display before equalization.

Next, the fine adjustments to maximize separation can be made. While monitoring both the residual right channel separation and the oscilloscope, insert the left channel group delay in either the L + R or L − R path (Fig. 11) and adjust the coarse group delay. If the display opens up (Fig. 15) rather than closes, and the separation worsens, it has been inserted in the wrong path. Reverse the location and adjust the coarse and fine group delay until the display closes (Fig. 16). Then, fine tune the envelope level until the display lies exactly on the X axis and the left to right channel separation nulls (Fig. 17).

Apply a 1 kHz tone to the input of the left-channel only, at a level equivalent to 50% amplitude modulation. The oscilloscope should show a vertical display with only phase error. Insert the right channel group delay in the same path as the left channel and adjust until the display closes. The residual separation in the left channel will also null. Theoretically, the envelope level adjustment should not have to be adjusted for the right channel, but often the right to left separation can be improved slightly by fine tuning the level, at the expense of left to right separation. It is best to

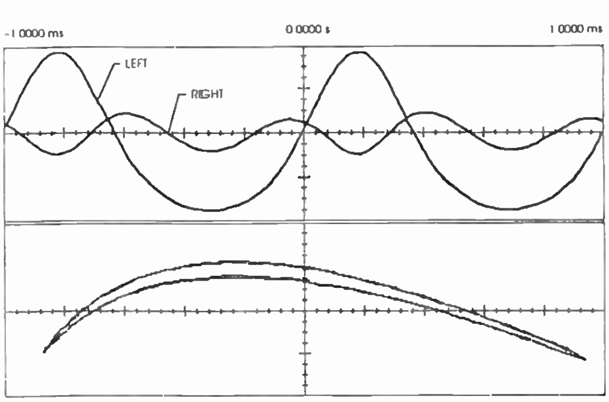

Figure 14B. X-Y display caused by improper L + R polarity at transmitter.

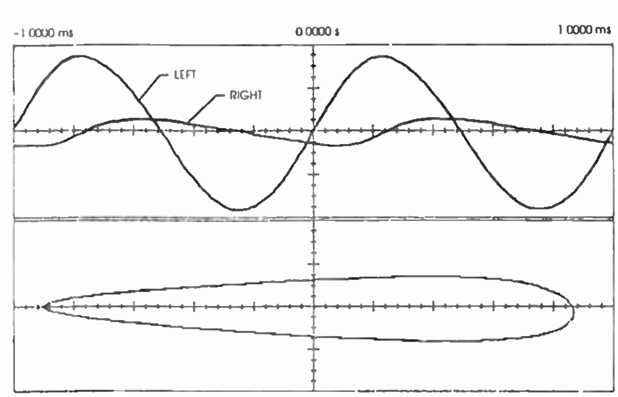

Figure 15. Left channel only with phase equalization error.

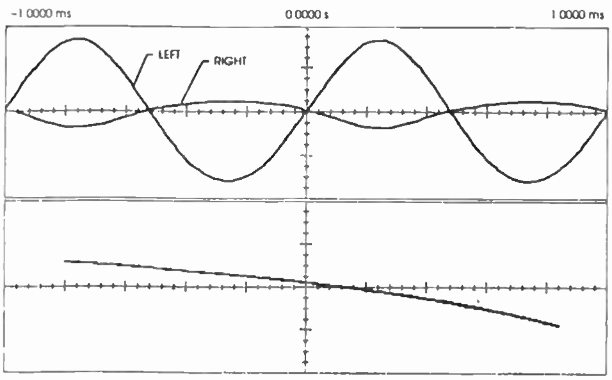

Figure 16. Left channel only with amplitude equalization error.

compromise the two to obtain the same amount of separation left to right as right to left. Some exciters are equipped with a balance control to help this problem. Refer to the individual service manual for the correct adjustment procedure.

The next step is to check the low-frequency separation. A good frequency to look at is 100 Hz. If the separation has degraded significantly, the low frequency equalizer can be used to correct the problem. Again, this is usually only necessary in plate modulated transmitters, or ones which employ low level audio input high-pass filters. The procedure is very similar to the group delay adjustment.

If low-frequency equalization is used, recheck separation at 1 kHz and adjust the group delay, if necessary, to compensate.

At this point, the transmitter should be equalized for good separation (30 dB to 40 dB) from 50 Hz to a few kilohertz. A quick check of separation at 5 kHz to 10 kHz will most likely show a rapid degradation in separation performance.

With the left channel high-frequency equalization controls set at minimum, insert the HF equalizer in one of the paths. Input 7.5 kHz left channel at a level sufficient to produce 50% envelope modulation. Observe the oscilloscope display while adjusting the HF cutoff control. If the phase degrades (display opens), then switch the paths. If it improves, adjust until it closes. Input 1 kHz and readjust the group delay to compensate for the added mid-frequency delay, and repeat until 1 kHz and 7.5 kHz are equalized for phase.

If the display at 7.5 kHz is not on the X axis, adjust the HF peaking and then the HF cutoff until the display lies on the X axis with minimum phase error. Again, adjust the group delay control at 1 kHz to compensate and repeat the procedure until maximum separation is achieved at both 1 kHz and 7.5 kHz. Repeat the procedure for the right channel.

Once this is done, spot check the separation performance from 1 kHz to 10 kHz. Using good judgement, it may be necessary to compromise the performance at 7.5 kHz to improve it elsewhere. The procedure is identical with the exception of X kHz in place of 7.5 kHz. While there is no such thing as a typical proof, it should be possible to achieve greater than 20 dB separation out to 10 kHz.

The Stereo Proof

When satisfactory separation performance is obtained, the final step in the AM stereo installation is to run a full proof of performance, both monaural and stereo. In particular, pay attention to high-frequency distortion. It may be necessary to fine tune the equalization to reduce distortion at the expense of a few dB of separation. An acceptable proof should show less than 3% THD and greater than 20 dB separation at all frequencies. This proof is a valuable tool during routine maintenance to gauge performance and to assess whether the equalization needs adjusting.

ROUTINE MAINTENANCE

Any change in the transmission system amplitude or phase response will cause a degradation in stereo performance. These changes will occur for several reasons; including seasonal environment changes, routine transmitter tuning, and vacuum tube variations over its lifetime.

It is a good practice to include a spot check of stereo performance as a routine maintenance item. This should be done at an interval of no more than every six months. Left unattended, these normal system variations can cause a serious degradation in audio quality, but a small time investment will insure continued high-quality AM stereo performance.

SUMMARY

Properly installed, AM stereo can offer many advantages to the AM broadcaster with the ever increasing pressure for high fidelity audio. Good planning, execution and follow up to the installation, are essential to avoiding the creation of new problems.

APPENDIX A

INDEPENDENT SIDEBAND AM STEREO

Leonard R. Kahn
Kahn Communications, Inc., Carle Place, New York

INTRODUCTION

Under good reception conditions, and with wideband AM receivers, AM stereo systems can provide performance virtually equivalent to FM.

AM broadcasting's major strength is its superior coverage (for Class I and II stations), which is due to its frequency band and the modulation method which allows acceptable reception under poor signal-to-noise and signal-to-interference conditions. Wideband FM trades bandwidth for improved signal-to-noise performance under good signal-to-noise and interference reception conditions. FM is not, however, noted for its good performance under poor reception conditions.

The ISB stereo system is a frequency separation system and is free of phase sensitivity. It is able to utilize a stereo decoder that remains in stereo under all conditions of reception.

FUNDAMENTALS OF ISB AM STEREO

The Kahn/Hazeltine AM stereo system is an independent sideband (ISB) system wherein the L stereo channel information is transmitted by the lower sideband, and the R stereo channel information by the upper sideband. The envelope of the wave is a linear function of L+R. A suitable stereo receiver for the Kahn/Hazeltine system is essentially an ISB receiver, and stereo separation is determined by the frequency of sidebands relative to the carrier. Thus, the Kahn/Hazeltine system is properly designated as a "frequency separation" system. The stereo separation characteristic of the Kahn/Hazeltine system is not a function of the phase of the carrier component relative to the sidebands, as is the case in other AM stereo systems, which may be described as "phase separation" systems.

Basic structure:	**Independent sideband**
Stereo information provided by:	Frequency separation Left Lower SB Right Upper SB
Pilot:	15 Hz, 0.1 radian
Envelope function:	L+R
Preferred receiver stereo decoder:	Uses inverse modulation by L+R function

One of the basic disadvantages of an AM wave (and, indeed, FM waves) is that the sidebands must be properly phased relative to the carrier. Accordingly, any phase anomaly in the path of the AM wave, such as narrowband antennas, antenna null areas, close-in fading, reradiation from power lines and buildings, off-tuned receivers, and co-channel interference can create a phase shift between the carrier and the sidebands. This can cause (1) loss of desired envelope modulation, and (2) envelope distortion.

ISB AM stereo signals can be received under fading conditions, in antenna nulls, and also under co-channel interference, in some cases over that of conventional AM monophonic transmission. The reason for this is that, for an undistorted, fully-modulated envelope, sidebands need not be symmetrical in an ISB stereo transmission.

Referring to Fig. A-1, it is seen that for a conventional AM wave, when the carrier is shifted relative to the sidebands by 90° the fundamental component of the envelope modulation disappears. This is true for all odd multiples of ±90° (i.e., ±90°, ±270°, ±450°, . . .). Thus, when an envelope detector is used, the distortion is infinite. With a synchronous demodulator, the distortion is indeterminent because while there is no distortion, there is also no signal. The phasor diagrams in Fig. A-1 illustrate the effects of carrier/sideband phase errors on conventional AM signal and the worst case condition of a form of ISB AM stereo.

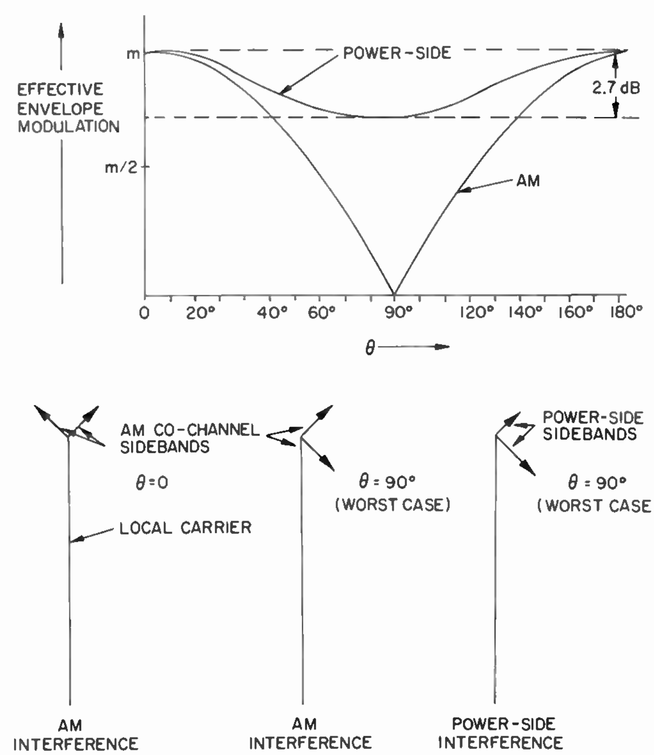

Figure A-1. Phasor diagrams for conventional AM wave and a form of ISB AM stereo wave, showing effect of carrier-to-sideband phase shift.

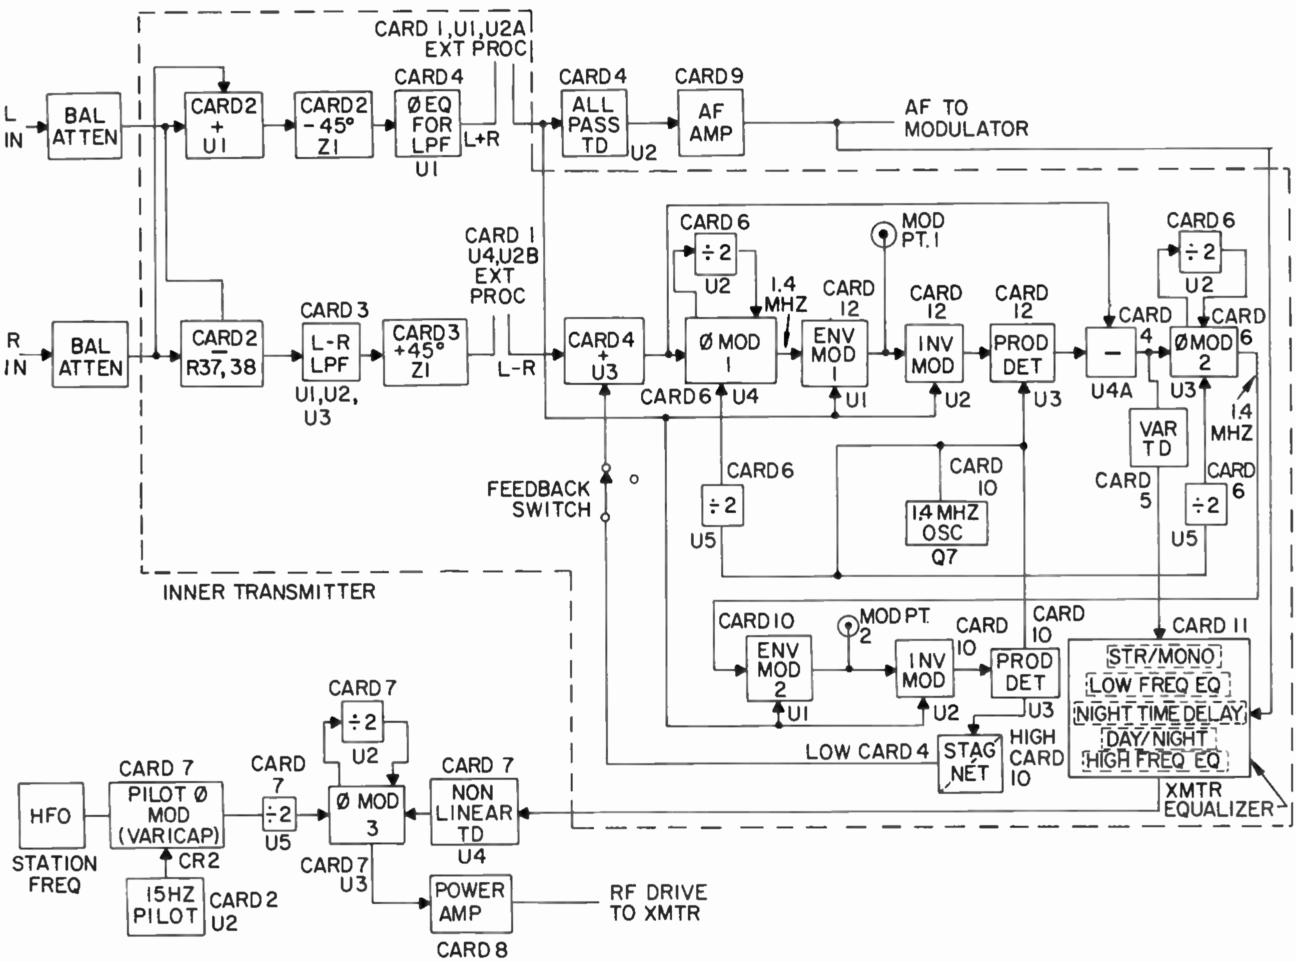

Figure A-2. Block diagram of Kahn/Hazeltine Model STR-84 Independent Sideband AM Stereo exciter.

DESCRIPTION OF ISB AM STEREO

Fig. A-2 is a block diagram of an ISB AM stereo exciter. Included in the following description is a brief analysis of the spectrum and distortion characteristics of this equipment.

Most of the blocks shown in Fig. A-2 are enclosed in dotted lines. These blocks comprise the "inner" two low-level transmitters. Both transmitters operate at 1.4 MHz, unless the station's operating frequency is too close to 1.4 MHz to avoid spurious problems. The output of the second inner transmitter is a low-power, low-distortion AM Stereo signal.

The circuitry outside the dotted lines serves three basic functions:

1. Allows the input signal to be adjusted to the proper level for the inner transmitters.
2. Preconditions the L + R and L − R signals fed to the station's transmitter so as to cause the station's transmitter to track the performance of the second inner transmitter, thereby producing a low distortion AM stereo signal.
3. Produces a 3-watt phase-modulated signal with the necessary L − R component and 15 Hz stereo pilot.

The L and R inputs are fed to attenuators, which in turn feed sum and difference networks. The output of the sum network, the L + R wave, feeds a phase equalizer. The phase equalizer matches the phase characteristic of the low-pass filter in the L − R channel, which ensures that under all conditions of modulation, adjacent channel interference is not significantly increased and all occupied bandwidth regulations are fully met.

The output of this equalizer feeds a phase-difference circuit. This all-pass network, in conjunction with the all-pass phase shift network in the L − R path, provides a constant phase difference of approximately 90° over the desired stereo frequency range.

The output of the phase-shift network feeds an output terminal which may, in turn, feed an external L + R audio processor.

If external audio processing is not utilized, the phase-shift network can be connected directly to a time-delay circuit, which in turn feeds the audio input circuit of the external transmitter. An advantage of providing system compatibility with an L + R audio processor is that any waveform characteristics imparted to the L + R wave (such as clipped peaks) can reach the transmitter without tilting the envelope of the transmitted wave. On the other hand, any clipping of the L and R waves fed to the input of the exciter will generally cause tilting of the audio wave. Therefore, audio clippers or asymmetrical modulation circuits should only be used in the designated external processor ports or *after* the exciter.

The output terminals for the composite L + R limiter feed a fixed time-delay circuit. This delay circuit is provided to cause the net delay in the overall L − R path (including the RF circuits of the associated transmitter) to be less than the delay in the overall L + R path (including the modulator circuits in the associated transmitter), by an amount that falls within the adjustable range of the variable time-delay circuit in the L − R path.

The output of the time-delay circuit feeds a DC coupled amplifier (including protective clipping circuits), which in turn feeds the associated transmitter.

The L − R path, is more complex than the L + R path. The L and R inputs feed the linear difference circuit. The output of the difference circuit feeds a low-pass filter, which provides a flat response (±0.5 dB) up to 6.24 kHz and allows some separation up to almost 7.5 kHz. As mentioned above, this filter is provided to limit the L − R frequency response to restrict adjacent channel interference which would be caused by the second order sideband component necessary for envelope detector compatibility.

The output of the LPF is fed to a phase network which, as mentioned above, provides, in cooperation with the phase network in L + R path, a quadrature relationship between the L − R and the L + R audio waves. The output of the phase network may be fed to an outboard composite processor which functions in cooperation with the composite limiter in the L + R path. The output of the external L − R processor limiter in the L + R path. The output of the external L − R processor feeds a summation circuit.

Assume, for example, that negative feedback is absent (i.e., the feedback switch is in the open position). The L − R, without any feedback term at the output of the summation circuit, feeds the phase modulator. Also feeding the phase modulator is a divide-by-two frequency divider, which in turn is fed by a 1.4 MHz crystal oscillator. The phase-modulated output of the phase modulator is a 1.4 MHz because this phase-locked-loop (PLL) circuit also incorporates a divide-by-two frequency divider, resulting in a frequency multiplication of two. The output of the PLL phase modulator is amplitude modulated by the L + R audio wave. When the proper amounts of phase modulation and amplitude modulation are provided, a wave having an ISB structure is produced. For a 1 KHz L-only signal, the upper sideband will be approximately 25 dB stronger than the lower sideband.

Fig. A-3 shows the spectrum calculation of *MOD PT. 1*, which monitors the output of the first inner loop transmitter. This calculation assumes the feedback path is open, the envelope modulation is 50%, and 0.5 radian of phase modulation is present. It is also assumed that the timing of the two components is perfect (i.e., no relative timing error). It is noteworthy that for L-only modulation, the upper sideband is present and the sidebands are reversed. As will be seen below, this situation is corrected at *MOD PT. 2*. Also, note that while the second order undesired sideband is only 29.7 dB below the modulated carrier (30.2 dB below the unmodulated carrier), theoretically the first order undesired sideband is fully suppressed. The fact that there can be complete suppression of the first order undesired sideband can be recognized by considering the following relationship between J0, J1, and J2, which are Bessel functions of the first kind.

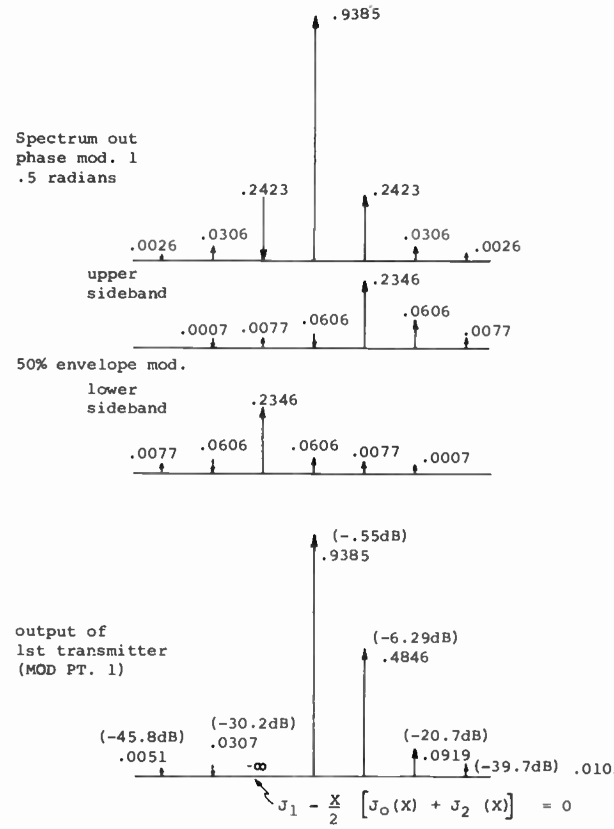

Figure A-3. Spectrum calculation of *MOD PT. 1*, which monitors the output of the first inner loop transmitter.

$$\frac{X}{2}\left[J_0(X) + J_2(X)\right] = J_1(X)$$

The above equation may be verified by examining the power series that define these Bessel functions. (It is noteworthy that this relationship can be used accurately to measure phase or frequency modulation where the value of X is less than one radian. If envelope modulation can be accurately measured to 100% and a spectrum analyzer is available, or some other means for measuring the first-order undesired sideband, it is only necessary to envelope modulate the phase or frequency-modulated wave and measure the amount of envelope modulation that causes the first order sideband to disappear.)

The output of the first transmitter is fed to the first simulated receiver. The simulated receiver incorporates a decoder and, accordingly, the wave from the amplitude modulator is inversely modulated. The output of the inverse modulator feeds a quadrature demodulator comprising a 90° phase shifter, which shifts the phase of the 1.4 MHz carrier wave, and a product demodulator, which multiplies the inverse modulated output with 90° phase shifted IF carrier. The audio output component of the product demodulator has approximately 12% of harmonic distortion. If this L − R component is combined with a distortion free L + R component, the total distortion would be about 6%. This distortion is reduced later in the system to substantially below 1%. The audio signal is then fed to a linear difference circuit which combines the audio out of the simulated receiver with a sample of the L − R wave which was fed to the first inner transmitter.

This L − R wave is 180° out of phase with the fundamental component of the audio wave at the output of the simulated receiver. The level of this undistorted L − R wave is made equal to twice the level of the fundamental component from the simulated receiver. This puts the distortion out of phase with the original wave from the simulated receiver and maintains the original distortion percentage. This operation also inverts the sidebands so that a left stereo signal is transmitted as a lower sideband.

The audio wave is then fed to a second inner transmitter comprising a phase modulator and an amplitude modulator. This second inner transmitter also operates at a frequency of 1.4 MHz.

The output of the second inner transmitter (available at *MOD. PT. 2*) has a much cleaner overall spectrum than the output of the first inner transmitter.

Fig. A-4 shows calculations for the spectrum characteristics at *MOD. PT. 2*, the output of the second inner transmitter. The output of the station's transmitter should match this spectrum, assuming the use of a low distortion transmitter with proper equalization. The spectrum output of the second phase modulator (PM_2) was determined by performing a Fourier analysis of the following equation:

$$PM_2 = \sin[w_c t + 0.5(-\cos w_A t - 0.023\cos 3w_A t)]$$

The spectral output components of PM_2 are shown in Fig. A-4 where the wave is amplitude modulated (lines 2 & 3) and the summation is shown (line 4) for each spectral component.

The actual amount of distortion can be determined by referring to Fig. A-5. The initial line is copied from the bottom line of Fig. A-4 and is the output spectrum of the second inner transmitter. This wave is inverse modulated by slightly over 26%. The resultant wave at the output of the inverse modulator is shown on the

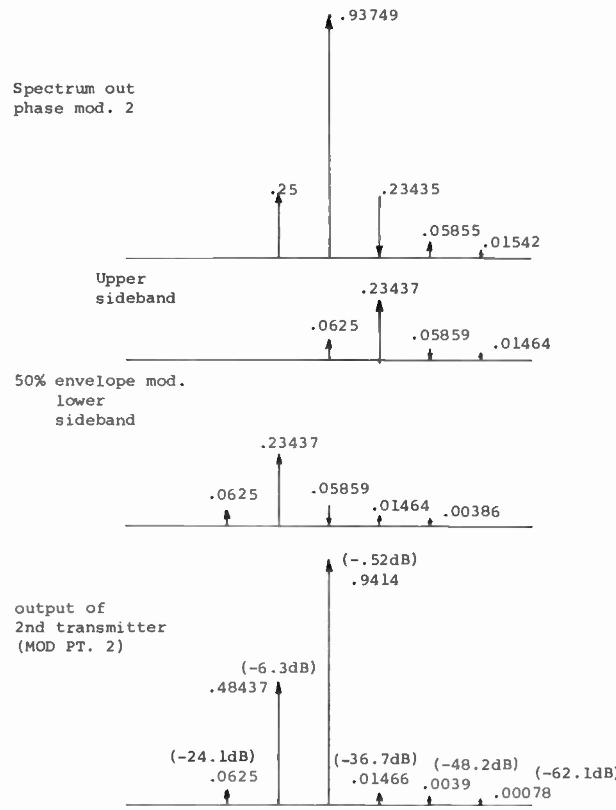

Figure A-4. Calculations for the specturm characteristics at *MOD PT. 2*, the output of the second inner transmitter.

bottom line. This wave is quadrature demodulated to derive the L − R signal. This calculation is shown at the bottom of Fig. A-5 indicating a total RMS second and third harmonic distortion of 2.01%. However, to determine the overall L- or R-only distortion, the figure can be reduced by a factor of 2 if we assume a perfect envelope detector is used to demodulate the envelope and obtain the L + R component. (Envelope detectors are available with distortion figures of less than 0.1%)

Accordingly, a total distortion figure of 1% can be achieved, without the negative feedback circuit in operation. With 10 dB to 12 dB of negative feedback in the L − R path, the total distortion is in the range of 0.25 to 0.3%. In practice 0.6% distortion figures have been obtained with inexpensive, though good quality, ISB AM stereo receivers.

Returning to the description of the overall block diagram of Fig. 2, the audio output of the second simulated receiver is used in a negative feedback circuit and is connected to the feedback switch. When the feedback switch is closed, the audio feedback wave is fed to the combining circuit which, in turn, feeds the first phase modulator. The result is that the proper L − R component is generated to produce a low distortion signal when demodulated by an appropriate AM stereo receiver.

The special audio that is fed to the second phase

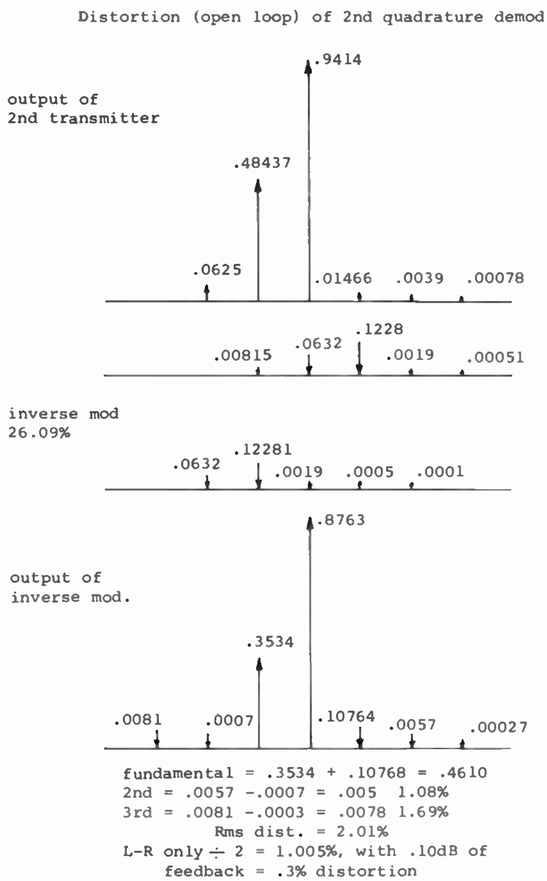

Figure A-5. Resulting distortion in the output of the inverse modulator.

modulator is also fed to the third phase modulator which operates at one-half the carrier frequency.

A divide-by-two circuit is inserted after the phase modulator of the PLL, causing the voltage-controlled oscillator to operate at the desired carrier frequency. The L − R audio wave is also passed through a day/night equalizer circuit. The L − R audio wave is passed through a variable time delay, and this time-delay circuit can be adjusted so that the overall time delay in the L − R path equals that in the L + R path including, of course, the delays in the associated transmitter. The audio is then passed through an adjustable, nonlinear time-delay circuit which, in turn, feeds the third modulator. The resulting phase-modulated wave is fed to a tuned RF amplifier, which produces three to four watts at the station's carrier frequency. It is noteworthy that no mixing circuits are used to produce the output phase-modulated wave. This significantly reduces the requirements of the filtering circuits normally provided to maintain low spurious heterodyne products when conventional frequency translation circuits are needed.

The output of the tune RF amplifier is used to take the place of the crystal oscillator in the station's AM transmitter. When this phase modulated wave is properly combined with the L + R modulations at the normal audio input of the transmitter, a specially contained, low distortion ISB wave is produced, similar to the wave observed at *MOD PT. 2*.

APPENDIX B

MOTOROLA C-QUAM® AM STEREO SYSTEM

Greg Buchwald
Motorola Inc., Schaumburg, Illinois

C-QUAM SYSTEM EQUATIONS

Any broadcast signal can be broken into three major components: amplitude, frequency, and phase. The equation for a monophonic transmission can be described by:

$$E_R = (1 + L + R)\cos(\omega_c t + \phi)$$

where 1 represents the carrier, L + R represents the monophonic (or Left and Right) information to be sent, $\omega_c t$ represents the carrier frequency, and ϕ represents phase modulation information which is, ideally, zero.

In fact as one uses ±100% modulation of L + R as an example and substitutes ±1 into the equation, it is obvious that at L + R = +1, the carrier level is instantaneously twice as high and at L + R = −1, the carrier level is instantaneously 0.0, or cutoff has occurred. From this equation it is also obvious why negative modulation is limited to 100% while positive modulation can exceed 100%. In the United States, the positive limit is 125% or 1.25 in the equation.

To insert stereophonic information, one could alter the amplitude, frequency, or phase of the transmitted signal. Altering the amplitude is to be avoided since the envelope would no longer represent 1 + L + R, but instead, a distorted component containing L + R. Substantial alteration of the frequency is also to be avoided. This leaves only the phase component available for modulation.

One method of adding a second channel of information to an existing carrier and utilizing the same spectral assignment is to make use of *quadrature modulation* (QUAM) techniques. Linear QUAM, not unlike that used to convey the chroma information in NTSC color transmission, can be used to convey the second channel of information. Advantages of QUAM are:

- No increase in occupied bandwidth
- Little signal-to-noise (SNR) degradation
- No loss of existing coverage
- The potential for synchronous reception techniques

However, the major disadvantage is that the envelope term is not 1 + L + R, but, instead is:

$$\sqrt{(1 + L + R)^2 + (L - R)^2}$$

leading to high levels of distortion in current monaural, envelope detector receivers and some difficulty in the conversion of existing broadcast transmitters due to additional requirements placed on the modulator stage.

The C-QUAM system was derived from QUAM, therefore it retains, to a large extent, the advantages of QUAM. In fact, C-QUAM can also use synchronous detection techniques particularly when conditions warrant. One difference between the generation of the C-QUAM signal versus the QUAM signal is found in the envelope audio term. By substituting the distorted term required by QUAM with the simple summation of the left and right channels, the envelope is made compatible with existing receivers. Mathematically, the system has been designed as follows.

The equation for the QUAM signal is:

$$E_R = \sqrt{(1 + L + R)^2 + (L - R)^2}\cos(\omega_c t + \phi)$$

where: $\phi = \tan^{-1}\left[\dfrac{L - R}{1 + L + R}\right]$

The desired envelope component is:

$$E = (1 + L + R)$$

Motorola engineers found that the cosine of the instantaneous phase modulation is:

$$\cos\phi = \frac{1 + L + R}{\sqrt{(1 + L + R)^2 + (L - R)^2}}$$

If QUAM is multiplied by cos ϕ:

$$\frac{1 + L + R}{\sqrt{(1 + L + R)^2 + (L - R)^2}} \times$$
$$\sqrt{(1+L+R)^2 + (L-R)^2}\cos(\omega_c t + \phi)$$

Then the resultant is:

$$E_R = (1 + L + R)\cos(\omega_c t = \phi)$$

where: $\phi = \tan^{-1}\left[\dfrac{L - R}{1 + L + R}\right]$

In the process, the envelope term is made compatible by sending $1 + L + R$ while the inphase (I) and quadrature (Q) components are multiplied by $\cos\phi$. Therefore the broadcast C-QUAM signal has the following characteristics:

Envelope (E) =	1 + L + R
Inphase (I) =	(1 + L + R)cosϕ
Quadrature (Q) =	(L − R)cosϕ

It can be seen that the mono, $1 + L + R$, signal may be directly derived from the envelope detector output, while a quadratine detector combined with division by $\cos\phi$ may be used to demodulate the $L - R$. The art of demodulation of C-QUAM signal will be discussed later.

THE C-QUAM ENCODING SYSTEM

There are several forms by which the C-QUAM encoder may be implemented. In the first form, used at the time of this writing by Motorola and Delta Electronics, a series of linear, balanced multipliers is employed to generate a quadrature modulated signal. The signal is then amplified to the point of limiting in order to remove the QUAM envelope term. The

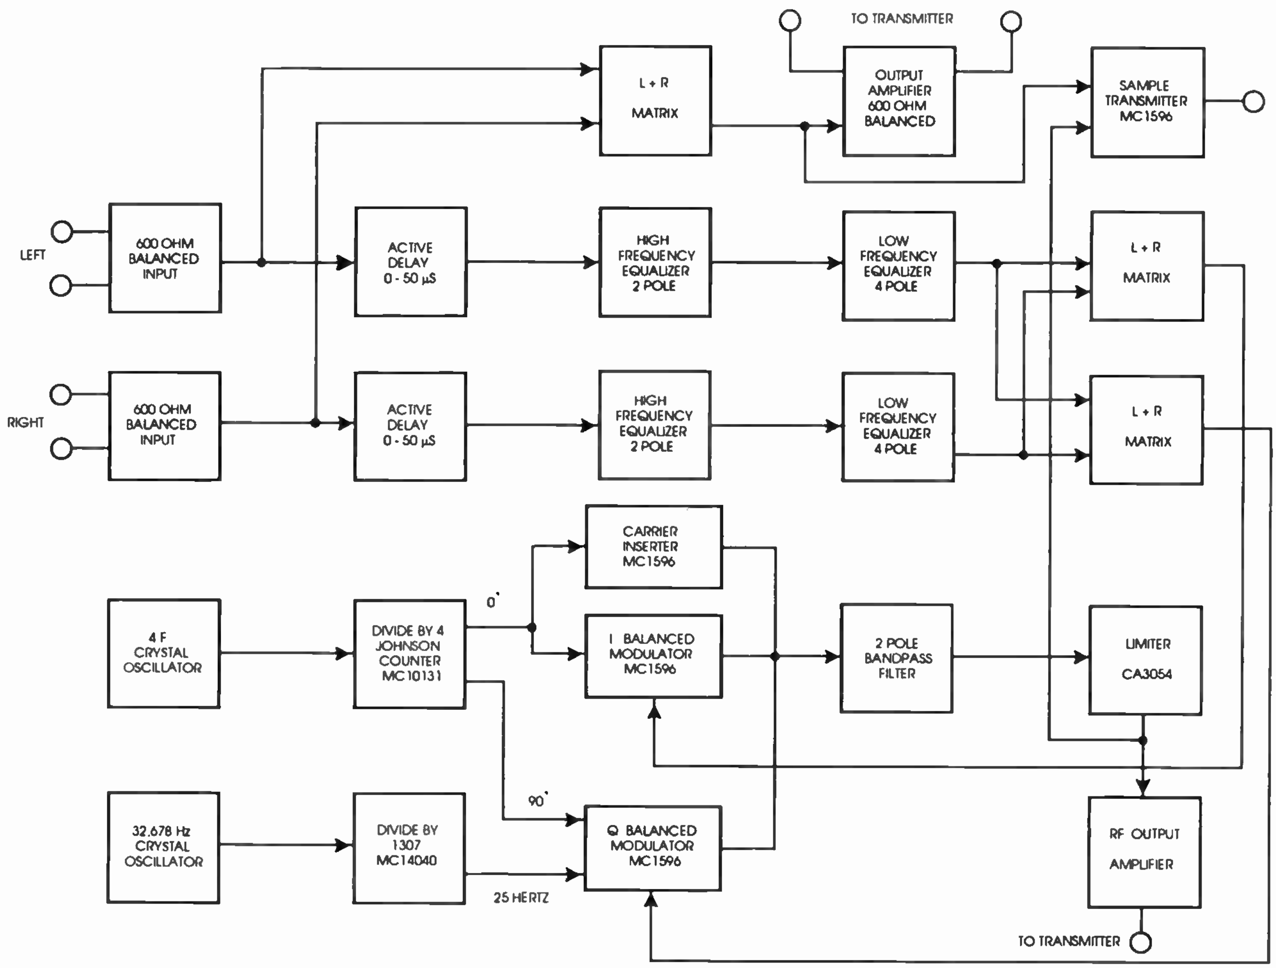

Figure B-1. Block diagram of C-QUAM exciter.

summation of the left and right channels provides a distortion-free monophonic audio term which modulates the transmitter. The resultant phase modulated signal is used to replace the crystal oscillator stage of the transmitter. The existing broadcast transmitter conveys the $L-R$ information in the form of complex phase modulation, and the envelope conveys the L + R information to both the existing monophonic as well as newer stereophonic receivers.

Other modulation techniques include the matrix switching method used by Harris Corporation and the Time Division Multiplex method used by Broadcast Electronics. The latter eliminates the need for audio matrices in the stereo modulator path.

To help visualize the generation of the signal, refer to Fig. B-1, the block diagram for the exciter. Since the linear, balanced modulator technique is the easiest to understand, it will be described herein. Interested readers are encouraged to study literature produced by other C-QUAM broadcast equipment manufacturers to obtain a full understanding of the various modulation techniques.

Beginning with the RF stages, a crystal at four times the carrier frequency ($4F_c$) is fed to a digital divider circuit which results in an output that is an on-frequency carrier signal at 0°, 90°, 180°, and 270°. These RF signals are utilized in pairs as differential references for three balanced modulators. The purpose of each balanced modulator is to supress the carrier feed-through and produce sideband information only when audio is present. It can be seen that the first two modulators are fed with the 0° and 180° reference signals. These modulators, therefore, produce an output referenced in-phase or synchronous to the carrier frequency. The third modulator is, conversely, fed with the 90° and 270° outputs from the RF divider and therefore forms a quadrature modulator stage. The first modulator is fed with a DC voltage which causes a precise offset from the null of the 0° carrier reference, thereby producing a precise DC carrier term at its output. The second modulator is fed with $L+R$ and therefore produces in-phase, $L+R$ modulation sidebands. The final modulator is fed with $L-R$ audio information and produces quadrature sidebands relating to the stereophonic information. It is important to note that the carrier-producing modulator is used in preference to simply unbalancing the in-phase ($L+R$) modulator for lower distortion.

The three balanced modulator outputs are summed and bandpass filtered to remove odd-ordered harmonics of the desired carrier frequency. Removal of odd-order harmonics prior to limiting is important since odd-ordered products represent a DC term which can unbalance the subsequent limiting stage, thereby introducing distortion. After bandpass filtering, the RF signal is amplitude limited by multiple stages which exhibit approximately 50 dB of limiting gain. The envelope component is therefore removed, leaving only the phase modulated carrier component. This constant amplitude RF signal is then further amplified to a level adjustable from zero to 30 volts, peak to peak. It is this amplified, constant amplitude carrier signal which is interfaced to the transmitter to create the composite stereo transmission.

Unlike FM stereo where a composite signal is fed into a wideband modulator input, the AM stereo signal is constructed at the power amplifier stage of the converted broadcast transmitter. A portion of the signal from the exciter enters the transmitter through an RF interface and follows one path to the RF power amplifier, while the remaining element, L + R, enters through the audio input terminals and follows a different path to the modulator where it is finally combined with the RF phase modulated information. Since two different circuit paths are used, the time delay along each path may be different, often by 40 μs or greater. This level of delay can be understood when one considers the phase shift through the low-pass filter in a conventional PDM transmitter which may exhibit a fifth or seventh order elliptical function. If the delay between the paths is not matched, both reduced separation and increased distortion will result. Loss of separation is easily understood since proper dematrixing of the audio signals in the receiver will occur only if the phase and amplitude of L + R and L − R are closely matched. The increase in distortion is a concept that can only be clearly understood when one examines the phase modulated component of the signal and finds that an L + R term is found in the PM component. If this L + R term does not match the envelope term, an increase in distortion would result. Therefore, the audio equalizer is a very important section of the exciter.

In the simplest form of equalization, a delay circuit in the audio path to the quadrature modulator section of the exciter would be utilized, thereby introducing time delay into the L + R and L − R audio fed into the QUAM generator so that it matches the L + R audio delay through the broadcast transmitter. Although adequate results will occur with this approach, a modification of this approach allows for additional correction of the signal to compensate for bandwidth or sideband symmetry problems commonly associated with broadcast antenna systems, particularly directional arrays.

A once-common form of single sideband generation particularly popular in the 1950s, utilized a scheme known as the "phasing method." The process was simple because one could simultaneously amplitude and phase modulate a signal, essentially generating a QUAM signal. If the processs is taken one step further so that both the RF terms and the audio terms fed to each modulator are shifted 90°, a single sideband transmission results without the use of expensive, sharp cutoff RF filters. The same holds true for AM stereo signal generation. If a small amount of phase shift is introduced into the audio, driving the phase modulated path of the transmitter with reference to the envelope audio path, the signal will take on an unsymmetrical sideband structure. If the antenna system exhibits an overall tilt towards the upper sidebands, for example, one would only need to predistort the signal so the the lower sidebands were favored in the transmitter, thereby restoring symmetry in the radiated signal.

The exciter can perform this task by inserting the delay sections into the left and right channels prior to matrixing. It is clear from Fig. B-1 that this is the case for most C-QUAM exciters. The audio is delayed independently in the left and right channels. It is then matrixed to produce L + R and L − R which feed the QUAM generator. An uncompensated summation of L + R is used to feed the external broadcast transmitter. Such equalization, known as differential equalization, can be quite powerful in correcting situations where asymmetrical antenna sideband radiation would otherwise limit stereo performance.

The audio equalizer is broken into several components. The first is the constant time delay circuitry which is used to compensate for the bulk of differential transit delays through the transmitter. The second section is the high-frequency equalizer which is used to compensate for additional phase shift (nonlinear group delay) characteristics in the broadcast transmitter audio path. These nonlinear delay characteristics are introduced by rolloff in the modulator stages, phase shift in PDM filters, and reflected antenna impedances. The final section is the low frequency equalizer which, not unlike tilt correction commonly found in audio processors and limiters, anticipates the phase shifting and amplitude rolloff action of modulation transformers, reactors, and coupling capacitors in older, plate modulated transmitters. By introducing a similar rolloff and phase shift into the phase modulated audio path, separation may be maintained at frequencies below 50 Hz.

The last section of the exciter to be discussed is the pilot generator. The pilot tone, a 25 Hz sine wave audio component, is injected into the L − R modulator at a 5% modulation level in the L − R channel. The purpose of the pilot tone is to indicate the presence of stereophonic information. This is different from the pilot tone signal in the FM stereo system where the 19 kHz signal is used as a synchronizing term in the demodulator. Indeed, AM stereo receivers could be built without the pilot tone detector, however, the consumer has grown accustomed to seeing a stereo indicator on the radio, hence it is incorporated into the system.

C-QUAM DECODING/RECEIVING TECHNIQUES

There are over a dozen ways to decode a C-QUAM transmission. The most common approach is the "feedback decoder" technique (Fig. B-2). In this drawing, there are three detectors: envelope, inphase, and quadrature.

The envelope detector demodulates the monophonic, L + R information. It may be a simple diode detector, however, most stereo demodulator integrated circuits utilize a limiter/multiplier approach which offers superior performance. Distortion mesaurements in the 0.1% to 0.3% region are commonly found at 99% negative modulation when this technique is used.

The inphase and quadrature demodulators are identical in action to the balanced modulators found in the exciter. Each has a reference signal, either 0° for the I detector, or 90° for the Q detector, and is phase locked to the incoming, received signal. However, referring back to the system equation, the actual received I signal is not $1 + L + R$, but instead, $(1 + L + R)\cos\phi$, and the received quadrature signal is $(L - R)\cos\phi$ rather than $L - R$ as desired. In a proper C-QUAM decoder, the incoming RF/IF signal must be divided by the term $\cos\phi$, generally prior to quadrature demodulation. In the feedback decoder, the divider stage accomplishes this task. The derivation of the $\cos\phi$ term conveyed in the phase modulated component is, however, an interesting process.

As indicated earlier, the I detector output would, since it is both phase and amplitutde sensitive, be $(1 + L + R)\cos\phi$ assuming no divider action. If the $\cos\phi$ component is eliminated from the I detector output, the I detector would produce a signal identical in theory to the envelope detector. Asssuming further that the I and Q detectors are fed from the same IF signal path, as $\cos\phi$ is removed from the I detector output, it is also removed from the Q detector output, leaving L − R as the result. Since it is known that the IF signal must be divided by $\cos\phi$, a divider stage is placed in the IF path feeding the I and Q detectors. If the output of the I detector is then analyzed against the envelope detector output in a high gain comparator, the resultant is $\cos\phi$. By connecting the output of the comparator to the control port of the divider, a feedback loop results which will cause the $\cos\phi$ signal normally found at the output of the I detector to be effectively transferred to the input of the divider. Since the IF path is therefore divided by $\cos\phi$, the Q detector performs the task of directly demodulating L − R.

The remaining circuitry in the decoder detects the pilot tone and dematrixes the $L + R$ and $L - R$ audio terms into the original left and right components.

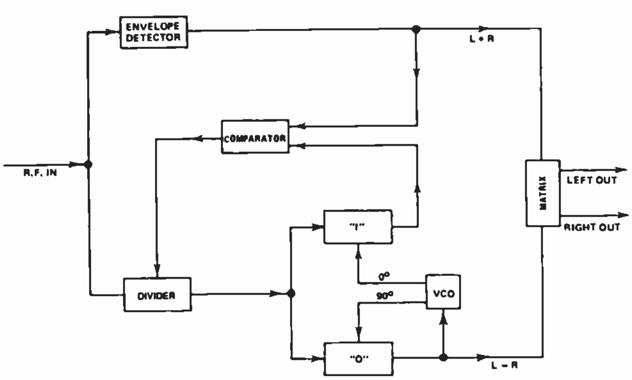

Figure B-2. Block diagram of feedback decorder.

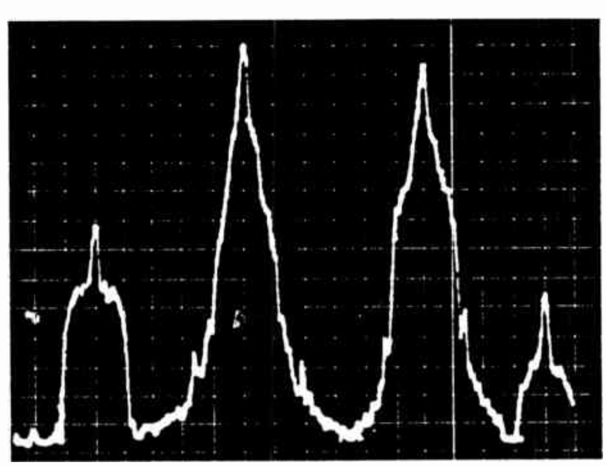
PERFORMANCE CONSIDERATIONS

The C-QUAM system is capable of on-air performance figures in excess of 40 dB separation and under 1% distortion from 100 to 5000 Hz, particularly on newer solid-state broadcast transmitters. It is not uncommon to obtain separation figures in excess of 30 dB from 50 Hz to the 10 kHz NRSC limit.

RF spectra is also well controlled within the NRSC limits of occupied bandwidth now adopted by the FCC. A spectral photograph of four C-QUAM stations, three of which operate at a power level of 50 kW, depicts the spectral signal of C-QUAM broadcasts. It is virtually indistinguishable from monophonic broadcasts, see Fig. B-3.

The broadcaster is free to choose the type of audio limiting desired for use with the C-QUAM signal with the exception that, if matrix type limiters are utilized, they must contain single channel limiting circuitry, or the single channel limiter found in all C-QUAM exciters must be enabled. Since the L + R monophonic signal is summed and directly coupled to the broadcast



Frequency at 10 kHz / Division
Amplitude Response at 5 dB / Division

Figure B-3. Spectral photograph of four C-QUAM broadcasts.

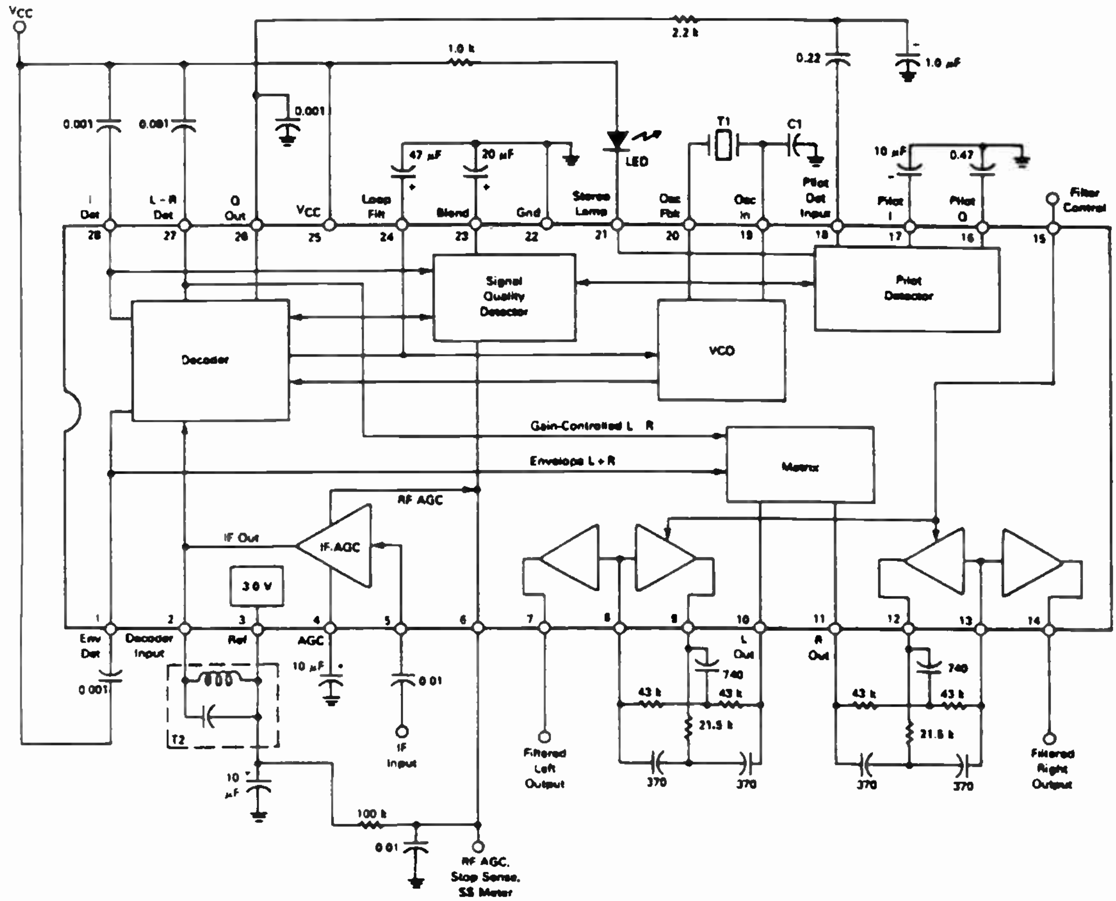


Figure B-4(A). Block diagram of the MC13022.

transmitter, no additional tilt or overshoot is placed upon the audio allowing full modulation of the envelope component. The modulation constraints of the system are as follows:

L + R (monaural modulation)	+ 125, − 100% (FCC limits—higher mod is possible)
L − R (stereo difference channel only)	± 100% (±45° phase modulation)
L, R only (single channel, ref. to L + R)	+ 125, − 75% (limit of 71.56° phase modulation)
PILOT TONE (injected into L − R channel)	25 Hz ±0.1 Hz, 5% + 1/ − 0% injection level, sine wave.

In addition, audio preemphasis may be used. Motorola recommends use of the NRSC modified 75 μS standard, however, tests with up to 30 dB preemphasis yield operation within FCC occupied bandwidth limits. The C-QUAM system has been used at audio bandwidths up to 15 kHz with excellent results, however, Motorola must emphasize the current FCC rules limiting audio bandwidth and subsequent RF emissions to 10 kHz as dictated by the current NRSC guidelines and adopted by the FCC.

Use of the C-QUAM system will not reduce the monophonic coverage of the broadcast station. Since the envelope is sent as a compatible signal (i.e., the amplitude modulation of the station continues as 1 + L + R), the stereo component should pass undetected in existing mono receivers and full modulation of the envelope may be contemplated. The stereo receiver will experience a slight S/N degradation due to the fact that a second channel of information has been opened to allow passing of the stereo information. The degradation is usually under 3 dB and is typically 1.5 dB, which is nearly imperceptible under normal stereo programming conditions. All C-QUAM receivers contain circuitry that restores receiver to mono reception when conditions warrant, thereby assuring no loss of coverage to the listener.

Receiver technology continues to expand with the advent of newer generation C-QUAM decoders. Original decoder ICs demodulated the incoming signal but performed very little conditioning of the signal to extend the performance of the receiver. Later generation decoders contain circuits which allow new receivers to be designed with adaptive bandwidth and synchronous detection features which improve reception under weak signal conditions. The MC13022 decoder IC, see Fig. B-4 A and B, contains such circuitry which allows receiver designers to produce radios that

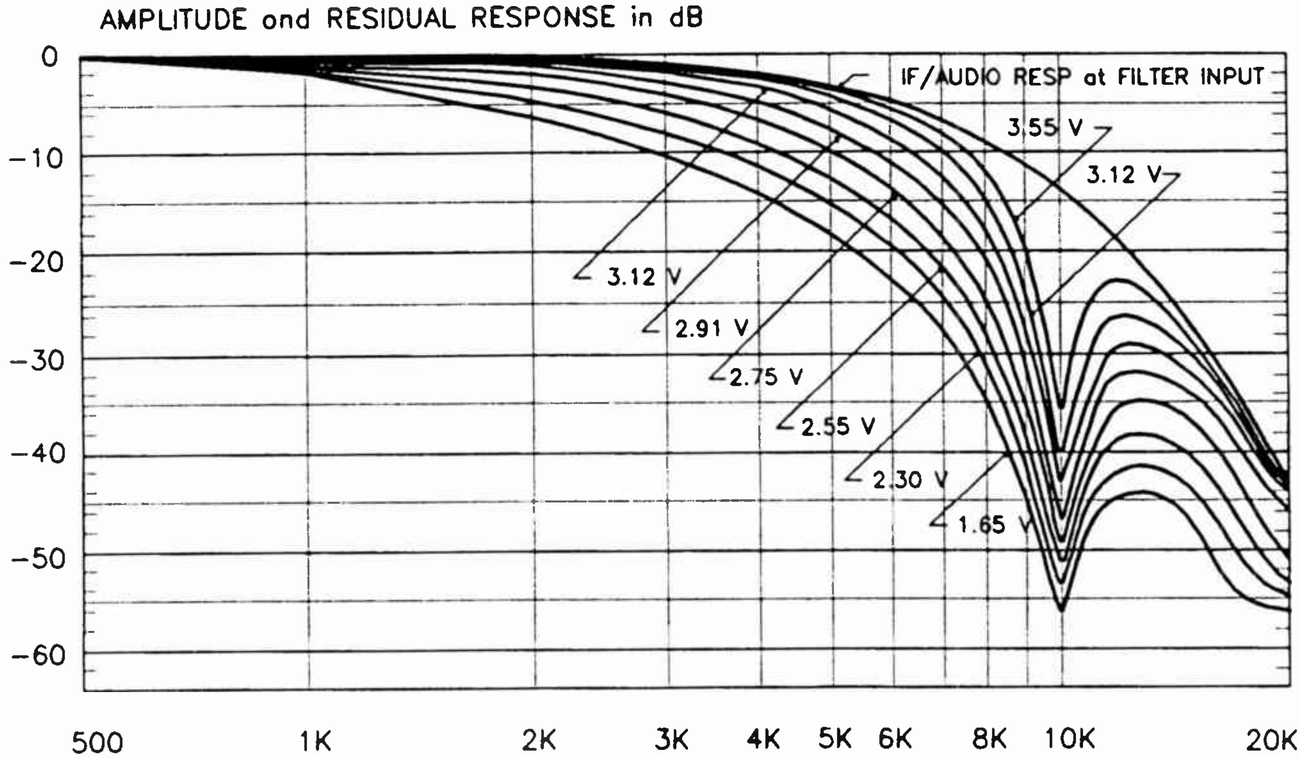

Figure B-4(B) MC13022 Variable Q notch filter response curves.

operate at NRSC bandwidths under stronger signal conditions and automatically variable bandwidths sliding to three to four kHz under weak incoming signal conditions. The merits of such a system are obvious. The listener can enjoy wideband AM reception when signal conditions warrant while the receiver will automatically reduce the bandwidth under poor conditions, thereby retaining the listener. In addition, NRSC de-emphasis is easily implemented with the MC13022. Future generation ICs are expected to further reduce the cost of adding AM stereo to existing designs, perhaps to a point of zero additional cost.

CONCLUSION

The C-QUAM AM stereo system has been designed to fulfill the demands of the AM broadcast service. It is easy to install and maintain, it occupies essentially no additional spectra, it is capable of excellent performance from 50 Hz up to the NRSC limit of 10 kHz, and performs well with matrix audio limiters which insure monophonic coverage and loudness. The C-QUAM system was designed with the receiver manufacturer in mind as well. Low cost implementations are possible with the ever-growing family of ICs available and performance rivaling FM stereo is available, particularly in the automotive and portable receiver markets. C-QUAM has repeatedly been selected as the standard for stereophonic broadcasting due to the fact that it addresses both broadcast and receiver industry related issues and exhibits superior performance.

3.3 FM Broadcast Transmitters

INTRODUCTION

History of FM Broadcasting

Although the mathematical principles explaining frequency modulation (FM) had been known for many years, the advantages and practical application to radio broadcasting were not realized until the 1930's, when Major Edwin H. Armstrong did extensive developmental work proving that FM radio transmissions were possible. Many theoreticians claimed to have proof that Armstrong's experiments were impossible, based on mathematical models, claiming that an infinite transmission bandwidth would be required. He never received proper credit for his many contributions to the radio communications industry during his lifetime. (See Ref. 1 at the end of this chapter for more information about the career of Major Armstrong.)

Among the advantages of FM are freedom from static, wide audio bandwidth, and the ability of an FM receiver to capture the stronger of two signals transmitted on the same carrier frequency.

In 1940, following extensive public hearings, the Federal Communications Commission established the FM Broadcast Service and set aside 40 channels in the 42 to 50 MHz band with commercial operation scheduled to begin January 1, 1941. Although World War II stopped all nonmilitary radio construction, more than 40 FM stations continued to serve over 400,000 receivers. To eliminate the interference problems resulting from skywave reflection in the prewar FM band, the Commission moved the FM Broadcast Service to the 88 to 108 MHz band in 1945, thereby increasing the number of available channels to 100. However, the expected growth of FM broadcasting did not materialize. Since conversion of prewar FM receivers to the new band was not practical, purchase of a new receiver was the only way to receive the new FM stations. Television appeared to offer much more to the consumer than FM radio, since most FM stations merely duplicated the programming of an affiliated AM station. Despite the potential for a higher quality broadcast service, there was little public demand for new FM receivers and virtually no public reaction when FM stations dropped popular programs from their schedule or were off the air due to equipment failures. It is not surprising, therefore, that in May 1950, there had been only 16 new FM license applications during the previous 15 months in which 259 FM stations ceased operations. It was not until after the introduction of stereo multiplex FM broadcasting that public awareness of the FM band increased and then skyrocketed in the 1970's to make FM the dominant medium for musical programming.

Characteristics Of FM Compared To AM

Reduced Noise

The 88 MHz to 108 MHz FM broadcast band is relatively free of atmospheric and other noise interference. Emission at these frequencies is not propagated great distances by the ionosphere as it is in the 550 kHz to 1600 kHz AM broadcast band. Therefore, noise from lightning discharges is limited to line-of-sight distances and is almost negligible. Manmade noise is a far greater source of noise, particularly in urban areas. The level of manmade noise falls off at increasing higher frequencies so that the microvolts-per-meter noise level is about one-tenth as great in the FM band as it is in the AM band.

In addition, FM has an improved noise threshold characteristic when compared to AM. Limiting circuitry symmetrically clips the RF waveform in an FM receiver to remove any amplitude variations produced by static or impulse noise before they reach the demodulator which responds only to phase or frequency changes in the signal. The FM improvement factor is illustrated in Fig. 1. Note the sharp knee in

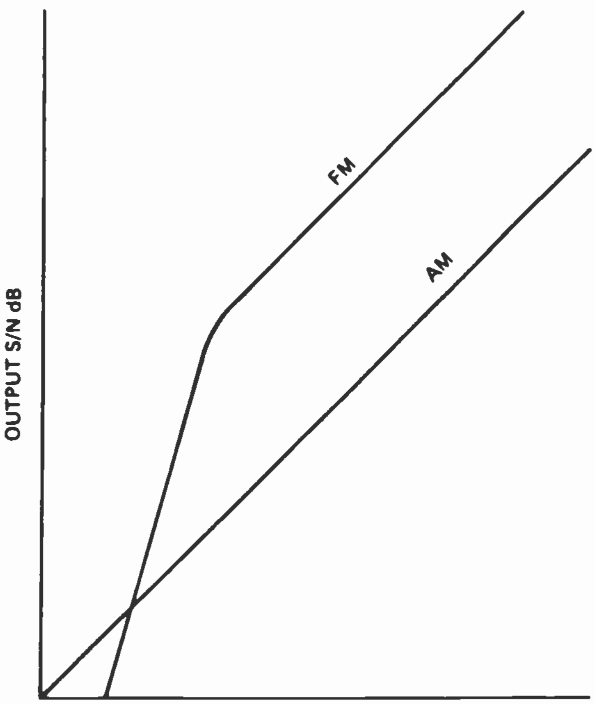

Figure 1. FM improvement factor.

the threshold curve above which noise and interference are suppressed, resulting in an improved signal to noise (S/N) ratio. This same capture effect causes a weaker FM signal on the same channel to be suppressed, resulting in greatly reduced co-channel interference.

For even greater noise reduction, preemphasis (75 micro-second time constant) is employed in the transmitter, whereby the audio frequency components above about 2.1 kHz are boosted in amplitude at the rate of 6 dB per octave before being applied to the modulator. Flat frequency response is restored in the receiver's deemphasis network by attenuating the higher frequencies the same amount they were boosted in the transmitter. At the same time, the high frequency noise components, which are characteristic to FM, are also attenuated, resulting in greatly reduced background noise. Preemphasis is discussed in more detail in the FM theory and FM exciter sections of this chapter.

The net result of the above factors is a much better signal-to-noise ratio on FM than on AM, and the ability to transmit much wider bandwidth information on FM. The lower background noise, along with wider frequency response, means that a signal of higher quality and wider dynamic range can be enjoyed.

Occupied Bandwidth

The advantages of the FM broadcast medium over the AM broadcast medium do not come free of compromise. A standard FM broadcast channel occupies more than ten times the bandwidth of an AM broadcast channel. This is because the more complicated nonlinear sideband structure of a frequency modulated carrier with wide deviation requires much more bandwidth than the simpler linear distribution of sidebands in an AM system. More details on the amplitude and spacing of FM sidebands are given in the section on FM modulation theory in this chapter. Fortunately, the FM broadcast band is located in the VHF portion of the frequency spectrum where more bandwidth is available than in the medium wave AM broadcast band.

High Fidelity

Uniform frequency response over the audible range of at least 50 Hz to 15 kHz, very low amplitude distortion (harmonic and intermodulation), very low noise level, and good transient response (uniform time delay versus frequency) are necessary for Hi-Fi performance. The FM channel authorizations provide for adequate audio frequency response and a low-noise radio link to the listener. The rest of the performance is a matter of equipment design.

Stereophonic Transmission

The wide channel allocations and ability of FM to multiplex compatibly several audio channels on one carrier permitted development of a practical stereo broadcasting system. This provides a means for the broadcast industry to provide the public with reproduction quality as good as or better than that which is available on stereo records or tapes. The advent of the *compact disc* and other digital audio source equipment will continue to challenge equipment manufacturers and station engineers further to improve the performance of the entire FM broadcast chain. Detailed technical information about stereophonic transmission theory and standards is provided in the chapter about FM Stereo and SCA.

Subsidiary Communications Authorization

The wide channel bandwidth authorized for FM broadcasting also makes it feasible to multiplex two subsidiary (SCA) audio or data channels together with the stereo transmission. SCA channels provide an important source of revenue to many stations as well as provide many useful audio and digital services to the community. Detailed technical information about SCA transmission theory and standards is provided in the chapter about FM Stereo and SCA.

FCC Transmission Standards

The Federal Communications Commission regulates and enforces the technical standards that apply to radio broadcasting in the United States. In theory, this will assure that the public is provided with a consistently high standard of transmission quality from station to station. The Rules and Regulations covering transmitter technical performance are set forth in Part 73 of the FCC Rules and Regulations available from the

U.S. Government Printing Office in Washington, D.C. The rules and regulations are changed from time to time to keep pace with new technology and changes within the broadcast industry. Every broadcast engineer should have access to a current copy of these Rules and Regulations so that the station's technical performance is maintained within the prescribed limits.

FREQUENCY MODULATION THEORY

Angular Modulation

Frequency modulation and phase modulation (PM) are both special cases of angular modulation. In any angular modulation system both the frequency and phase of the carrier vary with time as a function of the modulating signal.

The relationship between the frequency deviation of the carrier, the phase deviation of the carrier, and the sinusoidal modulating frequency is defined as the modulation index (m) where

$$m = \frac{\text{frequency deviation (peak-to-peak Hertz)}}{\text{modulating frequency (Hertz)}} \quad (1)$$

Since frequency modulation and phase modulation are both subsets of angular modulation, they are virtually indistinguishable from one another except in the modulator characteristics.

In a PM system, the modulating signal causes the phase of the carrier wave to vary according to the instantaneous amplitude of the modulating signal. A phase modulator generates a constant amount of phase deviation of the carrier with a constant amplitude modulating signal independent of the frequency of the modulating signal. The frequency deviation of the carrier produced by a phase modulator does increase as the modulating frequency is increased, even though the level of the modulating voltage is held constant. The net effect is that the phase modulator behaves as if it were a frequency modulator with a 6 dB/octave rising slope on the modulating signal input.

A frequency modulator generates a constant frequency deviation of the carrier, with a constant amplitude modulating signal independent of the frequency of the modulating signal. The phase deviation of the carrier produced by a frequency modulator decreases as the modulating frequency is increased, even though the level of the modulating voltage is held constant. The net effect is that the frequency modulator behaves as if it were a phase modulator with a 6 dB/octave falling slope on the modulating signal input.

In FM broadcasting, the signal should have frequency deviation that is proportional to the amplitude of the modulating signal, but independent of the frequency of the modulating signal as is generated by a frequency modulator.

The instantaneous frequency (rate of change of phase) of the RF output wave differs from the carrier frequency by an amount proportional to the instantaneous value of the modulating waveform. For example, consider a 100 MHz carrier wave frequency modulated by a 1000 Hz audio tone, and assume that a 1 volt input to the modulator causes ±20 kHz of frequency deviation on the positive and negative peaks of this tone. If the audio input amplitude is increased to 2 volts, the peak deviation will become ±40 kHz varying in sine-wave fashion from one peak deviation to the other and back again at the 1000 Hz rate. In FM broadcasting, the FCC has established that a peak frequency deviation of ±75 kHz shall constitute 100% modulation.

When preemphasis is used ahead of the frequency modulator, the system becomes a phase modulator at audio frequencies above the turnover point of the preemphasis network. This is because the frequency response of the preemphasis network rises at the rate of 6 dB/octave above this point. FM broadcasting with preemphasis really becomes a mixture of FM at low modulating frequencies and PM at high modulating frequencies.

FM Sideband Structure

The frequency modulated RF output spectrum contains many sideband frequency components, theoretically an infinite number. They consist of pairs of sideband components spaced from the carrier frequency by multiples of the modulating frequency. When the modulation index is small (m = 0.5) the amplitude of the second and higher order sidebands is small so that the output consists mainly of the carrier and the pair of first-order sidebands, as illustrated in Fig. 2A. The total transmitter RF output power remains constant with modulation, but the distribution of that power into the sidebands varies with the modulation index so that power at the carrier frequency is reduced by the amount of power added to the sidebands.

As the modulation index is increased, as in wide deviation FM broadcasting, the higher order sidebands become more prominent. The amplitude and phase of the carrier (J_0) as well as the sidebands (J_1 thru J_n) can be expressed mathematically by making the modulation index (m) the argument of a simplified Bessel function.

E(t) = total RF output voltage (2)

$A[J_0(m)\sin \omega c(t)]$ carrier amplitude

$+[J_1(m)\sin(\omega c+\omega m)t]$ first-order upper sideband

$-[J_1(m)\sin(\omega c-\omega m)t]$ first-order lower sideband

$+[J_2(m)\sin(\omega c+2\omega m)t]$ second-order upper sideband

$+[J_2(m)\sin(\omega c-2\omega m)t]$ second-order lower sideband

$+[J_3(m)\sin(\omega c+3\omega m)t]$ third-order upper sideband

$-[J_3(m)\sin(\omega c-3\omega m)t]$ third-order lower sideband

$\pm[J_n(m)\sin(\omega c\pm n\omega m)t]$ . . .higher order sidebands

where: A $=$ The unmodulated carrier amplitude constant
J_0 $=$ The modulated carrier amplitude
$J_1, J_2, J_3 \ldots J_n$ are the amplitudes of the nth order sidebands
m $=$ The modulation index
ωc $= 2\pi F_c$ (The carrier frequency)
ωm $= 2\pi F_m$ (The modulating frequency)

The numeric values of the Bessel functions (J_0 thru J_n), which express the amplitudes of the various frequency components, can be found in mathematical tables. Fig. 3 shows a graphical representation of how the Bessel function values for the carrier and the first eight pairs of sidebands vary with the modulation index.

In a monophonic FM broadcast transmitter, the modulation index can become very high at low modulating frequencies. With a 50 Hz audio input signal of sufficient amplitude to produce 75 kHz deviation (100% modulation), the modulation index is:

$$m = \frac{75000}{50} = 1500 \qquad (3)$$

With a 15000 Hz input at the same deviation (also 100% modulation), the modulation index is only:

$$m = \frac{75000}{15000} = 5 \qquad (4)$$

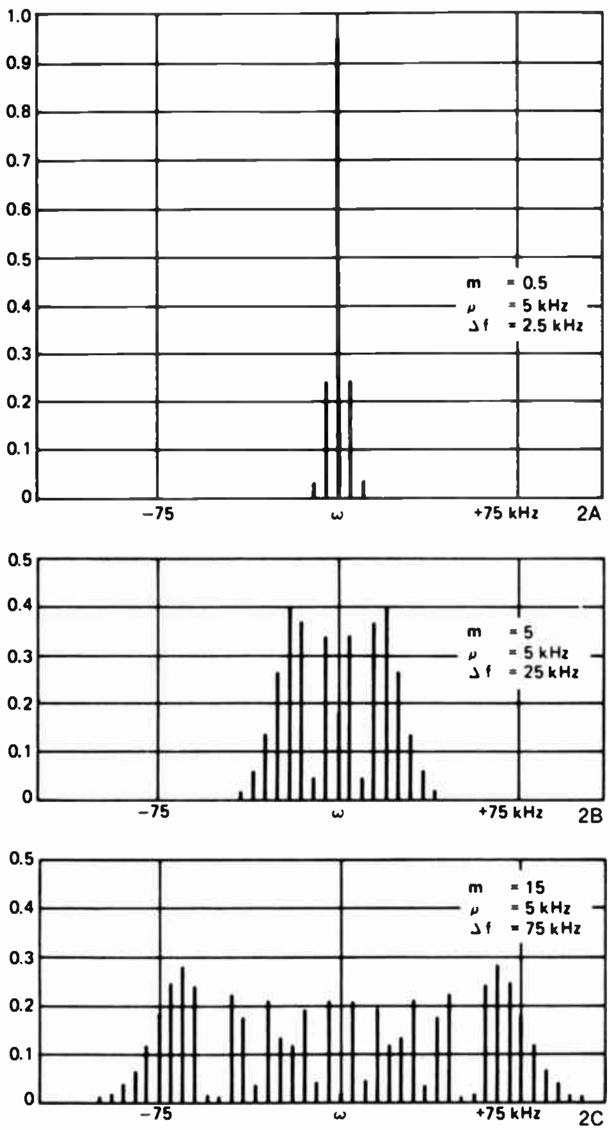

Figure 2. RF spectrum with modulation indexes of 0.5, 5.0, and 15.

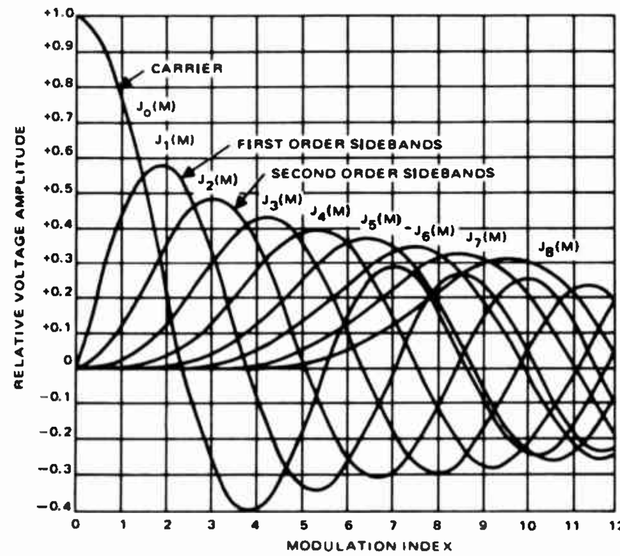

Figure 3. Relationship of carrier and sideband amplitudes to modulation index.

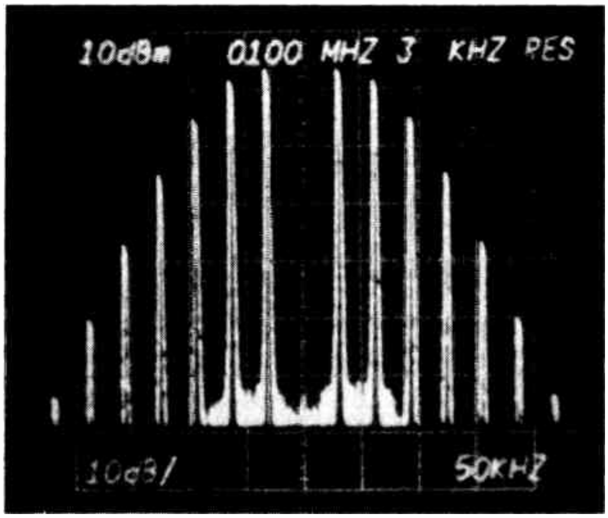
Figs. 2B and 2C illustrate the frequency components present for modulation indices of 5 and 15. Note that the number of significant sideband components becomes very large with a high modulation index. The total bandwidth occupied extends beyond ±75 kHz from the carrier depending upon the modulating frequency. This single tone modulating frequency analysis is useful in understanding the general nature of FM and for making tests and measurements. When program modulation is applied, there are many more sideband components present and they are varying so much that sideband energy becomes distributed over the entire occupied bandwidth rather than appearing at discrete frequencies.

Bessel Nulls

At certain modulation indices, the carrier amplitude goes to zero with all the transmitted power distributed at frequencies other than the carrier frequency. This carrier null phenomenon is useful as an extremely accurate method for measuring the frequency deviation and to check the calibration of modulation monitors. Referring again to Fig. 3, note that the carrier amplitude goes to zero and reverses sign at several values of modulation index including: 2.405, 5.520, and 8.654.



FOR M = 2.405, F_M = 31,185Hz, F_C = 100.00MHz

Figure 4. FM RF spectrum showing occupied bandwidth and Bessel Null single tone @ ± 75 kHz deviation.

Fig. 4 is a photograph taken from an RF spectrum analyzer showing the first Bessel null (m = 2.405) of a carrier at a frequency of 100 MHz.

To determine the audio input level required to achieve 75 kHz deviation, apply an audio tone of exactly 8667 Hz (75,000 divided by 8.654). Increase the audio level until the carrier disappears for the third time. At this audio level the deviation is exactly 75 kHz. The carrier amplitude (null) detector must have sufficient selectivity to separate the carrier from the sidebands and could be a spectrum analyzer or a receiver with a narrow IF bandwidth. The FM signal can be heterodyned down to a convenient frequency for measurement. Heterodyning does not alter the modulation index. When a frequency (or phase) modulated wave is multiplied or divided, this also multiplies or divides the frequency deviation and the modulation index by the same amount.

A listing of useful carrier and first order sideband nulls as function of the modulation index (m) and the modulating frequency (F_m) is given below:

NULL	MODULATION INDEX (m)		(F_m) FOR 75 kHz DEVIATION	
	CARRIER	1st SIDE-BANDS	CARRIER	1st SIDE-BANDS
1st	2.405	3.832	31,187	19,574
2nd	5.520	7.016	13,587*	10,690
3rd	8.654	10.174	8,667	7,372
4th	11.792	13.324	6,361	5,629
5th	14.943	16.471	5,023	4,554
6th	18.071	19.616	4,150	3,823
7th	21.212	22.759	3,536	3,295

* This tone is recorded on track 38 of the NAB Broadcast Audio System Test CD.

Occupied Bandwidth

After examining the Bessel function and the resulting spectra, it becomes clear that the occupied bandwidth of an FM signal is far greater than the amount of deviation from the carrier that one might incorrectly assume as the bandwidth. In fact, the occupied bandwidth is infinite if all the sidebands are taken into account, so it is now clear that a frequency modulation system would require the transmission of an infinite number of sidebands for perfect demodulation of information. In practice, a signal of acceptable quality can be transmitted in the limited bandwidth assigned to an FM channel.

Effects of Bandwidth Limitation

Practical considerations in the transmitter RF circuitry make it necessary to restrict the RF bandwidth to less than infinity. As a result, the higher order sidebands will be altered in amplitude and group delay (time). Bandwidth limitation will cause distortion in any FM system.

Consider the block diagram shown in Fig. 5A, where a perfect FM modulator is connected to a perfect demodulator via an RF path of infinite bandwidth. The demodulated audio shown in Fig. 5B contains no distortion components.

In Fig. 6A, a passive LC bandpass filter is inserted between the modulator and demodulator in order to restrict the bandwidth. Audio distortion products now appear at the output of our perfect demodulator as shown in Fig. 6B. These distortion products are due solely to the bandwidth restriction (300 kHz BW_3) imposed by the passive bandpass filter.

Figs. 7A and 7B show the effects of a narrowband RF bandpass filter on the RF spectrum of a composite signal consisting of a stereophonic subcarrier modulated only on the left channel with 4.5 kHz, plus a 67 kHz unmodulated SCA subcarrier. The only distortion evident on the RF spectrogram is the loss of some sidebands greater than 150 kHz from the center frequency, and some amplitude differences between the upper and lower sideband pairs. Fig. 7B shows the corresponding effects observed on the demodulated baseband spectrum for the same signal. Note the creation of many undesired intermodulation terms which cause crosstalk into both the stereophonic and SCA subcarrier bands. The change in the RF spectrum is subtle, but the resulting spectrum after demodulation is clearly modified.

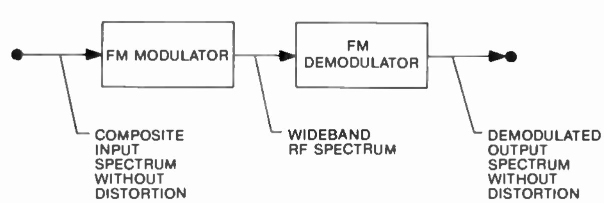


Figure 5A. Wideband RF path.

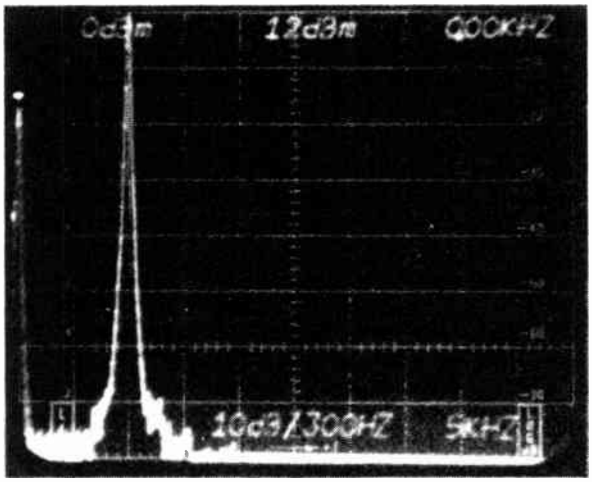
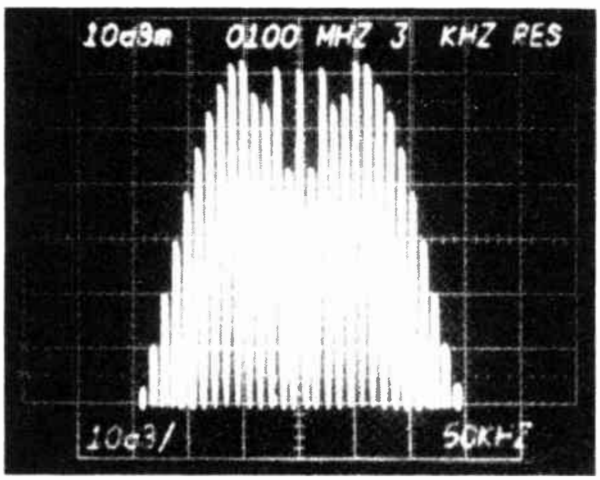
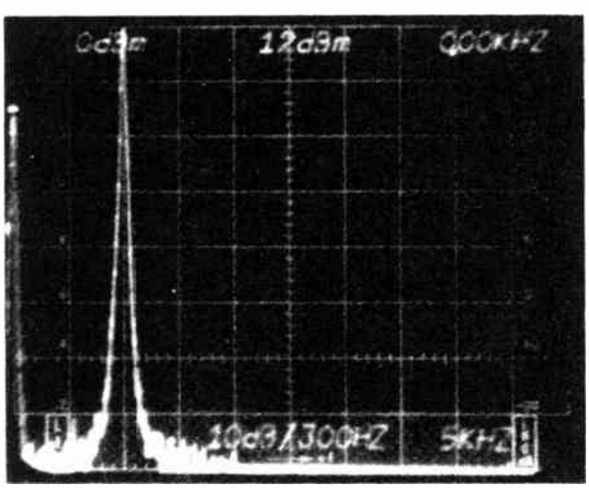


BASEBAND SPECTRUM TO FM MODULATOR



RF SPECTRUM TO DEMODULATOR



DEMODULATED BASEBAND SPECTRUM

Figure 5B. Single tone (10 kHz) modulation through wideband RF path.

As one can see, the distortion in any practical FM system will depend on the amount of bandwidth available versus the modulation index being transmitted.

Group Delay Response Symmetry versus Amplitude Response Symmetry

While both the amplitude response and group delay (time) response have an effect on the amount of distortion added to the FM signal, the symmetry of the group delay response is more important than the total group delay variation or the amplitude response symmetry. Best FM modulation performance is always obtained when the system is tuned for symmetrical group delay (time) response. Depending on the circuit topology, the tuning conditions for symmetrical group delay response may not coincide with the symmetrical amplitude response.

Limiting Factors within an FM Transmitter

Relating the specific quantitative effect of the bandwidth limitations imposed by a particular transmitter to the actual distortion of the demodulated composite baseband is a complicated problem indeed. Some of the factors involved are:

1. Total number of tuned circuits involved.
2. Amplitude and group delay response of the total combination of tuned circuits in the RF path.
3. Amount of drive (saturation effects) to each class "C" stage.
4. Nonlinear transfer function within each amplifier stage.

Improvement of the RF Path

The following design techniques can help improve the transmitter's bandwidth:

1. Maximize bandwidth by using a broadband exciter and a broadband IPA stage.
2. Use a single-tube design or a broadband, completely solid-state design where feasible.
3. Optimize both grid circuit and plate circuit of the tuned stage for the best possible amplitude response and symmetrical group delay response.
4. Minimize the number of interactive tuned networks.
5. Use a broadband antenna system that provides a low standing wave ratio on the transmission line.

For more detailed information about FM modulation theory, see Refs. 2, 3, and 4 at the end of this chapter.

PREEMPHASIS

The standards adopted for FM broadcasting require the use of preemphasis. The standard preemphasis curve is defined as an ideal RC network with a time constant of 75 microseconds. The 3 dB point is at a frequency of:

$$f = \frac{1}{2\pi RC} = \frac{1}{2\pi 75 \times 10^{-6}} = 2122\ \text{Hz} \qquad (5)$$

The 75 microsecond curve and the tolerance allowed by the FCC is shown in Fig. 8.

The reduction in receiver output noise due to the use of preemphasis in monophonic transmission is illustrated in Fig. 9. The noise voltage in a narrow bandwidth (for example, 1 Hz) increases directly with frequency, therefore, the power spectral density increases as the square of frequency as shown. When preemphasis is used, the noise voltage is attenuated above 2.1 kHz so that it remains constant with frequency. The power spectral density is also constant above 2.1 kHz. The area between these curves represents the noise power that is removed by the use of preemphasis. This diagram indicates the importance of preemphasis for high-fidelity transmission because the high-frequency noise at the receiver would be very much greater without deemphasis.

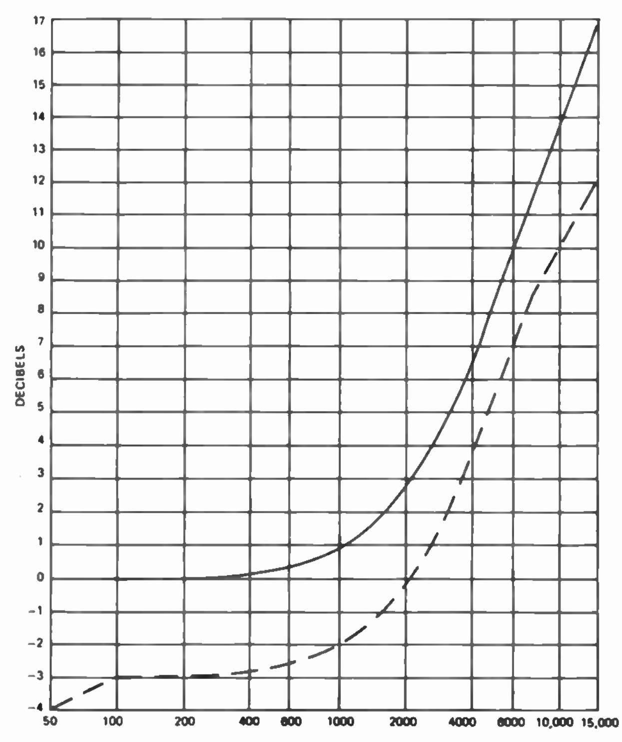

Figure 8A. FCC Standard 75 microsecond preemphasis curve (solid line) and tolerance limits (solid and dashed lines).

FREQUENCY IN HERTZ	DECIBELS
400 HZ	0.16 dB
1,000	0.87
2,000	2.76
3,000	4.77
4,000	6.58

11,000	14.45
12,000	15.18
13,000	15.86
14,000	16.49
15,000	17.07

Figure 8B. 75 microsecond preemphasis response.

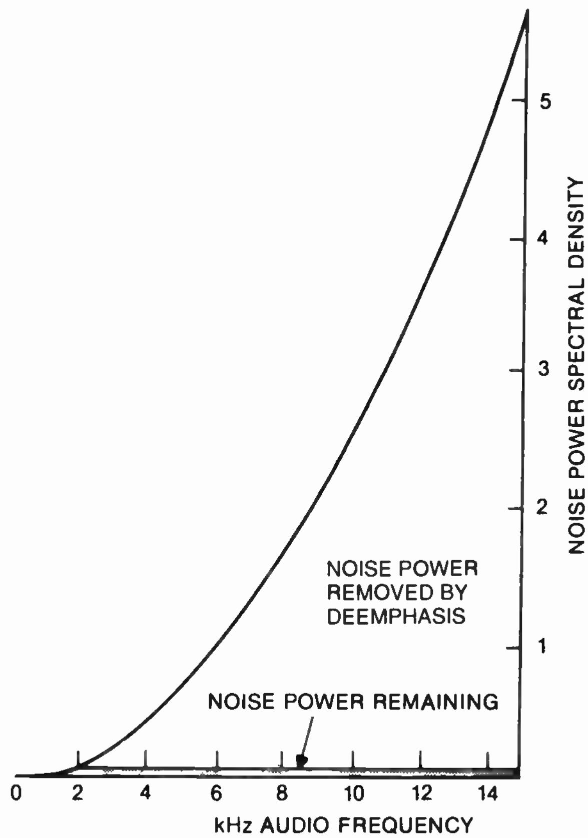

Figure 9. Noise power spectral density before and after deemphasis in receiver.

Preemphasis is practical because program energy tends to peak at several kilohertz and then falls off fairly rapidly at the higher frequencies. For this reason, the higher frequencies can be boosted in amplitude without causing much increase in modulation level. There is some increase, however, so the net improvement due to preemphasis is the ratio of the areas under the two curves of the diagram less this reduction in audio input level required to keep within the 100% modulation limit. Modern audio processing equipment takes the preemphasis curve into account when controlling peak modulation levels.

In the section on FM modulation theory, it was mentioned that the use of preemphasis ahead of an FM modulator actually causes the system to behave like FM at low modulating frequencies and like PM at high modulating frequencies.

The location of the preemphasis network in the system depends on whether the station is operating in the monaural or stereo mode. In the case of monaural transmission, the preemphasis network is usually located in the FM exciter just ahead of the modulator stage. Stereo transmission requires that the FM modulator have a flat response to the composite baseband signal from the stereo generator, so the individual preemphasis networks for the left and right channels are located in the stereo generator before the left and right audio channels are multiplexed into the composite baseband signal. The preemphasis time constant may be reduced to 25 microseconds if Dolby type "B" noise reduction is being used by the station. This will assure reasonable compatibility at low modulation levels, with the standard 75 microsecond receiver deemphasis.

FM TRANSMITTER POWER OUTPUT REQUIREMENTS

The transmitter power output (TPO) required is determined by the class of station, antenna height above average terrain, transmission line losses, and the antenna array gain. The required effective radiated power (ERP) is first determined, then the transmitter power output (TPO) can be calculated. Depending on the particular situation, the TPO could vary from as little as 50 watts to as much as 70 kilowatts.

THE FM TRANSMITTER

The purpose of the FM transmitter is to convert one or more audio frequency (composite baseband) input signals into a frequency modulated, radio frequency signal at the desired power output level to feed into the radiating antenna system. In its simplest form, it can be considered to be an FM modulator and an RF power amplifier packaged into one unit.

Actually the FM transmitter consists of a series of individual subsystems each having a specific function:

1. The FM exciter converts the audio baseband into frequency modulated RF and determines the key qualities of the signal.
2. The intermediate power amplifier (IPA) is required in some transmitters to boost the RF power level up to a level sufficient to drive the final stage.
3. The final power amplifier further increases the signal level to the final value required to drive the antenna system.
4. The power supplies convert the input power from the AC line into the various DC or AC voltages and currents needed by each of these subsystems.
5. The transmitter control system monitors, protects, and provides commands to each of these subsystems so that they work together to provide the desired result.
6. The RF lowpass filter removes undesired harmonic frequencies from the transmitter's output, leaving only the fundamental output frequency.
7. The directional coupler provides an indication of the power being delivered to and reflected from the antenna system.

Fig. 10 shows a simplified block diagram of a typical FM transmitter.

FM EXCITERS

The heart of an FM broadcast transmitter is its exciter. The function of the exciter is to generate and modulate the carrier wave with one or more inputs (mono, stereo, SCA) in accordance with the FCC standards. The FM modulated carrier is then amplified by a wideband amplifier to the level required by the transmitter's following stage.

Stereo transmission places the most stringent performance requirements upon the exciter. Since the exciter is the origin of the transmitter's signal, it determines most of the signal's technical characteristics; including signal-to-noise ratio, distortion, amplitude response, phase response, and frequency stability. Waveform linearity, amplitude bandwidth, and phase linearity must be maintained within acceptable limits throughout the baseband chain from the stereo and subcarrier generators to the FM exciter's modulated oscillator. From here, the FM carrier is usually amplified in a series of class "C" nonlinear power amplifiers, where any amplitude variation is removed. The amplitude and phase responses of all the RF networks which follow the exciter must also be controlled to minimize degradation of the baseband.

Before the advent of stereo broadcasting, most of the FM exciters employed phase modulation techniques. Some of these were adapted to stereo but it was difficult to achieve and maintain the performance requirements for stereo transmission.

In the FM modulation theory section, the important relationship between PM and FM was discussed. If the audio frequency response is made to fall off at the rate of 6 dB/octave across the entire audio band at the input of a phase modulator, the resulting modulated output will be identical to that of a frequency modulated carrier. In 1948, James R. Day, an associate of Edwin

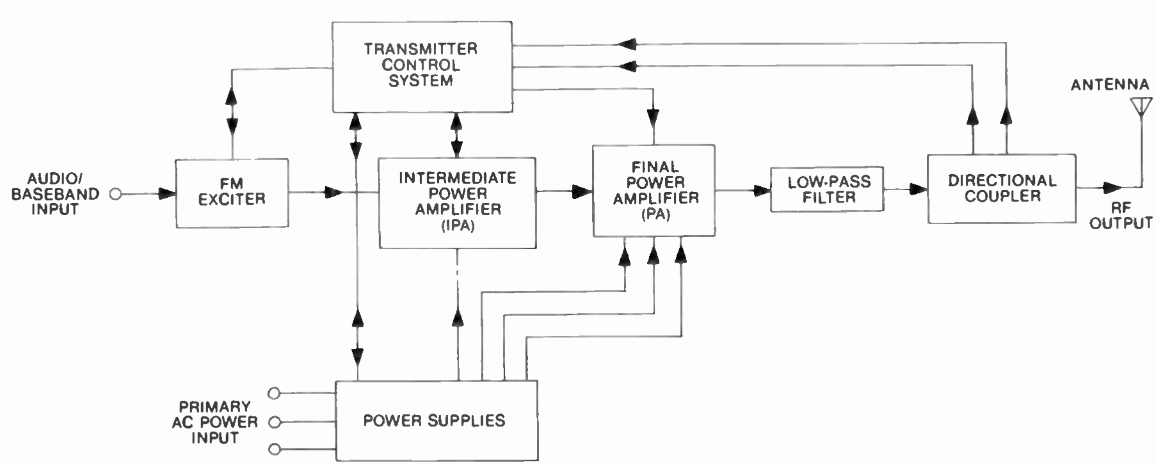

Figure 10. Simplified block diagram of an FM broadcast transmitter.

H. Armstrong, demonstrated a "Serrasoid" phase modulator which used pulse circuits to achieve large phase shifts with low distortion. The "Serrasoid" modulation technique, in conjunction with the audio response shaping mentioned above, became the standard method of generating wide deviation FM with low distortion.

This principle called "indirect FM" was used in many FM broadcast transmitters prior to the advent of stereo broadcasting. The advantage was that the carrier frequency could be generated by a stable crystal oscillator with the phase modulation occurring in later stages. The amount of phase deviation with low distortion was limited in most systems, so it was necessary to start with a low frequency oscillator and multiply its frequency and modulation index many times to achieve 75 kHz deviation at low modulating frequencies. This technique has been abandoned in favor of direct FM systems.

Direct FM

Direct FM is a modulation technique where the frequency of an oscillator can be made to change in proportion to an applied voltage. Such an oscillator, called a voltage tuned oscillator (VTO), was made possible by the development of varactor tuning diodes which change capacitance as their reverse bias voltage is varied (also known as a voltage controlled oscillator or VCO).

If the composite baseband signal is applied to the tuning terminal of a VTO, the result is a *direct* FM modulated oscillator. Fig. 11 is a block diagram that fits most of the modern direct FM exciters on the market.

The signal-to-noise ratio of an FM exciter is dependent on the short-term stability of the modulated oscillator. That stability is determined by factors such as operating level, noise figure of the oscillator transistor, circuit configuration, method of amplitude limiting, loaded "Q" of the oscillator tank circuit, and the mechanical stability of components. Optimization of these factors has resulted in a signal-to-noise ratio of better than 90 dB below 100% modulation in the current generation of FM exciters.

FM Modulator Linearity

Nonlinearities in the FM oscillator can, by altering the waveform of the baseband signal, create distortion in the demodulated output at the receiver. A secondary effect of this distortion may include stereo crosstalk into the secondary communications authorization (SCA).

The composite baseband signal is translated to a frequency modulated carrier frequency by the modulated oscillator. Frequency modulation is produced by applying the composite baseband signal to a voltage tunable RF oscillator. The modulated oscillator usually

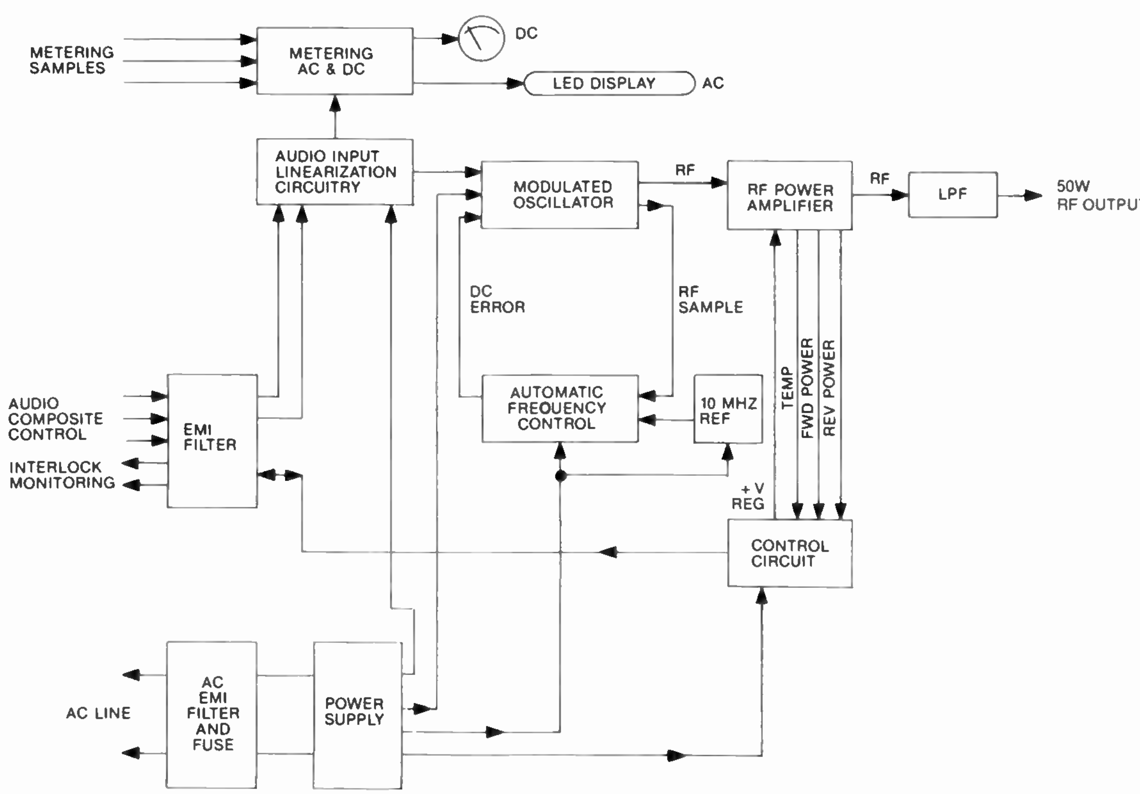

Figure 11. FM exciter block diagram.

operates at the carrier frequency and is voltage tuned by varactor diodes, operating in a parallel LC circuit.

To have perfect modulation linearity, the RF output frequency (F_c) must change in direct proportion to the composite modulating voltage (V_m) applied to the varactor diodes (C_v). This requirement implies that the capacitance of the varactor diodes must change as nearly the square of the modulating voltage as shown in following relationships:

(F_c) is proportional to (V_m) (Desired linear voltage to frequency translation) if:

$$F_c = \frac{1}{2\pi\,[(L)(C_t)]^{1/2}}$$

and: $$C_v = \frac{K}{(V^2_m)} \quad (\text{if } C_{fixed} = 0) \qquad (6)$$

where: F_c = Instantaneous carrier frequency
L = Inductance of resonant circuit
C_t = Total capacitance across L (C_{fixed} + $C_{varactors}$)
C_v = Capacitance of varactor tuning diodes
K = Varactor constant
V_m = Baseband modulating voltage

Unfortunately, the voltage versus capacitance characteristic of practical varactor diodes is not the desired square law relationship. All varactor-tuned oscillators have an inherently nonlinear modulating characteristic. This nonlinearity is very predictable and repeatable for a given circuit configuration, making correction by complementary predistortion of the modulating signal feasible. Suitable predistortion can be applied to the composite baseband signal by using a piece-wise linear approximation to produce the desired complementary transfer function. Fig. 12 shows a typical network of switching diodes and resistors used for complementary predistortion of the composite baseband. Fig. 13 shows how the predistortion network is cascaded with a nonlinear voltage-tuned oscillator to produce a linearized FM modulator.

It is also possible to improve both the linearity and signal-to-noise ratio of the modulated oscillator by demodulating its RF output to baseband and then

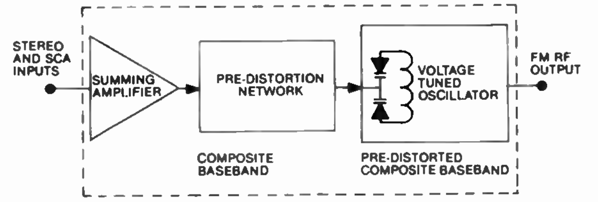

Figure 13. Linearized FM modulator block diagram.

feeding some of this baseband with the proper phase relationship back into the composite input of the modulator. This type of configuration places the entire modulated oscillator within a negative feedback loop and transfers the responsibility for maintaining linearity to the demodulator. Digital demodulation schemes can be made very linear, but the additional complexity and the potential problems with loop stability have limited the applications of this approach to linearization.

Modulator linearization has reduced harmonic and intermodulation distortion to less than 0.01% in the current generation of equipment. Any distortion of the baseband signal caused by the modulated oscillator will have secondary effects on stereo and SCA crosstalk, which are quite noticeable at the receiver in spite of the rather small amounts of distortion to the baseband. For example, if the harmonic distortion to the baseband is increased from 0.05% to 1.0%, as much as 26 dB additional crosstalk into the SCA can be expected.

For illustrative purposes, Figs. 14A, 14B, and 14C give representations of the fundamental and second order terms in the composite baseband spectrum with increasing amounts of harmonic distortion in the modulated oscillator. Fig. 14B shows this spectrum after 0.05% harmonic distortion has been added to each component. Note that the second order stereo (L − R) sidebands are 78 dB below 100% modulation, or about 58 dB below a 67 kHz SCA with a 10% injection. With normal energy distribution in L − R and the SCA, crosstalk from stereo into the SCA will be more than 60 dB below the SCA subcarrier. Fig. 14C shows the same baseband spectrum with 1.0% harmonic distortion. The second order stereo sidebands are only 32 dB below the SCA. Crosstalk may now increase as

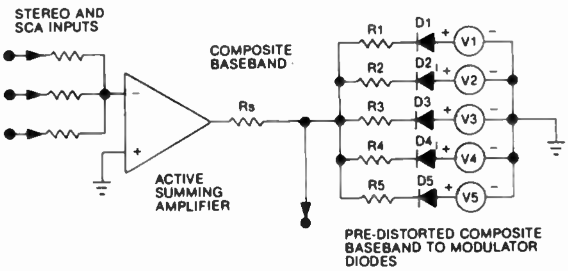

Figure 12. Predistortion network.

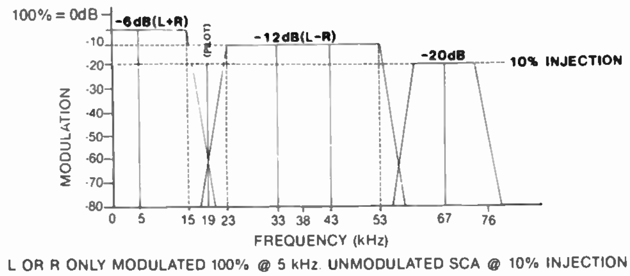

Figure 14A. Ideal demodulated composite baseband spectrum with no modulator distortion.

Figure 14B. Demodulated composite baseband spectrum with 0.05% harmonic distortion in modulator.

much as 26 dB, depending on the respective energy distributions in (L − R) and the SCA.

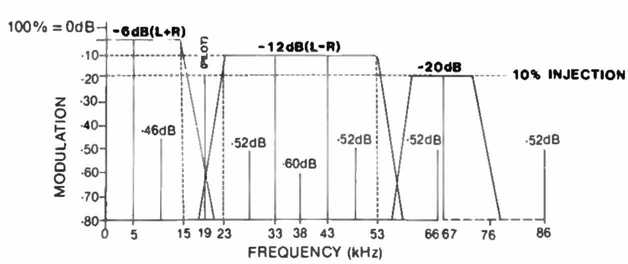
Transient intermodulation (TIM) distortion is usually not a factor in varactor-tuned modulated oscillators. The modulation bandwidth capability is generally more than ten times the composite bandwidth, and no negative feedback is used to maintain linearity.

Assuring that the composite baseband signal undergoes minimal distortion in the modulation process will suppress undesired harmonic and intermodulation products in the baseband, making the FM exciter transparent to the signals coupled into it. All exciter stages after the modulated oscillator operate as broadband amplifiers with minimal bandwidth limitations. The best FM exciter technology presently available is capable of transmitting compact disk quality with less than 0.01% distortion and a signal-to-noise ratio of better than 90 dB.

Automatic Frequency Control

The frequency stability of direct FM oscillators is not good enough to meet the FCC frequency tolerance of ±2000 Hz. This requires an automatic frequency control system (AFC) that uses a stable crystal oscillator as the reference frequency.

The modulated oscillator need not have good long-term stability since the AFC feedback loop will correct for long-term drift to keep the average carrier frequency within limits. The modulated oscillator does need excellent short-term stability (less than 1 second) because the control loop time constant must be long enough so that the AFC circuit does not try to remove desired low frequency audio modulation. This means that the oscillator is essentially running open-loop at frequencies above a few hertz so that the noise performance of the modulator will also be determined by the short term stability characteristics of the oscillator.



L OR R ONLY MODULATED 100% @ 5 kHz. UNMODULATED SCA @ 10% INJECTION. INTERFERING SECOND HARMONIC STEREO SIDEBANDS ARE 32 dB BELOW SCA. ONLY FUNDAMENTAL AND SECOND HARMONIC TERMS ARE SHOWN.

Figure 14C. Demodulated composite baseband spectrum with 1.0% harmonic distortion in modulator.

Phase-Locked Loop Automatic Frequency Control

Phase-locked loop (PLL) technology has provided a means of precisely controlling the carrier's average frequency while permitting wide deviation of the carrier frequency at baseband modulating frequencies. This implies that a PLL system behaves like an audio high-pass filter with higher modulating frequencies being ignored by the control loop while lower frequencies are considered to be errors in the average frequency and are tracked out by the loop. An added advantage of the PLL is the ability to synthesize the desired frequency from a single reference oscillator, thereby eliminating the need to change crystals when changing the frequency of the exciter.

The block diagram shown in Fig. 15 includes the key elements in the PLL. The output of the modulated oscillator operating at the carrier frequency is digitally divided down to a frequency of a few kilohertz or even less, called the comparison frequency. Likewise, the reference crystal oscillator is also digitally divided down to the reference frequency. The two frequencies are compared in a digital phase/frequency detector to develop an error voltage which corrects the carrier frequency of the modulated oscillator. The reason for dividing the modulated oscillator frequency so many times is to reduce the modulation index enough to limit the peak phase deviation at the reference frequency to a value that will not exceed the linear range of the phase/frequency detector. If the linear range is exceeded, the loop will lose lock. This is why some exciters may lose AFC lock in the presence of low frequency modulation components.

The phase detector output is integrated and low-pass filtered to remove the comparison frequency and all other frequency components above a few Hertz so that the AFC circuit does not try to track-out low frequency modulation. Some FM exciters use a dual-speed PLL in order to keep the loop turn-over frequency low enough to maintain good amplitude and phase response at 30 Hz, while also providing quick lock-up time. The PLL error correction circuitry must respond quickly during the initial frequency scan of the FM band to achieve lock-up to the precision reference oscillator in a few seconds. The loop bandwidth is wide during acquisition and lock-up. After lock is achieved, the bandwidth is reduced to provide the optimum modulation characteristic.

The reference oscillator is usually temperature compensated and requires no warm-up to maintain ±3

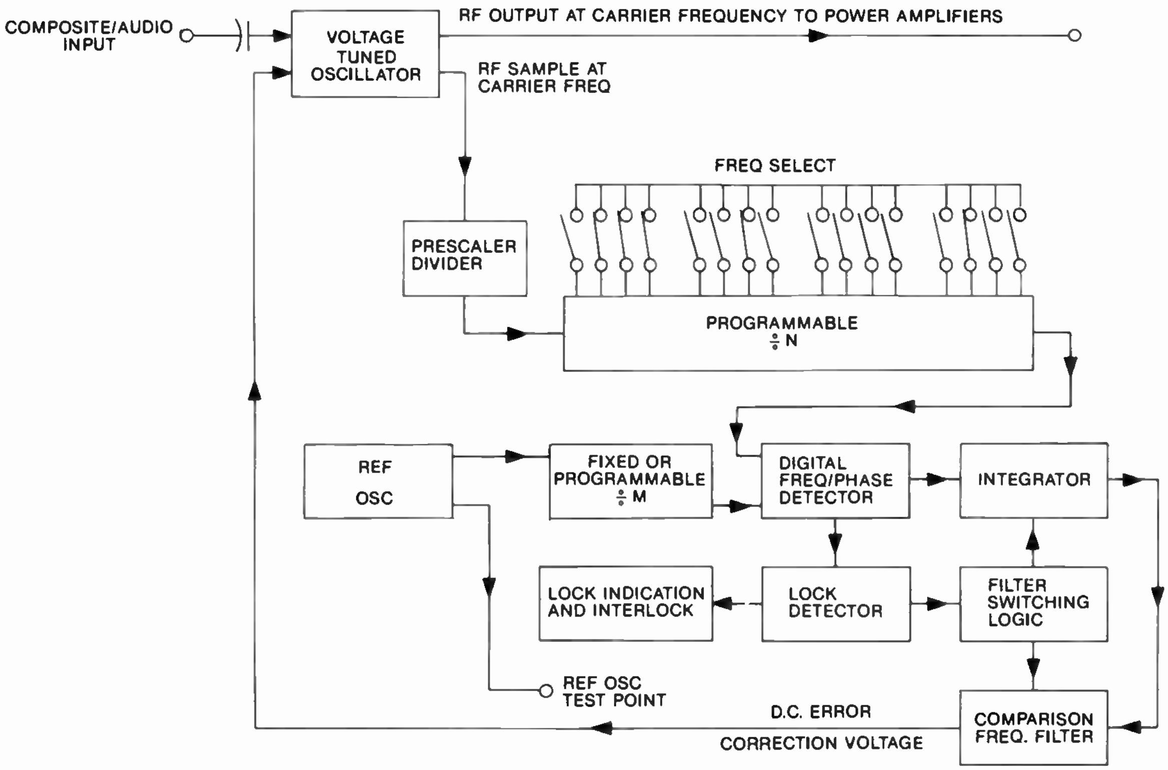


Figure 15. Phase-locked-loop frequency synthesizer.

PPM or better accuracy over the operating temperature range. 10 MHz is often selected as the reference frequency for convenient comparison to international frequency standards. (For more information about PLL frequency synthesizers see Ref. 5 at the end of this chapter.)

Direct Digital Synthesis

A new technology called *direct digital synthesis* (DDS) eliminates the need for a phase-locked loop (PLL) in the FM modulation process by directly synthesizing the carrier frequency, including FM modulation, from a look-up table in a programmable read-only memory (PROM) operating in conjunction with a fast digital-to-analog converter. When this technique is combined with digital signal processing (DSP) technology, the entire process of generating stereo baseband with SCAs, and FM modulating this baseband information onto the RF carrier, can be done entirely in the digital domain. Within the next few years, the cost to performance ratio of DDS/DSP technology will make it competitive with the current analog/digital technology used in present exciters. The full benefit of DDS/DSP technology will require digital mixing and digital transmission of audio information as a digital bit-stream all the way from the digital audio source thru a digital console, digital audio processing, and digital STL to the digital input port of the DSP/DDS exciter. This same technology is used fully in the digital audio broadcast (DAB) service, with technical standards presently being implemented worldwide.

Exciter Metering

Metering of important operating parameters can be provided by a combination of analog metering and a digital LED display. Steady-state parameters are usually selected by multiposition switch and displayed on a conventional analog multimeter. Typical steady-state functions include regulated, preregulated, and unregulated supply voltages; the AFC control voltage; RF power amplifier collector voltage and current; forward output power; and reflected power.

Either a color-coded LED display or a peak reading analog meter are usually provided to constantly monitor the time varying composite signal applied to the modulated oscillator. In either case, a high-speed peak detector gives accurate peak readings on signals from DC to 100 kHz. A one-shot multivibrator circuit provides a clear indication of short transient peaks exceeding 100% modulation.

Exciter Packaging

Protection of sensitive circuits within an FM exciter from external electromagnetic interference is important because the unit is often located in the near field of multiple broadcast antennas operating over a broad range of frequencies. The exciter should be protected from conducted eletromagnetic interference (EMI) by use of RC and/or LC filters on all leads entering the cabinet, including the AC line. Additionally, the power transformer may have an electrostatic shield between the primary and secondary windings. The modulated oscillator is often shock mounted to prevent the transmission of mechanical vibrations from the transmitter's blower. This avoids microphonic pick-up by the modulator that would degrade the FM signal-to-noise ratio. Magnetic shielding of the modulator is also used to prevent hum pick-up from nearby transformers. In some cases, a hum-bucking circuit is provided to help cancel hum induced into the modulator.

The mechanical construction of most present day exciters is designed around a plug-in modular or semi-modular approach, which allows easy removal of sub-assemblies for repair or replacement.

The exciter chassis may be mounted on pull-out slides so that all sub-assemblies are accessible while the unit continues to operate. Front-panel test jacks are often provided to allow measurement of the composite signal without removing or opening the unit.

Exciter Output Stage

The broadband RF amplifier in the exciter amplifies the output of the modulated oscillator from a power level of a few milliwatts up to an output level in the range of 5 to 50 watts. The output stage should be protected against damage by an infinite voltage standing wave ratio (VSWR) at any phase angle.

The typical RF amplifier is designed to have a bandwidth of at least 20 MHz, using successive broadband impedance matching sections for each stage. Each group of matching sections consists of micro-strip or lumped elements.

The broadband performance of the RF amplifier eliminates the need for adjustments to any particular frequency within the FM band. The exciter output is transparent to the signal generated by the modulated oscillator and the amplifier stability is enhanced under varying load conditions.

A micro-strip directional coupler is often incorporated in the RF amplifier output network. This coupler supplies information to the exciter control circuitry which provides automatic control of power output level and provides protection against operation under high VSWR conditions.

All standard FM exciters will produce at least 10 watts output so they can be used as a complete transmitter for educational stations with the addition of a harmonic filter to the output. For higher power levels, the exciter is used to drive an external power amplifier.

SYNCHRONOUS FM BOOSTERS

On July 16, 1987, the FCC approved Docket MM 87-13 which authorized FM stations to increase the power of their on frequency booster facilities from 10 watts maximum to "20% of the maximum permissible ERP for the class of primary station they rebroadcast."[1] The station may not, however, transmit beyond the predicted 1 mV/m contour of the main transmitter for class A and class C stations, the 0.5 mV/m contour for class B, or the 0.7 mV/m contour for class B1 stations.

Effects of Adding a Booster

For the purpose of analyzing the effects of a second carrier, the addition of a booster signal can be treated as interference. A second interfering carrier will both amplitude and phase (frequency) modulate an existing, desired carrier. The characteristics of this apparent modulation are given below.

$$Fm = |fc - fi| \qquad (7)$$
$$B = Ai/Ac$$

where: fc = Main carrier frequency
fi = Booster (interfering) carrier frequency
Ai = Booster (interfering) carrier amplitude
Ac = Main carrier amplitude
B = Percentage of amplitude modulation

Or, in words, an FM receiver detecting two carriers (unmodulated for simplicity), decodes a modulation tone equal in frequency to the absolute value of the frequency separation between the carriers. Moreover, the modulation index (both AM and FM) is simply the ratio of the carrier amplitudes. Notice, however, that the modulation index is never more than one, as increasing the amplitude of the interfering signal over that of the original carrier simply makes the carrier the interfering signal to the booster. For FM, B is measured in radians (see Eq. 7), while for AM, B is the percentage of amplitude modulation produced.

Synchronous Carriers

This gives rise to the need for synchronizing the carrier frequencies. An analysis of the equation for B (FM) shows, given a fixed carrier ratio (fixed modulation index), an increase in carrier frequency separation is equivalent to an increase in Δf, which for FM is equivalent to an increase in detected signal amplitude (see Eq. 8).

If, given $B = \Delta f/Fm$, B is held constant, and Fm is the frequency separation of the carriers, then:

$$\Delta f = B \times Fm \qquad (8)$$

Or, graphically, this phenomenon is shown in Fig. 16.

Knowing this, the advantages of frequency locking the carriers becomes obvious. By taking the limit as the difference in carrier frequency approaches zero, two things happen. First, the frequency of the detected tone approaches zero, and the equivalent FM deviation produced by that tone approaches zero. In other words, the interference disappears.

The Resultant Carrier

We are left with a single frequency carrier whose amplitude depends on the relative phase relationship between the two signals at any given reception point. If the signals are in phase and the carrier ratio is one

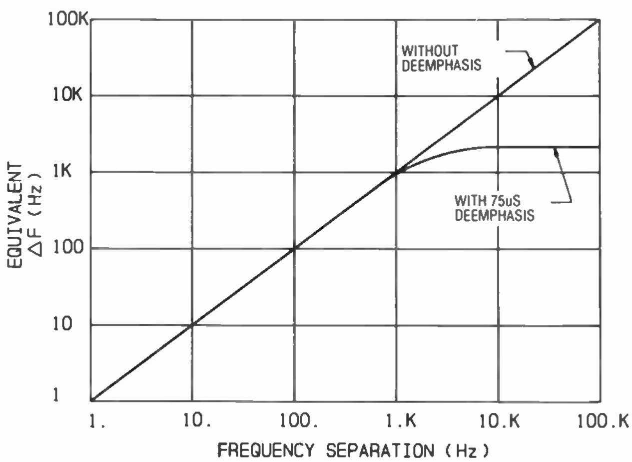

Figure 16. Relationship of carrier frequency separation to equivalent carrier frequency deviation (B = 1).

(0 dB), then the resultant amplitude is twice that of either carrier. On the other hand, if the carriers are 180° (out of phase), the net result is zero. Between these two extremes, the resultant amplitude and phase can be derived by Eq. 9.

$$Ar = \sqrt{[(Ac + A_1 \cos \omega_1(t))^2 + (A_1 \sin \omega_1(t))^2]} \quad (9)$$

where: Ar = Resultant carrier amplitude
Ac = Main carrier amplitude
A_1 = Booster carrier amplitude
$\omega_1(t)$ = Angle between A_1 and Ac

and: $$\phi r = \operatorname{Arctan} \frac{A_1 \sin \omega_1(t)}{Ar + A_1 \cos \omega_1(t)}$$

where: ϕr = Resultant carrier phase angle

Figure 17 shows this vector summation.

The Resultant Effect on Receivers

If we were in a reception area of equal, in-phase and frequency-locked carriers, located on a straight line between the two transmitting antennas, and provided

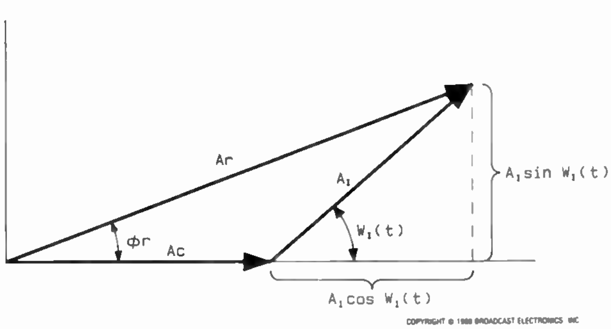

Figure 17. Vector summation of two carriers.

that the information on each carrier is occurring at the same time, all the conditions for adequate reception have been met. (See additional information under modulation delay equalization discussion.)

However, if we were to move 2.5 feet toward either transmitter (roughly equivalent to one-quarter wavelength at 100 MHz), we would now be in an area where the two signals are 180° out of phase, and there would no longer be a signal to detect. Notice that we have only moved one-quarter wavelength, yet have actually moved into a null! This is because we have moved one-quarter wavelength away from one transmitter and one-quarter wavelength closer to the other, giving a total one-half wavelength change. In a mobile receiver, this phenomenon is virtually identical to the "picket fencing" of multipath, except that the interfering signal is not reflected, but rather is a duplicate transmission from a booster site.

For the stationary receiver in an additive state, this is not a problem, and in fact, gross modulation problems can be effectively covered up by virtue of the capture effect of an FM receiver, provided the carrier ratios are adequate to accomplish this. This ratio depends on the particular receiver, but suffice to say it is a smaller ratio than is required to maintain adequate reception with a mobile receiver.

Even relatively small fluctuations in signal strength due to the adding and subtracting of carriers will cause a noticeable fluctuation in receiver signal to noise, unless the residual signal strength in the null area is adequate to keep the receiver well into quieting.

This effect, more than any other, makes the areas of "inadequate" carrier ratios unlistenable. It is important to note that for the mobile receiver, the "picket fencing" problem is present whether or not the carriers are locked.

MODULATION EFFECTS

So far, we have been dealt primarily with the effect of adding a second unmodulated carrier onto a main, unmodulated carrier. At best, understanding the consequences of imperfectly correlated modulation superimposed on two carriers is difficult, if not futile. There are, however, two areas of modulation equalization which are fairly straightforward.

Time Delay Equalization

Consider what happens to two identical signals which have a constant time delay between them. At any frequency where the time delay is equivalent to 180° or N multiples of 180°, there will be complete cancellation, producing a combing effect. This is especially destructive to composite FM stereo and subcarrier performance. In fact, a 7.5 μS group delay addition to one composite signal will cancel a 67 KHz subcarrier. Likewise, a 26.3 μS delay will cancel the stereo pilot tone.

Unfortunately, time delay equalization cannot eliminate cancellation of modulation components in equal carrier areas, since differences in propagation times between the main and the booster will be adequate in some cases to cause the cancellation. At best, the use of group delay can move the location of the nulls relative to the transmitters. Care must be taken to insure the network exhibits a constant group delay, as nonlinear delay can seriously degrade stereo performance, especially stereo separation.

Deviation Calibration

If the frequency deviation of both modulators is not precisely calibrated, a condition of dynamic interference will occur during modulation. For example, two separate modulators are fed identical amplitude, delay equalized sine waves. The level is adjusted to produce a nominal 100% (±75 kHz) modulation. The first modulator swings the carrier exactly ±75 kHz, as predicted, but the second modulator only modulates its carrier ±74 kHz (98.67%).

Careful examination shows that the second carrier will interfere with the first in the following manner. Assuming equal carriers in an additive RF location, and starting at time zero, we have two carriers of exact frequency, producing a single carrier whose amplitude is derived from Eq. 9. As we move positively in frequency with the modulation, the carrier frequencies diverge until, at the peak of modulation, the carriers are 1 kHz apart. From Eq. 7, this produces a 1 kHz FM modulation at a B of 1 (1 kHz deviation) and an AM modulation equivalent to 100% at 1 kHz.

Actually, the detected interference is a frequency sweep from DC to 1 kHz to DC and back to 1 kHz for each complete cycle of modulation applied.

Subjectively, this type of interference sounds similar to white noise, but it is only present during modulation. It is also most prevalent during the maximum modulation peaks, as this is the point of maximum carrier divergence with maximum detected loudness. This relationship of maximum interference during the periods of maximum modulation tends to mask the noise.

Correcting the Interference

Both forms of modulation related interference are most prevalent in areas of nearly equal carriers. With "adequate" carrier ratios, both types are effectively eliminated by the capture effect in the FM receiver. It is also important to keep the proper perspective in assessing the importance of these forms of interference. Remember, these are most prevalent in areas where, even without modulation, the carriers are adding and subtracting, tending to make the signal unlistenable as the receiver location is moved.

BOOSTER SYSTEMS

Two main components must be present at the booster station. A way must be found to transmit the station program material, either in the form of composite stereo, or possibly discrete left and right channels (or mono, if necessary). Composite stereo is preferred, otherwise a second stereo generator would be necessary at the booster. Some form of frequency locking information must also be present.

Using a Radio Link

By far, the most flexible method of interconnection is by the use of a radio link, such as a composite STL between the main transmitter and the booster. This method has several advantages, including high quality transmission, reliability, total signal control, and economy. It is also capable of transmitting the frequency reference signal with the composite stereo via subcarrier. In this way, one radio link supplies both the station programming and reference information.

An Alternate Approach—Leased Phone Lines

In some areas, frequency allocations for a radio link are not available. In such instances, dedicated phone lines may be the only alternative. A voice quality line can be used, provided that the frequency locking reference tone is in the 300 Hz to 3 kHz range. The reference tone could also be sent to the booster site on a composite FM subcarrier of the main transmitter.

RF POWER AMPLIFIERS

The remainder of the FM transmitter consists of a chain of power amplifiers, each having from 6 dB to 20 dB of power gain. Ideally, the transmitter should have as wide a bandwidth as practical with a minimum of tuned stages. Broadband solid-state amplifiers are preferred to eliminate tuned networks in the RF path. Higher powered transmitters in the multi-kilowatt range may use multiple tube stages each with fairly low gain, such as in the grounded grid configuration or a single grid driven power amplifier (PA) stage with high gain and efficiency. The dollars/watt economics of single-tube transmitters outweigh the bandwidth benefits of solid-state transmitters at the higher power levels with present technology. Design improvements in tube-type power amplifiers have concentrated on improving bandwidth, reliability, and cost effectiveness.

TRANSMITTER POWER OUTPUT REQUIREMENTS

The FCC regulates the power of FM broadcast stations in terms of effective radiated power (ERP). The authorized ERP applies only to the horizontally polarized component of radiation. Elliptical or circular polarization is also permitted where the ERP of the vertically polarized component may be as great as the authorized horizontal component. This means that twice as much total power may be radiated and twice as much transmitter power will be required.

The transmitter power requirement can be reduced by increasing the gain of the antenna. There is, of course, an economic trade off between the cost of a higher gain antenna versus the cost of a larger transmitter and the added primary power costs. For a high ERP, it is common to use antennas with up to 12 elements which provide a power gain of about 12.6 (or 6.3 in each polarization).

The long transmission lines associated with the tall towers commonly used are a source of considerable power loss. For example, the efficiency of 2,000 ft of 3⅛ in. rigid coax at 100 MHz is only about 62%.

FM transmitters are designed to operate over a range of power outputs so that with a few basic sizes any required power output can be furnished. Popular maximum ratings range from 100 watts to 70 kilowatts. Most installations use a maximum transmitter power output (TPO) of thirty kilowatts because it is more economical to achieve the maximum 100 kilowatts ERP with circular polarization by means of sufficient antenna gain.

RF Power Amplifier Performance Requirements

The basic function of the power amplifier is to amplify the power of the exciter output to the authorized transmitter power output level. Most of the overall transmitter performance characteristics are determined by the exciter, but a few are established or affected by the power amplifier characteristics:

1. The output at harmonics of the carrier frequency is almost completely a function of the attenuation provided by the output tank circuit and output low-pass/notch filters. The limit in decibels is [43 dB + 10(LOG watts) dB] or 80 dB whichever is less. (73 dB for 1 kW output or 80 dB for 5 kW and higher.)
2. The major source of AM noise usually originates in the last power amplifier stage. The FCC limit is 50 dB below 100% modulation.
3. The RF power output control system, which must keep the output within +5% and −10% of authorized output, is usually achieved in the final power amplifier.
4. Inadequate passband, particularly with respect to phase linearity across the signal bandwidth, can reduce stereo separation and cause SCA crosstalk.
5. The presence of standing waves on the transmission line to the antenna may also react with the power amplifier to cause degraded stereo separation and SCA crosstalk.

The power amplifiers should provide trouble-free service and be easy to maintain and repair. Good overall efficiency is also desirable to reduce the primary power consumption.

Power Amplifier Bandwidth Considerations

As mentioned earlier, the FM signal theoretically occupies infinite bandwidth. In practice, however, truncation of the insignificant sidebands (typically less than 1% of the carrier) makes the system practical by accepting a certain degree of signal degradation. The transmitter power amplifier bandwidth affects the modulation performance. Available bandwidth determines the amplitude response and group delay response. There is a trade-off involved between the bandwidth, gain, and efficiency in the design of a power amplifier.

The bandwidth of an amplifier is determined by the load resistance across the tuned circuit and the output or input capacitance of the amplifier. For a single-tuned circuit, the bandwidth is proportional to the ratio of capacitive reactance to resistance:

$$BW \propto \frac{K}{2\pi f R_L(C)} = \frac{K(X_c)}{R_L} \qquad (10)$$

where: BW = Bandwidth between half-power points (BW_3)
K = Proportionality constant
R_L = Load resistance (appearing across tuned circuit)
C = Total capacitance of tuned circuit (includes stray capacitances and output or input capacitances of the tube)
X_c = Capacitive reactance of C
f = Carrier frequency

The load resistance is directly related to the RF voltage swing on the tube element. For the same power and efficiency, the bandwidth can be increased if the capacitance is reduced.

INTERMEDIATE POWER AMPLIFIERS

The intermediate power amplifier (IPA) is located between the exciter and the final amplifier in higher power transmitters that require more than about 30 watts of drive to the final amplifier. The IPA may consist of one or more tubes or solid-state amplifier modules.

Interstage Coupling Circuits

The separate IPA output circuit and the final amplifier input circuit are often coupled together by a coaxial transmission line. Impedance matching is usually accomplished at either end by one of the configurations shown in Figs. 18A, 18B, 18C, and 18D.

All of the classical circuits shown in Fig. 18, except "D", require some interactive adjustment of the tuning and loading elements to provide a satisfactory impedance match for each operating frequency and RF drive level. The circuit in Fig. 18D utilizes multiple LC sections, with each section providing a small step in the total impedance transformation. This technique provides a broadband impedance match without adjustment; thereby improving the transmitter's stability, ease of operation and maintainability. A single grid resonating control is sufficient to tune and match the 50 ohm driver impedance to the high input impedance of the grid over the entire 88–108 MHz FM broadcast band with a 4:1 range of RF power levels.

The interconnecting transmission line between the coupling circuits should be properly matched to avoid

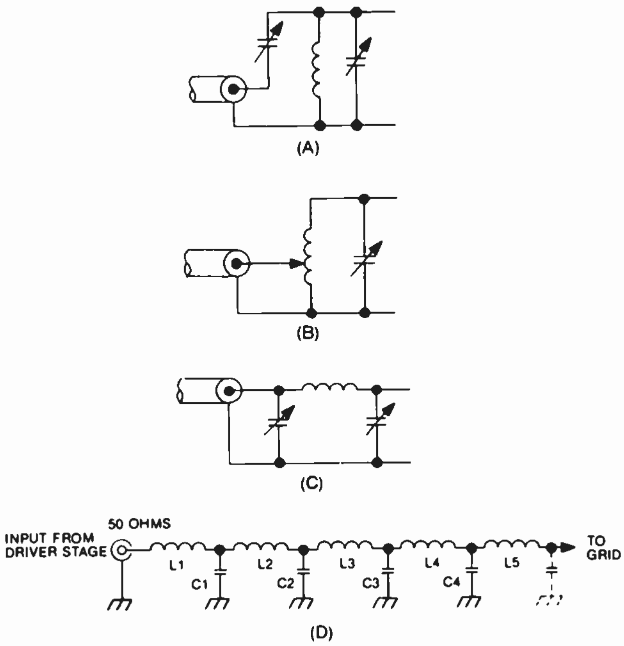

Figure 18. Interstage RF coupling circuits.

a high VSWR. Directional wattmeters are normally placed in the line to measure forward and reflected power from which standing wave ratio can be established. The VSWR is established by the match at the load end of the transmission line.

The transmission line matching problem is eliminated in some transmitters by integrating an IPA stage utilizing a tube(s) into the grid circuit of the final amplifier stage by having the plate of the IPA and the grid of the final tube share a common tuned circuit. This technique has the advantage of simplicity by not transforming the impedance down to 50 ohms and then back up to the grid impedance level, but does not allow the IPA to be connected directly to the antenna as a low-power back-up system.

Solid-state RF power devices possess a very low load impedance at the device output terminal, so that an impedance transformation that goes through the 50 ohm intermediate impedance level is required to couple these devices into the relatively high impedance of the final amplifier grid circuit. Therefore, virtually all solid-state IPA systems have a 50 ohm impedance point within the system that can be used to feed the antenna in an emergency.

High power transmitters utilizing a grounded-grid amplifier configuration in the output stage, require large amounts of drive power (typically greater than 1,500 watts). The IPA may be a standard 3 kW transmitter that can also be used as a stand-by transmitter.

Most of the newer design high-power transmitters only require between 150 and 600 watts of drive into a high gain final amplifier. This permits the use of a system of solid-state, wideband modules to boost the exciter's power up to the level required to drive the grid of the final tube.

Solid-State IPA Systems

A solid-state IPA almost always consists of a system of individual amplifier modules that are combined to provide the desired power output. The advantages of using several lower power modules instead of a single high-power amplifier are:

1. Redundancy is provided by isolating the input and output of each module, permitting uninterrupted operation at reduced power if one or more of the modules fails.
2. The ability to repair or replace failed modules without having to go off-the-air.
3. More effective cooling of each power device junction by splitting the concentration of heat to be dissipated into several areas instead of one small area.
4. Better isolation between the amplifier modules and the input circuit of the final power amplifier is provided by the combiner/isolator.
5. Redundant power supplies and air cooling systems for each module improve overall reliability.

Each RF power amplifier module consists of one or more solid-state devices with broadband impedance transformation networks for input and output matching. A new generation of class "C" BIPOLAR and MOSFET devices permit the design of broadband amplifier stages that exhibit both high efficiency and the wide bandwidth necessary to cover the FM broadcast band.

Regardless of which type of solid-state device is used, the input impedance is always lower than the desired 50 ohm input impedance, so a broadband impedance transformation scheme is required. This is usually accomplished by a combination of coaxial baluns and push-pull coaxial line sections that are cross-coupled to provide 4:1 or higher transformation ratios over the FM band.

By operating two devices in push-pull, the input impedance (differential) is double that of a single ended circuit and the suppression of even order harmonics is enhanced. Two devices fed in this manner also provide some degree of redundancy within the module itself since partial RF output can be obtained with one device failed. In a similar manner, the low output impedance of these solid-state devices can be transformed up to the desired 50 ohm module output impedance where combining occurs. Fig. 19 illustrates a simplified schematic of a broadband IPA module utilizing the push-pull configuration.

IPA Splitting and Combining

There are two types of splitting/combining schemes used:

1. 90° hybrid splitter or combiner ("N-1" hybrids required to split or combine "N" inputs). (See section on transmitter output combining.)

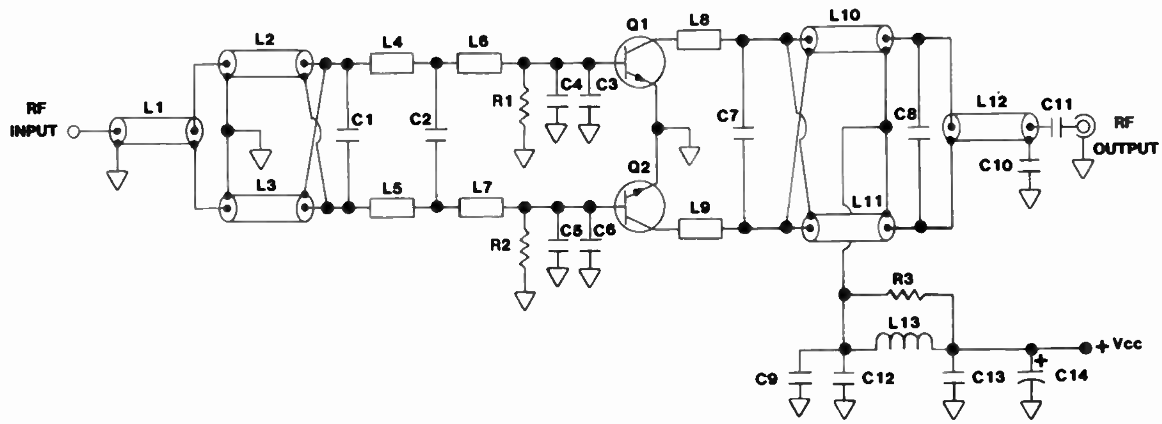

Figure 19. Simplified schematic of a broadband intermediate power amplifier module.

2. Wilkinson "N-way" in-phase splitter or combiner.

Either type of splitter/combiner must provide isolation between the individual power amplifier modules and low loss splitting or combining of the total power. By choosing the proper lengths for the coaxial interconnecting cables, either of the above methods can be configured to operate the individual modules "in-phase" so that the loading on each of the modules tracks the other modules when the impedance at the output of the combiner is varied.

The cascaded 90° hybrid system shown in Fig. 20 provides double isolation between the IPA and the grid circuit by first combining the two pairs of amplifiers and then combining the outputs of the first two combiners. A portion of the reflected power, caused by a mismatch at the output, will be dissipated in the reject loads so that the IPA modules will operate into a lower VSWR than exists at the output. The unbalanced 50 ohm reject loads are accessible for monitoring of reject load power, which is useful in determining the balance of the system. The coaxial interconnecting cables between module pairs must be offset in electrical length by one-quarter wavelength (90°) at the operating frequency so that the modules operate in phase while the hybrids operate in quadrature.

The Wilkinson system shown in Fig. 21 is a simple and effective way to split and combine modules operating in phase, but usually requires a balanced reject load making reject power measurements more difficult. By adding additional coaxial balun sections to the Wilkinson, it is possible to use unbalanced reject loads. Since the Wilkinson operates in phase, all of the coaxial interconnecting cables should be equal in length.

Since most IPA splitter/combiner systems are designed around a 50 ohm input and output impedance level, these systems can be easily used as a low power stand-by transmitter by routing the output to the

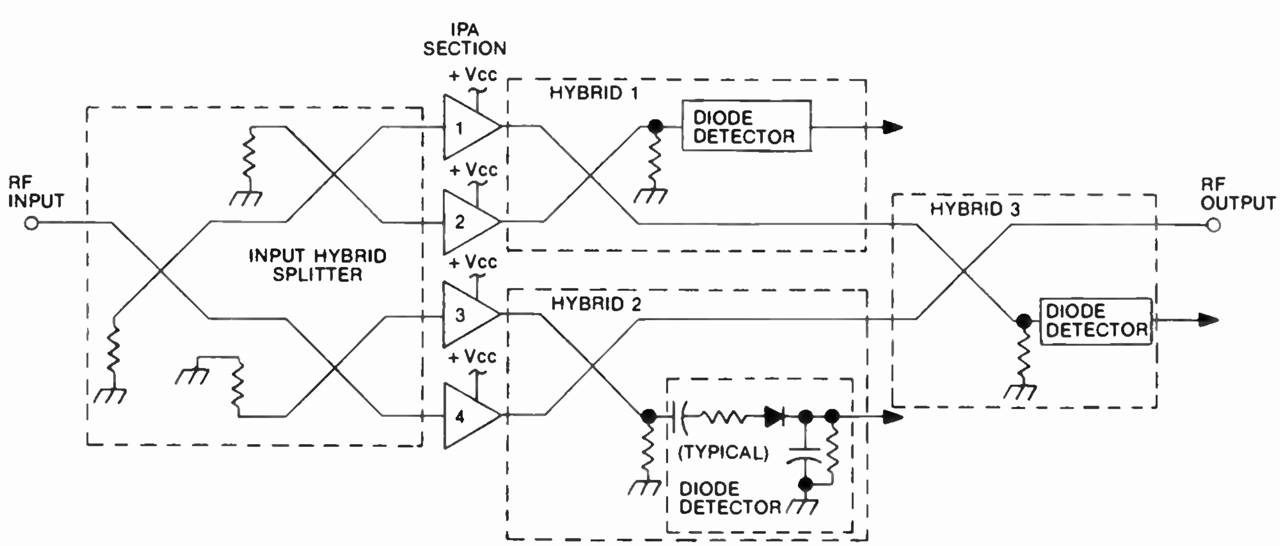

Figure 20. Cascaded 90° hybrid splitting/combining system.

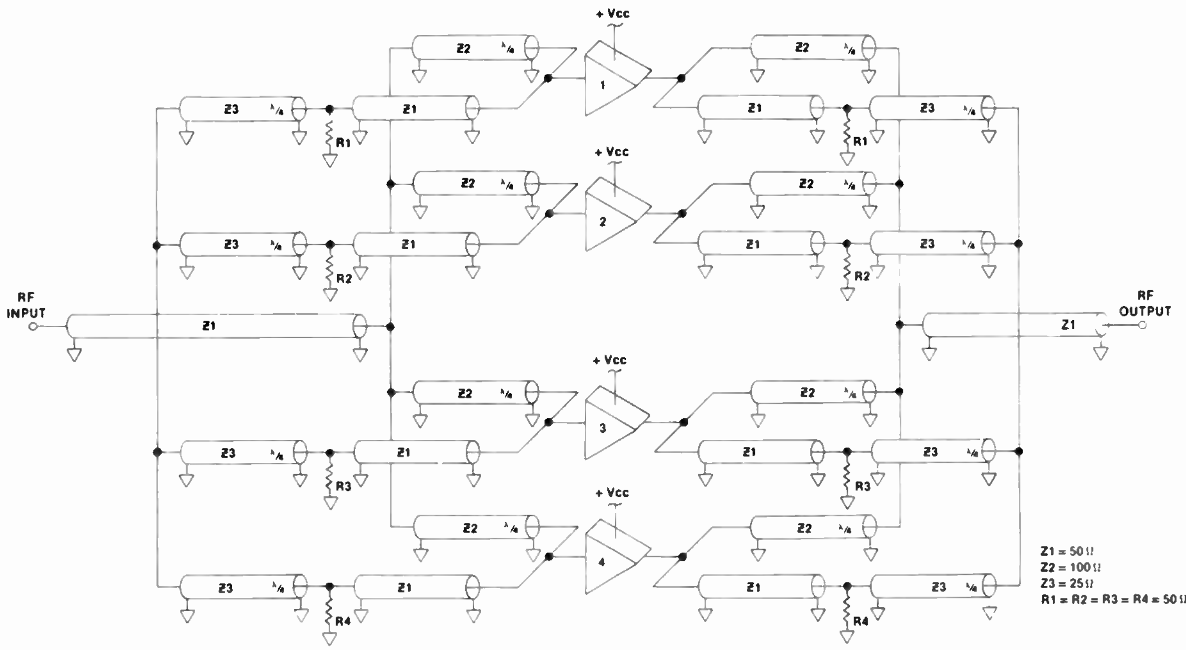

Figure 21. Wilkinson/Gysel in-phase splitting/combining system with unbalanced reject loads.

antenna system. An RF low-pass filter (LPF) is required only when directly feeding the antenna system. The harmonic suppression of the IPA is not as critical when driving a nonlinear power amplifier that also generates harmonics, because this stage will have its own LPF.

SOLID-STATE FM BROADCAST TRANSMITTERS

The techniques used to construct IPA systems can also be used to construct a completely solid-state transmitter using arrays of combined modules for the final output stage. An additional RF low-pass filter is usually required to meet FCC emission requirements. Several manufacturers offer solid-state FM broadcast transmitters with power outputs ranging from 100 watts up to 10 kilowatts, but present economic factors still favor the single tube FM transmitter for power levels above 5 kilowatts. In order for a solid-state transmitter to be cost and power consumption competitive with a single-tube transmitter, the efficiency of the solid-state RF power amplifiers and combining system have to be at least 80% efficient. This high efficiency is difficult to achieve with presently available solid-state devices at VHF frequencies.

Advantages of Solid-State Transmitters

The primary advantages of a solid-state transmitter are the built-in amplifier redundancy, the ability to cover the entire FM band without the need for retuning, and elimination of tube replacement costs. Even a tubeless transmitter is not entirely maintenance free, because high-power solid-state RF devices do age and wear out like tubes, depending on the junction operating temperature and internal current density. The typical life of an RF transistor conservatively operated, is typically at least ten years.

Output Filtering Requirements

Broadband, solid-state transmitters are much more likely to generate RF intermodulation products than single-tube transmitters which have selectivity in the output stage. Broadband, solid state, amplifiers may require tuned output band-pass filters when operating in a dense RF environment in order to prevent RF intermodulation products from being generated in the PA modules.

For more information about solid state amplifiers and hybrid splitter/combiners, see Refs. 6, 7, 8, and 9 at the end of this chapter.

VACUUM TUBE POWER AMPLIFIER CIRCUITS

The amplitude of an FM signal remains constant with modulation so that efficient class B and C amplifiers can be used. Most exciters being manufactured at this time, provide 10 watts to 50 watts of output power. It is technically feasible to develop transistor amplifiers for any required power, but they are not yet economically competitive at high power levels. Additional circuitry is involved because it takes the combined output of many transistors to produce a few kilowatts of power output. For this reason, the following discussion will relate to vacuum tube amplifier circuits.

FM broadcast power amplifier circuits have evolved into two basic types. One type uses a tetrode or pentode tube in a grid-driven circuit, while the other uses a high-mu triode in a cathode-driven (grounded-grid) circuit.

Cathode-Driven Triode Amplifiers

The high-mu triodes being used in cathode-driven (grounded-grid) FM amplifiers were originally developed for linear single sideband (SSB) amplifiers. Their characteristics are well adapted to FM broadcast use because the circuit is very simple and no screen or grid bias power supplies are required. Fig. 22 shows the basic circuit configuration. In this case, the grid is connected directly to chassis ground. DC grid current is the difference between DC cathode current and DC plate current. The output tank circuit is a shorted coaxial cavity which is capacitively loaded by the tube output and stray circuit capacitance. A small capacitor is used for trimming the tuning, and another small variable capacitor is used for adjusting the loading. A pi-network matches the 50 ohm input to the tube cathode.

The triodes are usually operated in the class B mode in order to achieve maximum power gain, which is on the order of 20 (13 dB). They can be driven into class C operation by providing grid bias. This increases the plate efficiency, but also requires increased drive power.

Most of the drive power into a grounded-grid amplifier is fed through the tube and appears in the stage's output. This increases the apparent efficiency so that the efficiency factor given by the manufacturer may be higher than the actual plate efficiency of the tube. The true plate efficiency is determined by dividing the output power by the total input power, which includes both the DC plate input power (Ip × Ep) and the RF drive power. Since most of the drive power is fed through the tube, any changes in loading of the output circuit will also affect the input tuning and driver stage.

There is RF drive voltage on the cathode (filament) of the tube, so some means of decoupling must be used to block it from the filament transformer. One method employs high current RF chokes since the inductance can be very low at this frequency range. The other commonly used method feeds the filament power through the input tank circuit inductor.

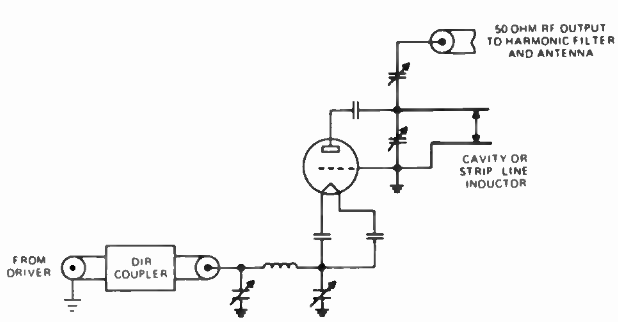

Figure 22. Cathode-driven triode power amplifier.

Cathode-driven stages are normally used only for the higher power stages. The first stage in a multi-tube transmitter is nearly always a tetrode because of its higher power gain.

Grounded-Grid versus Grid-Driven Tetrode Operation

Tetrodes may also be operated in the grounded-grid configuration by placing both the control grid and the screen grid at RF ground. Higher efficiency and gain can be achieved by placing negative bias on the control grid while placing a positive voltage on the screen grid of a cathode-driven tetrode.

The input capacitance of a tetrode in a grounded-grid configuration is much less than a grid-driven configuration and the input impedance is lower, providing better bandwidth.

Approximate input capacitances of some typical tubes are:

TUBE TYPE	Cin (PF) Grounded Grid	Cin (PF) Grounded Cathode
4CX 3,000A	67	140
4CX 3,500A	59	111
4CX 5,000A	53	115
4CX 15,000A	67	161
4CX 20,000A/8990	83	190

The typical drive power requirements, as a function of plate voltage, for a 5 kW power amplifier are:

Configuration	Plate Voltage/Drive Power 4500 Volts	5200 Volts
Grounded-Grid	340 Watts	280 Watts
Grid-Driven	190 Watts	140 Watts

Television transmitters sometimes use a grounded-grid tetrode configuration to increase the input bandwidth of the amplifier. There are several trade-offs between the performance of grounded-grid and grid-driven operation of a tetrode PA with respect to gain, efficiency, amplitude bandwidth, phase bandwidth, and synchronous AM under equivalent operating conditions:

1. When driving the PA into saturation, the bandwidth of the PA is limited by the output cavity bandwidth in the grounded-grid amplifier. The PA bandwidth in the grid-driven amplifier is limited by the input circuit "Q", which is basically determined by the amount of swamping resistance.
2. Output bandwidth under saturation can be improved in either configuration by reducing the plate voltage. This involves a trade-off in efficiency with a smaller voltage swing. The bandwidth improve-

ment can be obtained with a loss of PA gain and efficiency.

3. A grounded-grid saturated PA improves bandwidth over a grid-driven saturated PA at the expense of amplifier gain. Best performance for FM operation is obtained when the amplifier is driven into saturation where little change in output power occurs with increasing drive power. Maximum efficiency also occurs at this point.
4. The phase linearity in the 0.5 dB bandwidth is better in a grid-driven configuration. The class C, grounded-grid, PA exhibits a more nonlinear phase slope within the passband, yet has a wider amplitude bandwidth. This phenomenon is due to interaction of the input and output circuits because they are effectively connected in series in the grounded-grid configuration. The neutralized grid-driven PA provides more isolation between these networks, so they behave more like independent filters.

Grid-Driven Tetrode and Pentode Amplifiers

A small tetrode tube, such as the 4CX250B, is commonly used as the only amplifier stage in 250 watt transmitters and as the driver for higher power stages. The largest single stage transmitter presently available uses a high gain 5CX1500A pentode to deliver 2.5 kW. Higher power levels require two stages (an IPA and the final PA).

Transmitters using tetrode amplifiers throughout usually have one less stage than those using triodes. Since tetrodes have higher power gain, they are driven into class C operation for high plate efficiency. Against these advantages is the requirement for neutralization, along with screen and bias power supplies.

Fig. 23 shows a schematic of a grid-driven tetrode amplifier. In this example, the screen is operated at DC ground potential, and the cathode (filament) is operated below ground by the amount of screen voltage required. This is called grounded-screen operation. It has the advantage that stability problems, due to undesired resonances in the screen bypass capacitors, are eliminated. With directly heated tubes, it is necessary to use filament bypass capacitors. During grounded-screen operation, these bypass capacitors will need to have a higher breakdown voltage rating since they will have the DC screen voltage across them. The filament transformer must have additional insulation to withstand the DC screen voltage. The screen power supply provides a negative voltage in series with the cathode-to-ground, and must have the additional capacity to handle the sum of the plate and screen currents. A coaxial cavity is used in the output circuit so that the circulating current is spread over large surfaces keeping the losses very low. This cavity is a shorted quarter-wavelength transmission line section which resonates the tube's output capacitance. The length is preset to the desired carrier frequency and then a small value variable capacitor is used to trim

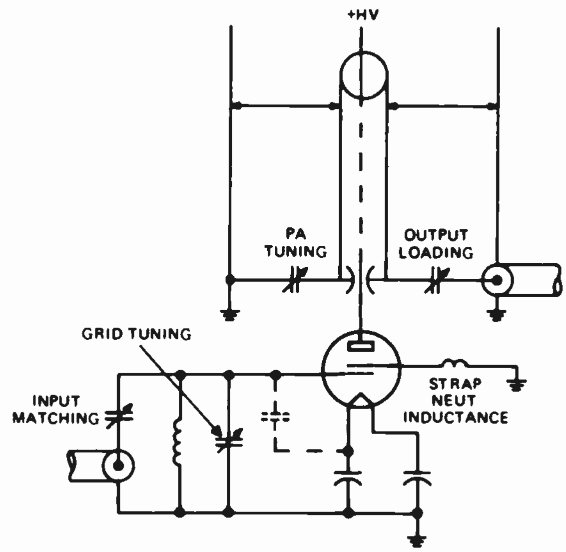

Figure 23. Grid-driven grounded screen tetrode power amplifiers.

the system to resonance. Capacitive output coupling is used from the high RF voltage point to the 50 ohm transmission line. The 50 ohm input is capacitively coupled into the grid circuit inductor to provide the correct impedance match.

Pentode amplifiers have even higher gain than their tetrode counterparts. The circuit configuration and bias supply requirements for the pentode are similar to the tetrode since the third (suppressor) grid is tied directly to ground. The additional isolating effect of the (suppressor) grid eliminates the need for neutralization in the pentode amplifier.

Impedance Matching Into The Grid

The grid circuit is usually loaded (swamped) with added resistance. The purpose of this resistance is to broaden the bandwidth of the circuit by lowering the circuit "Q" and to provide a more constant load to the driver. It also makes neutralizing less critical so that the amplifier is less likely to become unstable with varying output circuit loading.

Cathode or filament lead inductance from inside the tube, through the socket and filament capacitors to ground, can heavily load the input circuit. This is caused by RF current flowing from grid to filament through the tube capacitance and then through the filament lead inductance to ground. An RF voltage is developed on the filament which in effect causes the tube to be partly cathode driven. This undesirable extra drive power requirement can be minimized by series resonating the cathode return path with the filament bypass capacitors or by minimizing the cathode-to-ground inductance by using a specially designed tube socket using thin-film dielectric "sandwich" capacitors for coupling and bypassing.

High power, grid driven, class C, amplifiers require a swing of several hundred RF volts on the grid. To develop this high voltage swing, the input impedance of the grid must be increased by the grid input matching circuit. Since the capacitance between the grid and the other tube elements may be 100 picofarads or more, the capacitive reactance at 100 MHz will be very low unless the input capacitance is parallel resonated with an inductor. Bandwidth can be maximized by minimizing any additional circuit capacitance and utilizing a portion of the tube input capacitance as part of the impedance transformation network. Figs. 24A and 24B show two popular methods of resonating and matching into the grid of a high power tube. Both methods can be analyzed by recognizing that the desired impedance transformation is produced by an equivalent "L" network.

In Fig. 24A, a variable inductor (L_{in}) is used to raise the input reactance of the tube by bringing the tube input capacitance (C_{in}) almost to parallel resonance. Parallel resonance is not reached since a small amount of parallel capacitance (C_p) is required by the equivalent "L" network to transform the high impedance (Z_{in}) of the tube down to a lower value through the series matching inductor (L_s). This configuration has the advantage of providing a low-pass filter by using part of the tube's input capacitance to form (C_p), instead of an external bandwidth-reducing variable capacitor.

Fig. 24B uses variable inductor (L_{in}) to take the input capacitance (C_{in}) past parallel resonance so that the tube's input impedance becomes slightly inductive. The variable series matching capacitor (C_s) forms the rest of the equivalent "L" network. This configuration is a high-pass filter.

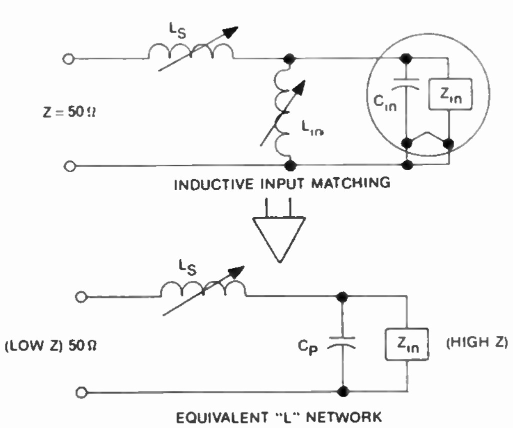

Figure 24A. Inductive input matching.

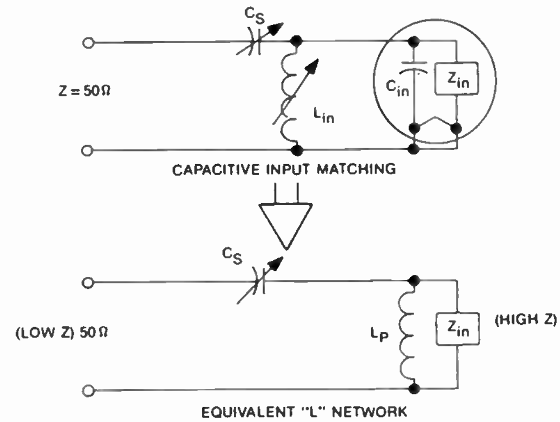

Figure 24B. Capacitive input matching.

Neutralization

Apparently none of the cathode-driven amplifiers utilizing triodes require neutralization. It is necessary that the grid-to-ground inductance, both internal and external to the tube, be kept very low to maintain this advantage. Omission of neutralization will allow a small amount of interaction between the output circuit and the input circuit through the plate-to-filament capacitance. This effect is not very noticeable because of the large coupling between the input and output circuits through the electron beam of the tube. Cathode-driven tetrodes have higher gain and therefore require some form of neutralization.

Grid-driven, high gain tetrodes need accurate neutralization for best stability and performance. Self-neutralization can be accomplished very simply by placing a small amount of inductance between the tube screen grid and ground. This inductance is usually in the form of several short, adjustable-length straps. The RF current flowing from plate to screen in the tube also flows through this screen lead inductance. This develops a small RF voltage on the screen, of the opposite phase, which cancels the voltage fed-back through the plate-to-grid capacitance. This method of lowering the self-neutralizing frequency of the tube works only if the self-neutralizing frequency of the tube/socket combination is above the desired operating frequency before the inductance is added. (Ref. 10 at the end of this chapter has more information on the theory of self neutralization.) Special attention must be given to minimizing the inductances in the tube socket by integrating distributed bypass capacitors into the socket and cavity deck assembly. Pentodes normally do not require neutralization because the suppressor grid effectively isolates the plate from the grid.

POWER AMPLIFIER OUTPUT CIRCUITS

Usually, the output circuit consists of a "high-Q" (low loss) transmission line cavity, strip line, or a lumped inductor that resonates the tube output capacitance. A means of trimming the tuning and a means of adjusting the coupling to the output transmission line must also be provided by the output circuit. The tank circuit loaded "Q" is kept as low as practical to minimize circuit loss and to maintain as wide an RF bandwidth as possible.

The Power Amplifier Cavity

The vacuum tube power amplifier is constructed in an enclosure containing distributed tank circuit elements for minimum loss. The efficiency of the PA depends on the RF plate voltage swing, the plate current conduction angle, and the cavity efficiency. The cavity efficiency is related to the ratio of loaded to unloaded "Q" as follows:

$$N = 1 - \left(\frac{Q_l}{Q_u}\right) \times 100$$

where: N = Efficiency in percent
Q_L = Loaded "Q" of cavity
Q_u = Unloaded "Q" of cavity

The loaded "Q" depends on the plate load impedance and output circuit capacitance. Unloaded "Q" depends on the cavity volume and the RF resistivity of the conductors due to skin effects. A high unloaded "Q" is desirable, as is a low-loaded "Q", for best efficiency. As the loaded "Q" goes up, the bandwidth decreases. For a given tube output capacitance and power level, loaded "Q" decreases with decreasing plate voltage or with increasing plate current. The increase in bandwidth at reduced plate voltage occurs because the load resistance is directly related to the RF voltage swing on the tube element. For the same power and efficiency, the bandwidth can also be increased if the output capacitance is reduced. Power tube selection and minimization of stray capacitance are areas of prime concern when designing for maximum bandwidth.

The methods used to improve the bandwidth of PA output circuits include minimizing added tuning capacitance. The ideal case would be to resonate the plate capacitance alone with a "perfect" inductor, but practical quarter-wave cavities require either the addition of a variable capacitor or a variable inductor using sliding contacts for tuning. The inherent mechanical and electrical compromises are the requirement for a plate DC blocking capacitor and the presence of maximum RF current at the grounded end of the line where the conductor may be nonhomogeneous, with accompanying losses in the contact resistance.

The Quarter-Wavelength Cavity

The quarter-wavelength coaxial cavity is the compact and popular output circuit illustrated in Fig. 25. The tube anode is coupled through a DC blocking capacitor to a shortened quarter-wavelength transmission line. The tube's output capacitance is brought to resonance by the inductive component of the transmission line that is physically less than a quarter-wavelength long. Plate tuning can be accomplished either by adding end-loading capacitance at the high-impedance end of the line with a variable capacitor or by sliding the ground plane at the low-impedance end of the line. The plate tuning capacitor may be a sliding or rotating plate near the anode of the tube. The center conductor of the transmission line (chimney) is at DC ground while the anode of the tube operates at a high RF and

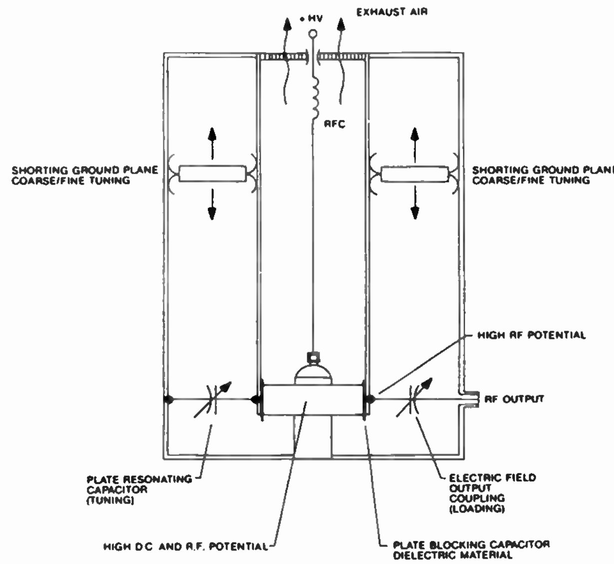

Figure 25. The quarter-wavelength cavity.

DC potential. DC voltage is fed through an isolated quarter-wavelength decoupling network inside the chimney to the anode of the tube, while the plate blocking capacitor prevents DC current flow from the anode into the chimney.

The Folded-Half-Wavelength Cavity

Another approach to VHF power amplification uses the re-entrant, folded half-wave cavity design illustrated in Fig. 26. The DC anode voltage is applied to the lower portion of the plate line through a choke at the RF voltage null point. This RF voltage null point is reasonably consistent through the entire commercial FM broadcast band. The second harmonic voltage peak, which is located at this same point, exhibits a high source impedance and high voltage, allowing suppression with a simple series LC arrangement. This method provides about 50 dB of suppression to the second harmonic with no power loss at the fundamental frequency. The half-wave line is tuned by mechanically expanding or contracting the physical length of a flexible extension (bellows) on the end of the secondary transmission line stub, which is located concentrically within the primary transmission line (chimney). The bellows assembly is constructed of beryllium copper, providing high conductivity and long flex life.

Coarse frequency adjustment is accomplished by presetting the depth of the top secondary section of plate line into the tank cavity. A plate blocking capacitor is unnecessary since an air gap is provided between the primary line carrying the DC plate voltage and the secondary line at DC ground potential. Ohmic losses are minimized because the high RF current point is located in the central area of the homogeneous primary line where no joints, fasteners, or obstructions occur. Due to the folded nature, this configuration requires

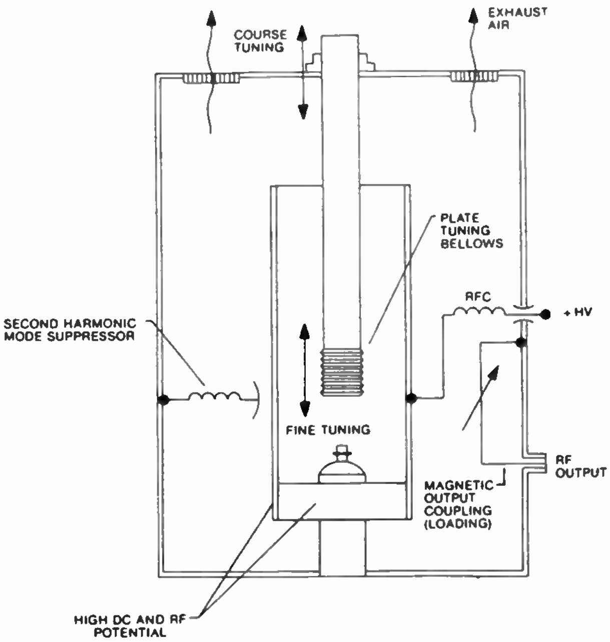

Figure 26. The folded-half-wavelength cavity.

only slightly more physical space than the quarter-wave design.

Other power amplifier configurations may use lumped components or hybrid combinations with distributed transmission line elements to achieve similar results. The discrete circuit elements are chosen for their individual inductance or capacitance, instead of being operated in a purely quarter-wave or half-wave mode. Stray inductance and capacitance add to the component values resulting in the hybrid nature of these circuits.

The RF voltage and current distributions for the quarter-wavelength and the folded-half-wavelength cavities are shown in Fig. 27.

Regardless of the specific configuration, the output circuit must transform the high resonant plate impedance down to the output transmission line impedance of 50 ohms.

The bandwidth of either a quarter-wave or half-wave transmission line cavity is optimized by choosing the highest characteristic impedance mechanically allowable. The center conductor is sized for minimum impedance discontinuity and is clamped to the outer surface of the anode fins for better heat transfer. In the folded half-wave cavity, the secondary tuning line (with adjustable bellows) is sized to maintain a similar characteristic impedance without appreciable end-loading capacitance.

(Refs. 10 and 16 at the end of this chapter give detailed information about the design of tube type RF power amplifiers.)

Output Coupling

Power may be coupled from a quarter-wavelength cavity to the transmission line by a capacitive probe located at the high RF voltage point located at the anode end of the quarter-wave line as shown in Fig. 25. The loaded "Q" of this circuit varies with the degree of capacitive coupling. Another method of coupling power from the quarter-wavelength cavity uses a tuned loop located near the grounded (high current) end of the line. In this case, the tuned loop operates both as an inductive and a capacitive pick-up device.

Power may be coupled from the half-wave line by an inductive loop located in the strong fundamental magnetic field near the center of the cavity as shown in Fig. 26. One end of the output loop that couples energy to the transmission line is electrically grounded to the cavity wall. Output loading is mechanically controlled by changing the position of the loop in the magnetic field generated at the null point of the primary line structure. Multiple phosphor-bronze leaves pro-

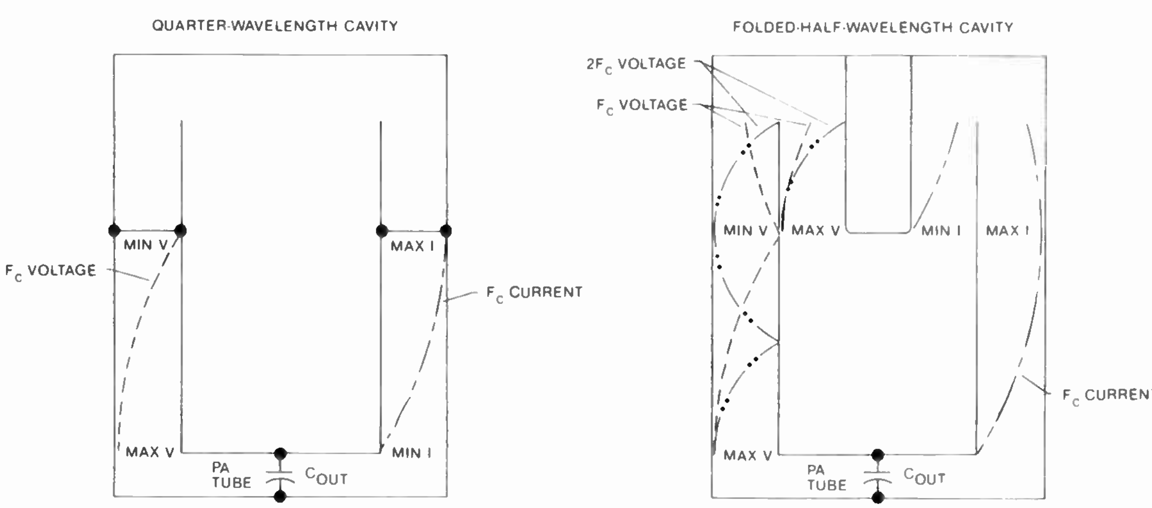

Figure 27. Cavity RF voltage and current distributions.

vide the connections to the loop allowing mechanical movement without sliding contacts. The loaded "Q" of the cavity varies as the square of the effective loop area and inversely as the square of the distance of the loop center from the cavity center axis. As this loop is positioned so that it links more or less magnetic field, it determines the output loading of the transmitter. Magnetic coupling at the voltage null point also eliminates interaction between the tuning and loading controls.

Power Amplifier Source Impedance

At the milliwatt levels used in RF test equipment, it is customary to provide both 50 ohm source and load impedances at both ends of a coaxial transmission line. This approach minimizes any reflections on the line since both the transmitter (source) and the termination (load) will absorb reflected energy. A 50 source impedance is usually provided by placing a 50 ohm build-out resistor in series with a low impedance voltage source (Thevenin equivalent). The closed circuit voltage with this configuration is exactly one-half of the open circuit voltage, meaning that half of the total available RF power is dissipated in the source resistance. The best possible efficiency for this system is 50% assuming the voltage source is 100% efficient without the source resistance.

It becomes obvious that while an FM transmitter is designed to drive a 50 ohm load, it does not itself have an output source impedance of 50 ohms. In order to achieve high efficiency, the transmitter must have a very low output source impedance so that nearly all of the power is delivered to the load. The plate dissipation indirectly represents some of the power lost within the low source resistance. Since the low source impedance of the transmitter provides a mismatch to reflected power from the load, this power is almost totally reflected back from the transmitter output stage toward the load again.

EFFECTS OF CIRCUIT TOPOLOGY AND TUNING ON FM MODULATION PERFORMANCE

FM broadcast transmitter RF power amplifiers are typically adjusted for minimum synchronous AM (incidental amplitude modulation) which results in symmetrical amplitude response. This will assure that the transmitter's amplitude passband is properly centered on the FM channel. The upper and lower sidebands will be attenuated equally or symmetrically which is *assumed* to result in optimum FM modulation performance. This will be true if the RF power amplifier circuit topology results in simultaneous symmetry of amplitude and group delay responses.

Actually, symmetry of the group delay response has a much greater effect on FM modulation distortion than the amplitude response. Tuning for symmetrical group delay will cause the phase/time delay errors to affect the upper and lower sidebands equally or symmetrically. The group delay response is constant if the phase shift versus frequency is linear. All components of the signal are delayed in time, but no phase distortion occurs.

The tuning points for symmetrical amplitude response and symmetrical group delay response usually do *not* coincide, depending on the circuit topology. Therefore, simply tuning for minimum synchronous AM (symmetrical amplitude response) does not necessarily result in best FM modulation performance.

Measurements taken on a typical FM transmitter as well as computer simulations[23] showed that tuning the RF power amplifier for symmetrical group delay response resulted in minimum distortion and crosstalk. It confirms that group delay response asymmetry causes higher FM modulation distortion and crosstalk than amplitude response asymmetry. Therefore, RF power amplifier circuit topologies that exhibit coincidence of symmetrical amplitude and group delay responses will result in a better overall FM modulation performance. The transmitter should be tuned for symmetrical group delay response, which results in best FM modulation performance rather than symmetrical amplitude response, which results in minimum synchronous AM.

POWER SUPPLIES

Power supplies provide the appropriate DC or AC voltages to the various subsystems with the transmitter. The range of voltages and currents provided can be from less than five volts at a few milliamperes, to over 10,000 volts at several amperes in a typical FM transmitter. Safety must be a prime consideration when working around potentially lethal power supplies. Power supplies must be designed with adequate bleeder resistors and interlocks to discharge high voltages before an operator can come in contact with these circuits. The degree to which the AC components are filtered out of the DC outputs of the power supplies will, in large part, determine the "asynchronous" (without FM modulation) AM noise of the FM transmitter.

FM transmitters usually contain multiple power supplies for each of the functional blocks within the system. These power supplies fall into two general categories:

1. Single-phase supplies (single input winding on the transformer).
2. Polyphase supplies (three or more input windings on the transformer).

Single-Phase Power Supplies

Single-phase power supplies with conventional full-wave rectification and filtering are most often used for the FM exciter, the control system, bias supplies, and the intermediate power amplifier (IPA). The filament transformer is also a single-phase transformer. A single-phase supply requires a larger filter choke to achieve the "critical inductance" requirement and a greater value of filter capacitance to maintain acceptably low ripple content compared to a polyphase supply. Large value filter components also mean that the greater stored energy in these components can have a more destructive effect if an arc-over occurs. Choke-input filter sections are normally used to help limit the in-rush current while the shunt capacitor is charging during turn-on. This also maximizes utilization of the transformer and rectifiers by keeping the charging current nearly constant, providing the best filtering action. Choke-input filters have the undesirable characteristic of poor voltage regulation over a wide range of loads. The output voltage will "soar" above the nominal value with no load unless there is enough current through the "bleeder" resistor to keep the choke in the constant current range. Fortunately, in a FM transmitter application, the load on the power supply is fairly constant since the power output of the transmitter does not vary significantly with FM modulation. In higher power transmitters where the main power source is three-phase, care must be taken to balance each of the individual single-phase loads among the three phases so that the total load on each of the individual phases is equal.

Polyphase Power Supplies

Polyphase power supplies are used for the final power amplifier high voltage supply in high power transmitters. Sometimes they are also used for tube or solid state IPA supplies. Large blowers used to cool transmitters are usually operated from a three-phase power source. Care must be taken to make the three line connections to the blower motor in the proper sequence so that the motor will turn in proper direction.

The most common type of polyphase supply is three-phase with full-wave rectification and LC filtering. Other polyphase systems encountered in broadcast equipment are usually multiples of the three phases with twelve phase rectifiers becoming more popular. The main advantages of a polyphase power supply are:

1. Division of the load current between three or more lines to reduce line losses and the size of each of the lines.
2. Greatly reduced filtering requirements after rectification due to the low ripple at the output of a polyphase full-wave rectifier.
3. Better voltage regulation with a choke input filter with typically 6% or less "soaring" from no load to full load.
4. Greater choice of output voltages from a given transformer by selection of either a DELTA or WYE configuration.

The main disadvantage of polyphase systems is their susceptibility to phase imbalance, which causes degraded performance of the power supply. If significant imbalance exists in a polyphase system, ripple rejection will be reduced in the polyphase rectifier with a resulting increase in AM noise.

The broadcast engineer should be particularly careful to be sure that the local utility does in fact, provide true three-phase power to the transmitter site. This can usually be verified by making sure that there are three transformers on the utility pole feeding the transmitter site. In many rural areas, the utilities are still synthesizing pseudo-three-phase service by providing the so called "open-delta"(V-V) or "Scott"(T-T) connection with two transformers instead of true three-phase service. Operation on an "open-delta" service will degrade the transmitter's performance and increase the susceptibility of the transmitter to damage from transients on the line. Most transmitter manufacturers state that their warranty is void if the transmitter is connected to an "open-delta" system.

Special Power Supplies

Trends toward completely solid-state power amplification demand lower voltages at much higher currents. Voltage regulation of these high current supplies is necessary to suppress ripple, but the design of these specialized regulators is different from the typical high-voltage power supply. Linear regulators are used at the lower power levels because they are low in efficiency, but they are simple and provide excellent ripple rejection without the need for suppression of switching transients. The linear regulators use series or shunt devices which change resistance dynamically to provide regulation with changes in load and therefore dissipate some of the power within the dynamic resistance.

Switch-mode regulators are used at higher power levels because they are high in efficiency, but they are more complicated and require additional suppression of the switching transients. The high efficiency comes from the digital "on" or "off" nature of the switching regulator which reduces resistive losses by using low loss reactive components to store energy during switching.

In some cases, phase control switching regulation is applied to the high voltage power supply feeding the final output tube. The regulation is accomplished by switching thyristors in the AC mains ahead of the primary winding of the transformer. As the switching duty cycle is reduced, the plate voltage is also reduced. Care must be taken to protect solid-state devices connected to the main power line from lightning transients. Heavy duty transient suppressors are available for this purpose.

Low-voltage/high-current power supplies contain extremely large amounts of stored energy that can be dangerous due to the high peak currents that can occur during a short circuit across a component with high stored energy. For this reason, special attention must be paid to methods of safely discharging these circuits without damage to components or injury to the operator. The voltage regulator should provide short-circuit protection with some type of current limiting. The main danger to the operator from this type of power supply is burns due to the nearly instantaneous heating of metallic tools or other conductors that accidentally get into a high current path such as a short across the filter capacitor.

(For more detailed information on power supply theory, see Refs. 2, 12, and 13 at the end of this chapter.)

Step-Start

Step-start is often used in large power supplies where peak in-rush currents become high when the power supply is first turned on. These peak currents are caused by the need to overcome the hysteresis effect to initially magnetize the core of the transformer when AC power is first applied and to charge the filter capacitor. Step-start systems temporarily insert a resistance or reactance in series with the power lines to limit the current to a reasonable value until initial magnetization of the core and filter charging are completed. The system should be designed so that failure of the step-start mechanism will not prevent getting "on-the-air" without step-start. This is accomplished by using "fail-safe" systems where the current limiting components are only in series with the line during the starting interval until the main circuit is closed in parallel with the step-start circuit, then the connection to the current limiting components is opened.

TRANSMITTER CONTROL SYSTEMS

Transmitter control systems are often overlooked or given little priority in the selection and maintenance of a broadcast transmitter. The transmitter's control system does however, serve several important purposes:

1. Must provide basic on/off control of the transmitter.
2. Must provide overload protection to protect the transmitter from damage.
3. Must provide safety interlock protection to prevent injury to people and accessory equipment such as RF switching equipment or RF loads.
4. Must provide a means for controlling the transmitter output power.
5. Must provide remote control capability and interfacing at installations where the transmitter is not at the same location as the control operator.
6. Must provide warm-up and cool-down timing sequences of filaments or other time sensitive operations.
7. May provide status indications of overloads or other critical parameters.
8. May provide automatic regulation of the transmitter output power.
9. May provide diagnostic indications to aid in adjustment and maintenance.
10. May provide totally automatic operation of the transmitter plant (ATS).
11. May provide integrated remote control capability.

The transmitter's ability to stay "on-the-air" will only be as good as the reliability of the control system, so it is easy to recognize the importance of the selection and correct operation of the transmitter control system.

Early transmitter technology relied on simple relay logic combined with electromechanical contactors to control the transmitter. The speed and variety of overload protection was limited and diagnostics were not available. While these systems had the virtue of being simple and immune to radio frequency interference (RFI), the relay logic required continuing maintenance in order to keep the contacts clean and adjusted.

Later, the transmitter control logic relays were replaced by solid-state digital logic. This provided much more flexibility and reliability, but also raised concerns about the ruggedness and ability of solid-state logic to survive lightning strikes. Although this concern is valid, modern solid-state logic systems are well protected against damage by optical isolation, shunt protection techniques, and RFI filtering. Operating experience with the current generation of transmitters has proven that a properly designed solid-state control system is far more reliable than its relay predecessors.

Automatic Power Control

Many transmitters also provide automatic power control (APC) circuitry to maintain the transmitter's power output within preset limits by correcting for changes in line voltage, component aging, or small amounts of drift in operating parameters. The APC circuitry compares a sample of the transmitter output power against a reference, and then adjusts the RF drive or other voltages within the transmitter to bring the output power within tolerance.

Some of the more sophisticated APC circuits also provide proportional VSWR foldback of the transmitter output power. If a sample of the reflected power on the transmission line exceeds a safe limit, the transmitter output power is proportionally reduced to a safe level until the problem is resolved. This feature prevents lost air time during antenna icing or other limited VSWR situations. All standard APC circuits should provide fast-acting shutdown of the transmitter during a catastrophic failure of the antenna system such as a short or open circuit. A well designed APC system should operate like a damped analog feedback system with fast response and low overshoot.

Microprocessor Control Systems

Recently, microprocessor technology has been applied to broadcast transmitter control systems. Microprocessor based control systems can expand the functions of the transmitter controller from basic housekeeping duties into powerful self diagnostics, controller redundancy, integrated remote control, user customization, and even self-correction of operational problems.

Microprocessor technology lends itself well to industrial control applications like broadcast transmitters because the hardware can be made just as reliable as hard-wired digital logic, but has the advantage of allowing changes and growth in the operational features by simple changes in software instructions without requiring a complete redesign of the hardware.

Several transmitter manufacturers are marketing transmitters with microprocessor based control systems. Some of the typical features that distinguish these control systems from nonmicroprocessor systems are:

1. Built-in trouble tree with fault location and diagnostic read-outs often using plain English messages (user-friendly).
2. Simultaneous read-outs of all operating parameters.
3. Real-time calculation of efficiency, dissipation, VSWR, and other parameters requiring mathematical operations.
4. Built-in clock/calendar for logging changes in operating status, power failures, and overloads.
5. Tolerance flagging on key operating parameters as warnings for logging and for preventive maintenance.
6. The ability to communicate with the outside world for remote control or logging purposes through a standard serial interface.
7. Integrated remote control capability without external remote control equipment and interfacing.
8. Provision to customize the system features to the individual requirements of the station through the use of software menus.
9. Tuning aids which will allow the operator to adjust the system for peak efficiency, minimum dissipation, and minimum VSWR by means of a real time display of these calculated parameters.
10. The method of communicating information to the operator varies from one system to another, but most use LED or LCD read-outs with codes or alphanumeric messages. Some microprocessor controllers use CRT displays so that a large amount of information can be displayed in several different formats.

Controller Back-Up Systems

A certain degree of redundancy is desirable in the transmitter control system so that the transmitter can stay on-the-air even if a portion of the system fails. There are several approaches being used in present equipment to provide back-up systems. A multi-level hierarchy can be used which automatically hands over basic control functions to a primary controller in the event of a problem in the microprocessor hardware or software. Good system design separates diagnostic and supervisory functions from basic control functions so that a failure in a higher level function will not affect the ability of the system to remain on-the-air without interruption. Watchdog circuits and software are embedded within the control system to detect failures and initiate corrective action before an interruption in service occurs.

It is also possible to have two entirely independent microprocessor systems operating in parallel with only one system in charge at one time. Sophisticated software is required to determine if the two systems agree and, if they don't agree, an algorithm must be used to decide which one is right so that control can be delegated to the properly functioning system.

The ability to quickly substitute another replacement control system or a simplified controller bypass unit is useful in the event of total failure of the control system.

Remote Control Interfacing

Regardless of the type of control system used, the ability to interface easily with standard remote control systems is very important. Most modern systems interface with parallel control lines for each individual function requiring a momentary contact closure of 24 volts or less at a current of 50 milliamperes or less. These levels are compatible with relay logic or optically isolated solid state logic. Analog levels output from the transmitter for remote meter readings generally are fully buffered and fall into the range of 0–10 volts DC for a full scale reading at an impedance level of less than 10K ohms.

With the advent of microprocessor-based control systems, there is a trend toward using standard computer asynchronous serial interfacing instead of parallel interfacing. Serial interfacing reduces the number of connections to the transmitter and can carry both control functions and digitized meter readings through the same interface. By converting analog information into digital information before transmission to the remote control point, the need for calibration and recalibration of the remote metering point is reduced. Microprocessor based control systems also allow the remote control system functions to be integrated directly into the transmitter itself, giving the remote control point access to more in-depth information about the transmitter than is possible by interfacing with an external remote control system. A low-cost personal computer or laptop computer can be used to control the transmitter through an ordinary dial-up phone line or through a radio link.

For more specific information, see the chapter on "Transmitter Remote Control Systems."

RF OUTPUT LOW-PASS FILTERS

The high efficiency, nonlinear RF power amplifiers used in FM broadcast transmitters generate significant amounts of energy on frequencies that are integer multiples (harmonics) of the desired fundamental frequency. The output circuit alone does not provide enough harmonic attenuation to meet FCC regulations. To comply with Part 73 of the FCC Rules and Regulations, and to prevent interference to other services, a low-pass filter must be installed in the transmission line at the output of the transmitter. The FM band is narrow enough that one low-pass filter design can be used for any FM channel carrier frequency. These filters usually consist of multiple LC sections arranged so that frequencies within the FM band are passed with little attenuation (typically 0.1 dB or less) while frequencies above the FM band are highly attenuated (60 dB or more).

The most common type of filter used in this application is called a "reflective" filter, meaning that the frequency components outside the passband are reflected back out of the filter toward the source because it provides a mismatch at these undesired frequencies. The filter can be constructed using either "lumped" inductors and capacitors, or by using a section of nonconstant impedance transmission line to form *distributed* inductors and capacitors. The filters designed for low power transmitters often employ *lumped* elements (coils and capacitors), because they are compact and can be integrated into the transmitter cabinet. The distributed type of filter is most often used with high power FM broadcast transmitters because of its simplicity, extreme ruggedness, and ability to handle higher power levels. The distributed filter does have the disadvantage of having larger physical dimensions than a similar lumped filter, which may necessitate mounting the filter external to the transmitter cabinet. Fig. 28 shows a cut-away view of a typical distributed low-pass filter. Note that the areas where the center conductor of the transmission line is smaller than that required for the input Z_o are inductive, while the areas where the center conductor is larger in diameter are capacitive.

When two filters (such as the output cavity and the harmonic filter) are connected together by a transmission line, the total harmonic attenuation will vary with interconnecting line length. The attenuation characteristics of the harmonic filter are specified for the condition where both the source and load impedances are equal to the desired transmission line impedance.

In actual use, the source impedance at the output of the tank circuit is much less than the 50 ohm load impedance presented by a properly terminated filter. If an unfortunate length of line is selected, the harmonic attenuation may be insufficient and the transmitter tuning may be affected. This undesirable condition can be corrected by changing the line length by approximately one-quarter wavelength. The line length between the tank circuit and harmonic filter is usually supplied pre-cut to a value known to be satisfactory by the transmitter manufacturer.

Harmonic Notch Filters

In some cases, a second harmonic notch filter is required in addition to the low-pass filter because the second harmonic component from amplifier is high and the cut-off slope of the low-pass filter is not steep enough to provide sufficient second harmonic attenuation. The additional attenuation required (typically 30 dB) can be provided by an absorptive notch filter, which places a short circuit across the transmission line at the second harmonic while providing a high impedance at the fundamental. A one-quarter wavelength (at the fundamental frequency) shorted coaxial stub is often used for this function. The second harmonic energy is dissipated in the equivalent series resistance of the series tuned circuit formed by the stub. Some types of transmitters, including those using the folded half-wavelength cavity, have internal second harmonic mode suppressors which eliminate the need for an external notch filter.

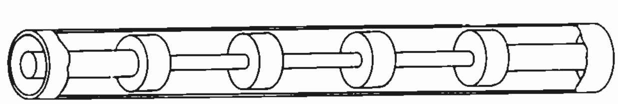

Figure 28. Cut-away view of a distributed low-pass filter.

TRANSMISSION LINE POWER AND SWR MEASUREMENTS

Directional wattmeters are instruments that measure the forward power (P_f) and reflected power (P_r) in a transmission line. The net power delivered to the load (antenna) is ($P_f - P_r$). If the transmission line is perfectly matched all the forward power will be absorbed by the load and there will be no reflected power. The peak voltage at each point along the line will be the same value and similarly the current at each point along the line will also have a uniform value. If the transmission line is mismatched, there will be reflected power with a resulting "standing wave" on the line. This means that the voltage and current distributions along the line will no longer be uniform with high values at certain points on the line and low values at points on the line that are one quarter wavelength away. The ratio of high value to the low value is called the standing wave ratio (SWR).

Standing Wave Ratio

The standing wave ratio (SWR) on the transmission line is related to the ratio of the forward to reflected power by the following formula:

$$SWR = \frac{1 + \sqrt{(P_r/P_f)}}{1 - \sqrt{(P_r/P_f)}} \qquad (12)$$

This relationship is shown graphically in Fig. 29 so the approximate SWR can be obtained without computation.

The standing wave is due to the presence of two components of power: one traveling toward the load; and the other reflected by the load mismatch, traveling back toward the generator.

These components are defined as:

$$P_f = \frac{E_f^2}{Z_o} = I_f^2(Z_o) \qquad (13)$$

$$P_r = \frac{E_r^2}{Z_o} = I_r^2(Z_o) \qquad (14)$$

$$P_n = (P_f - P_r) \qquad (15)$$

The subscripts (f) and (r) are used to denote the forward and reflected values of power, voltage, and current; while Z_o is the characteristic impedance of the transmission line. (P_n) is the net power absorbed by

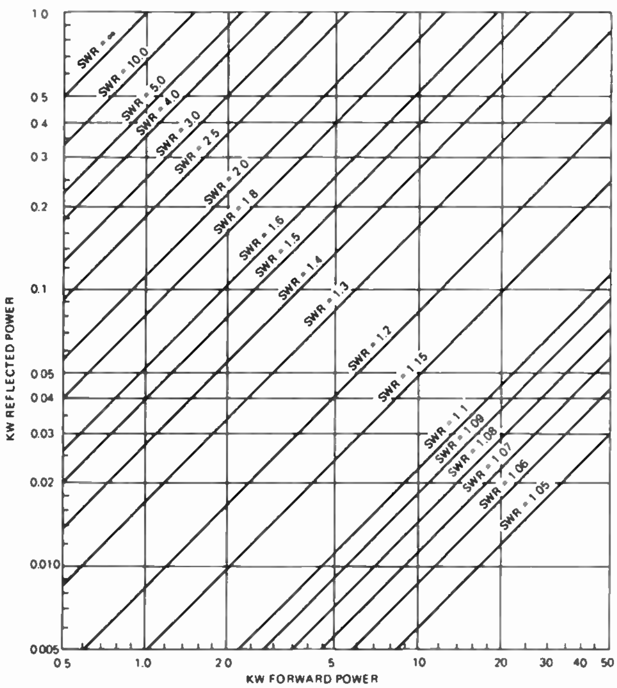

Figure 29. Chart of SWR versus forward and reflected power.

the load (transmission line loss and antenna radiation).

Since the forward and reflected voltage and currents are traveling in opposite directions, they will add in phase at some point along the line length to produce a voltage maximum. One-quarter wavelength along the line in either direction from this maximum, the forward and reflected components are out of phase and produce a voltage minimum. The forward and reflected components of current also add vectorially to produce a current standing wave. The magnitude of the standing wave is defined as:

$$SWR = \frac{E_{max}}{E_{min}} = \frac{I_{max}}{I_{min}} \qquad (16)$$

The ratio of the highest voltage point on the line to the lowest voltage point on the line is a commonly used measure of system performance defined as the voltage standing wave ratio (VSWR). A VSWR of 1.0:1.0 means that a perfect match has been achieved while a VSWR of 2.0:1.0 means that a mismatch is causing approximately 11% of the power to be reflected.

At the point of reflection (the load mismatch), the phase of the reflected current is reversed 180° from the forward current. The reflected voltage does not have this phase reversal. This displaces the voltage and current standing waves by 90° along the line so that the (E_{max}) and (I_{min}) occur at the same points, while (E_{min}) and (I_{max}) occur 90° (one-quarter wavelength) away, in either direction from (E_{max}) and (I_{min}).

The fact that the reflected current is reversed in phase makes it possible to measure forward and reflected power separately using a device called a directional coupler. A small voltage is obtained by inductive coupling which represents the current in the transmission line. To this is added a sample of the voltage across the line that is simultaneously obtained by capacitive coupling. These two samples are adjusted to be exactly equal when the line is terminated with its characteristic impedance (no standing waves and no reflected components). The two RF samples are added, which gives a resultant RF voltage proportional to the forward components of voltage and current as illustrated in Fig. 30A.

The forward components of the samples are equal and in phase, but the reflected components of voltage and current balance out. By having a second coupling section physically turned around in the opposite direction, the phase of the current sample is reversed and the reflected components add while the forward components balance out as illustrated by the vector diagram in Fig. 30B. These voltages output by the directional coupler, representing the forward and reflected powers, are usually rectified and buffered to feed the automatic power controller and a power indicating meter. Since power is proportional to the square of the voltage on the transmission line, the meter scale is calibrated to read the square of its input along with a diode correction factor so that forward and reflected power are read out directly.

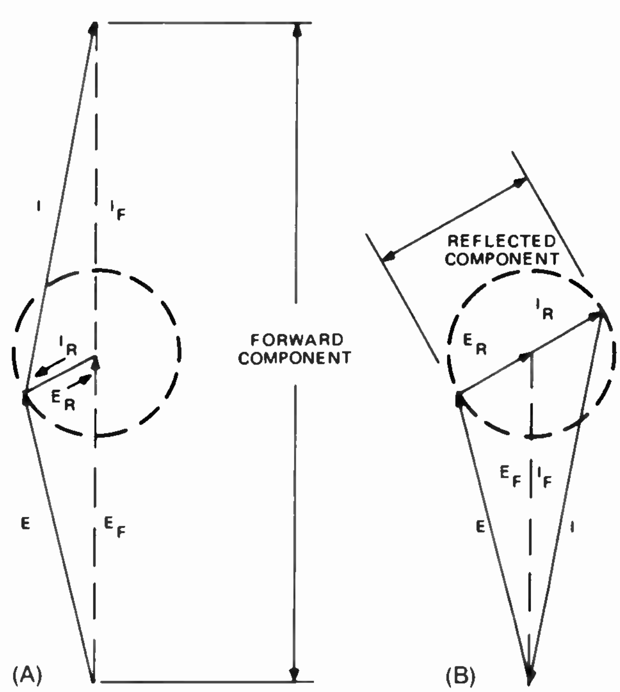

Figure 30. Phasor addition of voltage and current samples to separate forward and reflected components.

VSWR Measurement

Although some FM transmitters can operate into a VSWR of greater than 1.8:1.0, the VSWR on an FM antenna transmission line should normally be kept to a value of 1.1:1.0 or less for good stereo performance. It takes very little reflected power to produce substantial VSWR as shown in Fig. 29. For this reason, the reflected power is usually read on a more sensitive meter position. Problems in the antenna system such as loose connections or icing may cause excessive VSWR. Instruments external to the transmitter are available that monitor reflected power and energize an alarm if it becomes excessive. As long as the transmitter power output is fairly constant, the use of reflected power to indicate excessive VSWR is simple and adequate.

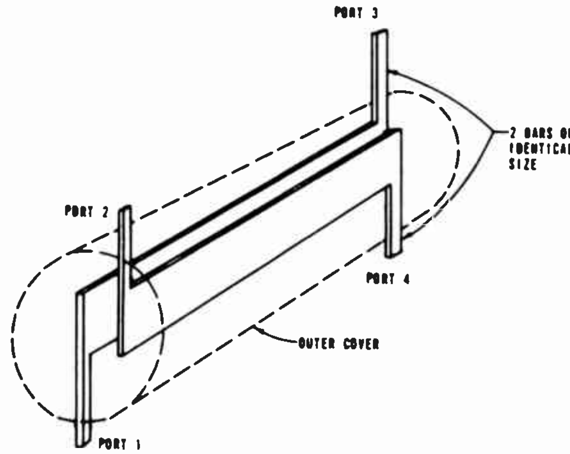

Figure 31. Physical model of 90° hybrid coupler.

COMBINED TRANSMITTERS

It is possible to combine the output of two RF power amplifiers for higher power levels. The important advantage is that the broadcast transmission is not interrupted if one amplifier fails. The radiated signal strength merely drops 6 dB until the failed amplifier is repaired and put back on the air. A dual amplifier system costs more than a single amplifier for a given total power output, but there are the economic advantages of reducing lost air time and eliminating the need for a separate standby transmitter. Automatic or manual output switching can be used to route the full power of the remaining amplifier directly to the antenna. Some stations go one step further and also install dual exciters with automatic switching so that if one exciter fails, the other unit is quickly switched into service.

Hybrid Couplers

Hybrid couplers are reciprocal, 4-port devices that can be used either for splitting or combining RF sources over a wide frequency range. Fig. 31 shows an exploded view of a typical 3 dB, 90° hybrid coupler. The coupler consists of two identical parallel transmission lines that are coupled over a distance of approximately one-quarter wavelength and are enclosed within a single outer conductor. Ports at the same end of the coupler are in-phase while ports at opposite ends of the coupler are in quadrature (90° phase shift) with respect to each other.

The phase-shift between the two inputs or outputs is always 90° and is almost independent of frequency. If the coupler is being used to combine two signals into one output, these two signals must be fed to the hybrid coupler in phase quadrature. The reason this type of coupler is also called a 3 dB coupler is that when used as a power splitter, the split is equal or half-power (3 dB) between the two outputs.

Hybrid Combiners

The output hybrid combiner effectively isolates the two amplifiers from each other. Tuning adjustments can be made on one amplifier including turning it on and off without appreciably affecting the operation of the other amplifier. Good isolation is necessary so that if one transmitter fails, the other will continue to operate normally instead of in a mistuned condition.

Two of the ports on the hybrid coupler are the inputs from the power amplifiers. The *sum port* is the antenna output terminal; and the *difference port* goes to a resistive dummy load called the "reject load," since only the rejected power due to imbalance appears here. When the power fed to each of the two inputs is equal in amplitude with a phase difference of 90°, the total power is delivered to the sum port (antenna). Very little of the power appears at the reject load if the phase relationship and power balance is correct. If the phase relationship is reversed between the two amplifiers, all the power is delivered to the reject load, so care must be taken to be sure that the proper one of the two possible 90° phase relationships is used. When all the ports on the hybrid combiner are properly terminated, isolation of 30 dB or more can be achieved between the power amplifiers. For perfect isolation between the amplifiers, the load impedance on the sum and difference ports must be exactly the same. This is approached in practice by providing a 1.0:1.0 VSWR with a resistive 50 ohm load for the termination (reject load) on the difference port and then reducing the VSWR on the antenna transmission line as low as possible by trimming the antenna match. This will keep the input port impedances from changing very much when one amplifier is not operating.

The input ports will present a load to each transmitter with a VSWR that is lower than the VSWR on the output transmission line. This is because part of the reflected power coming into the output port will be directed to the reject load and only a portion will be fed back into the transmitters. Fig. 32 shows the effect of output port VSWR on the input port VSWR, and on the isolation between ports.

If the two inputs from the separate amplifiers are not equal in amplitude or exactly in phase quadrature,

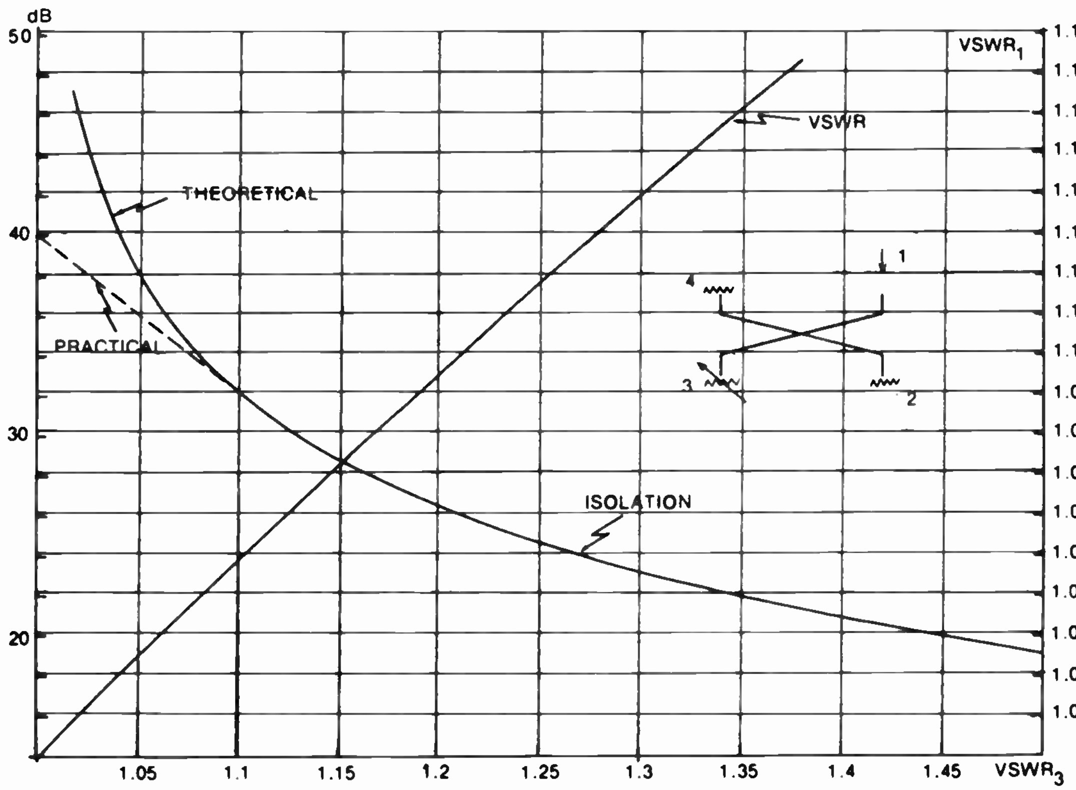

Figure 32. Isolation of hybrid coupler.

some of the power will be dissipated in the difference port reject load. The match in input power and phase is not extremely critical as shown in Fig. 33 and Fig. 34. The power lost in the difference port reject load can be easily reduced to a negligible value by touching up the amplifier tuning and by adjusting the phase shift. For example, if one amplifier is delivering only half the power of the other amplifier, only about 3% of the total available power will be dissipated in the reject load and 97% is still fed to the output transmission line.

If one transmitter fails completely, half of the working amplifier's output goes to the antenna and the other half is dissipated in the difference port reject load. This is why the radiated output drops by 6 dB or to one-fourth of the original combined power. The reject load must be rated to handle a minimum of one-fourth of the total combined power, but often the reject load is rated to handle one-half the total power so that it can also be used as a test load for one of the transmitters.

Hybrid Splitting of Exciter Power

Fig. 35 shows a block diagram of a pair of combined amplifiers with dual exciters. The exciters cannot be

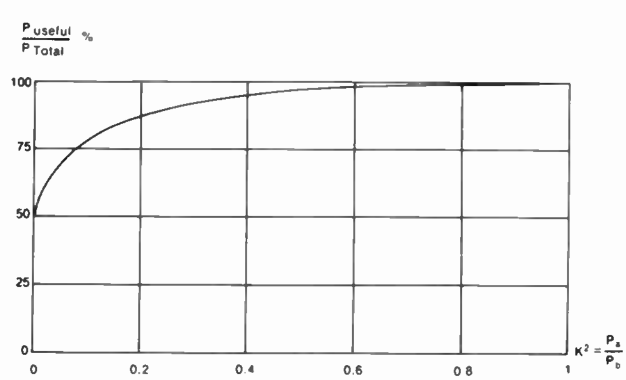

Figure 33. Power imbalance in hybrid couplers.

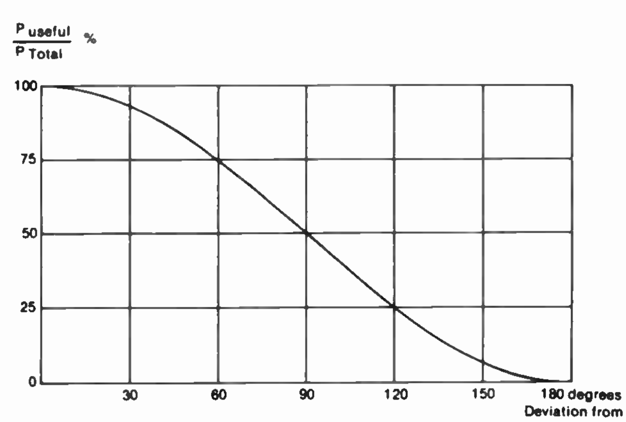

Figure 34. Phase sensitivity, hybrid coupler.

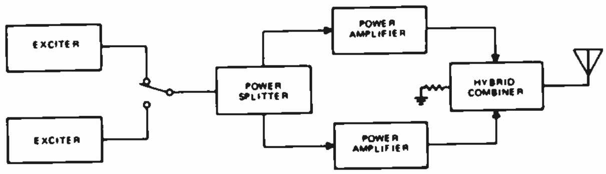

Figure 35. Block diagram of transmitter with two power amplifiers, a hybrid combiner and dual exciters.

operated in parallel like the amplifiers because their RF outputs would have to be on exactly the same carrier frequency and almost exactly in phase under all modulation conditions. An automatic or manual exciter switcher is used to direct the output of the desired exciter to the combined transmitter while the other stand-by exciter is routed to a dummy load. The one exciter in use, feeds a hybrid splitter/phase shifter which transforms one 50 ohm input into two isolated 50 ohm outputs that have a 90° phase shift between them with half the power going to each output. The operation of this hybrid splitter is the reciprocal of the hybrid combiner described above. The exciter must have enough power output capability to drive both power amplifiers. In some cases an additional IPA is required between the exciter and the splitter to boost the drive level. The length of coax from the power splitter to each amplifier input must be cut to a precise length so that the amplifiers will be fed in the proper phase relationship.

Each of the power amplifiers is assumed to have equal gain and phase shift. In practice, it may be difficult to get the amplifiers tuned so that their gains and phase shifts are equal at the same time. For this reason, a line stretcher or variable phase shift network is usually included with the exciter splitter so that the station engineer will have the ability to adjust phasing independent of amplifier tuning.

For more detailed information on the theory of hybrid couplers, see the chapter on television transmitters or Ref. 7 at the end of this chapter.

FILTERPLEXING

The practice of having several FM stations share a single broadband antenna system is becoming more popular in recent years. In order to connect several transmitters on different frequencies together onto one antenna system, a special device called a filterplexer is required. The purpose of the filterplexer is to provide isolation between the various transmitters while efficiently combining their power into a single transmission line. This is usually accomplished by a system of band-pass filters, band-reject filters, and hybrid combiners. The isolation is required to prevent power from one transmitter from entering another transmitter with resulting spurious emissions, as well as to keep the rest of the system running in the event of the failure of one or more transmitters.

An important consideration in the design of a filterplexing system is the effect on the phase response (group delay characteristic in the passband) of each of the signals passing through the system due to individual bandwidth limitations on each of the inputs.

RF Intermodulation Between FM Broadcast Transmitters

Interference to other stations within the FM broadcast band, as well as to other services outside the broadcast band, can be caused by RF intermodulation between two or more FM broadcast transmitters. Transmitter manufacturers have begun to characterize the susceptibility of their equipment to RF intermodulation, so this information will be available to the designers of filterplexing equipment.

The degree of intermodulation interference generated within a given system can be accurately predicted before the system is built if the actual mixing loss of the transmitters is available when the system is designed. Accurate data on *mixing loss* or *turn-around-loss* not only speeds the design of filterplexing equipment; but also results in higher performance and more cost effective designs, because the exact degree of isolation required is known before the system is designed. Filterplexer characteristics, as well as antenna isolation requirements, can be tailored to the specific requirements of the transmitters being used. The end user is assured in advance of construction that the system will perform to specification without fear of overdesign or underdesign of the components within the system.

Mechanisms Which Generate RF Intermodulation Products

When two or more transmitters are coupled to each other, new spectral components are produced by mixing of the fundamental and harmonic terms of each of the desired output frequencies. For example, if only two transmitters are involved, the third-order intermodulation (IM_3) terms could be generated in the following way. The output of the first transmitter (f_1) is coupled into the nonlinear output stage of the second transmitter (f_2), because there is not complete isolation between the two output stages. (f_1) will mix with the second harmonic of (f_2) producing an in-band third-order term with a frequency of $[2(f_2) - (f_1)]$. In a similar fashion, the other third-order term will be produced at a frequency of $[2(f_1) - (f_2)]$. This implies that the second harmonic content within each transmitter's output stage, along with the specific nonlinear characteristics of the output stage, will have an effect on the value of the mixing loss.

It is possible, however, to generate these same third-order terms in another way. If the difference frequency between the two transmitters $[(f_2) - (f_1)]$, which is an out-of-band frequency, remixes with either (f_1) or (f_2), the same third-order intermodulation frequencies are produced.

$$f_1 = 100.3 \text{ MHz} \qquad f_2 = 101.1 \text{ MHz}$$
$$2f_1 - f_2 = [2(100.3) - (101.1)] = [200.6 - 101.1] = 99.5 \text{ MHz}$$
$$2f_2 - f_1 = [2(101.1) - (100.3)] = [202.2 - 100.3] = 101.9 \text{ MHz}$$
OR
$$[f_1 - (f_2 - f_1)] = [100.3 - (101.1 - 100.3)] = [100.3 - 0.8] = 99.5 \text{ MHz}$$
$$[f_2 + (f_2 - f_1)] = [101.1 + (101.1 - 100.3)] = [101.1 + 0.8] = 101.9 \text{ MHz}$$

Figure 36. Third order intermodulation products.

Empirical measurements indicate that the $[2(f_2) - (f_1)]$ type of mechanism is the dominant mode generating third-order IM products in modern transmitters using a tuned cavity for the output network.

Fig. 36 shows an example of how the intermodulation product frequencies may be calculated. Fig. 37 and Fig. 38 show the resulting frequency spectra.

Intermodulation as a Function of Turn-Around-Loss

Turn-around-loss or *mixing loss* describes the phenomenon whereby the interfering signal mixes with the fundamental and its harmonics within the nonlinear output device. This mixing occurs with a net conversion loss, hence the term turn-around-loss has become widely used to quantify the ratio of the interfering level to the resulting IM_3 level. A turn-around-loss of 10 dB means that the IM_3 product fed back to the antenna system will be 10 dB below the interfering signal fed into the transmitter's output stage.

Turn-around-loss will increase if the interfering signal falls outside the passband of the transmitter's output circuit, varying with the frequency separation of the desired signal and the interfering signal. This is

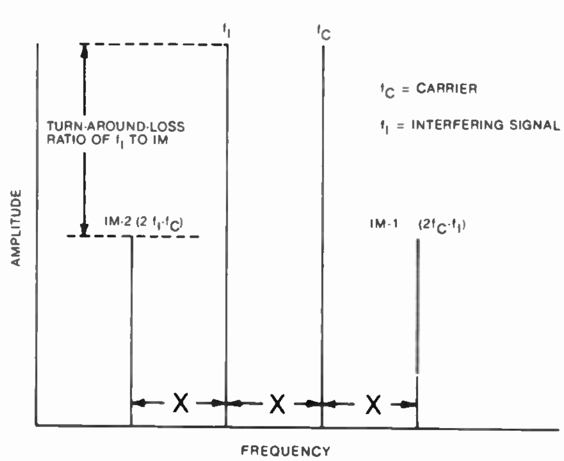

Figure 37. Frequency spectrum of third order IM with the interfering level equal to the carrier level.

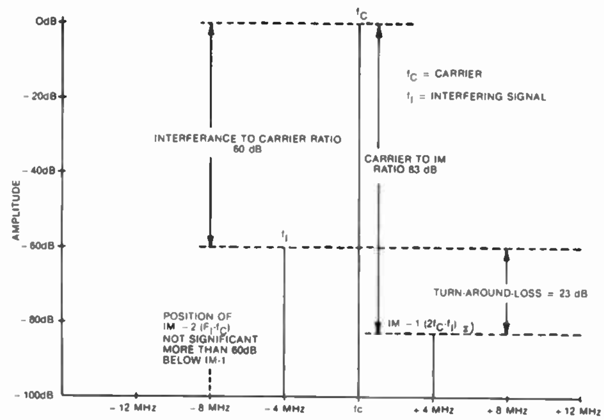

Figure 38. Typical frequency spectrum of third order IM of a broadcast FM transmitter.

because the interfering signal is first attenuated by the selectivity going into the nonlinear device, and then the IM_3 product is further attenuated as it comes back out through the frequency selective circuit.

Turn-around-loss can actually be broken down into three individual parts:

1. The basic in-band conversion loss of the nonlinear device.
2. The attenuation of the out-of-band interfering signal due to the selectivity of the output stage.
3. The attenuation of the resulting out-of-band IM_3 products due to the selectivity of the output stage.

As the turn-around-loss increases, the level of undesirable intermodulation products is reduced and the amount of isolation required between transmitters is also reduced.

The transmitter output circuit loading control directly affects the source impedance, and therefore affects the efficiency of coupling the interfering signal into the output circuit where it mixes with the other frequencies present to produce IM_3 products. Light loading reduces the amount of interference that enters the output circuit with a resulting increase in turn-around-loss. In addition, the output loading control setting will change the output circuit bandwidth (loaded "Q"), and therefore also affect the amount of attenuation that out-of-band signals will encounter passing into and out of the output circuit.

Second harmonic traps or low-pass filters in the transmission line of either transmitter have little effect on the generation of intermodulation products. This is because the harmonic content of the interfering signal entering the output circuit of the transmitter has much less effect on IM_3 generation than the harmonic content within the nonlinear device itself. The resulting IM_3 products fall within the passband of the low-pass filters and outside the reject band of the second harmonic traps, so these devices offer no attenuation to RF intermodulation products.

Special Requirements of Solid-State Transmitters

Wideband, solid-state, transmitters pose some special problems for filterplexing. Solid-state, nonlinear, power amplifiers are typically very efficient mixing devices and, because there is no output selectivity to attenuate out-of-band interference or out-of-band RF intermodulation products, the turn-around-loss can be as little as 6 dB regardless of frequency separation. Additional external bandpass filtering is usually required at the output of each solid-state transmitter to reduce RF intermodulation to acceptable levels.

For more detailed information about RF intermodulation between transmitters, see the chapters on FM and TV antenna systems and Ref. 14 at the end of this chapter.

OPERATIONAL MEASUREMENTS

Certain parameters are considered by the FCC to be important enough to justify almost continuous observation. Especially important are the modulation level, carrier frequency, and output power level. The FCC requires that some of the technical operating parameters be entered at regular intervals in the operation and maintenance logs. These logs must be kept available for inspection a minimum of two years from the date of entry. It is always important to consult the current revision of Part 73 of the FCC Rules and Regulations because they may have changed since this chapter was printed.

FM Modulation Measurement

The measurement of FM modulation can be accomplished with a broadcast type modulation monitor or with one of the newer modulation analyzers. Some FM exciters have built-in peak modulation displays for convenience in set-up and adjustment. Once the initial levels are correctly set, modern audio processing equipment will usually hold the modulation levels within the desired window.

Much interest and concern has developed throughout the broadcasting industry as to the best method for the determination of modulation percentage for complex program material. The inability of mechanical meter movements to follow short-duration, nonrepetitive peaks accurately has received special attention. Standard modulation meter movements cannot follow modulation peaks with the required accuracy. For this reason, modulation monitors have a peak-indicating device that can be preset to flash at the particular level of interest. This device should be used instead of the meter to determine peak modulation conditions of the transmitter.

The reason for setting a peak deviation limit is so that the related occupied bandwidth does not increase to the point of interfering with stations on adjacent channels. The FCC presently enforces the modulation limit by monitoring the instantaneous peak deviation of the station as displayed on an oscilloscope. This method of measurement does not exactly correlate with the station's occupied bandwidth because the duty-cycle of the modulation peaks is not taken into account. As a result, many sophisticated "peak limiting" and "overshoot control" devices have appeared on the market to maximize loudness without exceeding the peak deviation limit, by removing the low energy peaks that would extend beyond 100% modulation. The use of these devices does cause some degradation of the audio quality and they would no longer be used if the method of modulation measurement were changed to one based on occupied bandwidth. Recently introduced modulation measurement devices ignore short duration overshoots and provide modulation level indications that more accurately reflect the resulting occupied bandwidth. The FCC is considering rule changes that would allow enforcement of FM modulation by occupied bandwidth after the technical details on the exact method of measurement are worked out.

Carrier Frequency Measurement

The average carrier frequency must be measured and maintained to within ±2 kHz of the assigned channel with an accurate frequency monitor. These monitors fall into two categories; analog display of the frequency error from the nominal carrier frequency and digital display of the absolute carrier frequency. The trend is toward the digital counter because of its inherent accuracy and ease of use.

The requirement that a station utilize type-approved modulation and frequency monitors has been eliminated by the FCC. Each station is still required to maintain its frequency, modulation, and audio performance within the FCC limits defined in Part 73 of the Rules and Regulations, but the responsibility for selecting the method of measurement and type of measuring equipment is now up to the station operator. Every quality conscious station will want to have the necessary equipment to accurately evaluate the signal being broadcast. There are new options available in high performance yet general purpose test equipment, now that monitor type-approval is no longer required. For instance, modern modulation analyzers provide frequency agility as well as greater measurement capability than the more specialized modulation monitors. General purpose frequency counters are now available with sufficient accuracy to measure the carrier, subcarrier, and stereo pilot frequencies directly. Spectrum analyzers provide a wide range of capability including the measurement of harmonic and spurious frequencies at the carrier frequency, composite baseband, Bessel nulls, occupied bandwidth, stereophonic and SCA crosstalk, and synchronous AM.

Measurement of RF Power Output

The methods for determining RF output power are specified in Part 73 of the FCC Rules and Regulations. An accurately calibrated directional wattmeter provides an excellent means of making a direct measurement of RF output power. The directional wattmeter is seldom used as the primary RF power determining method because of the requirement for recalibration to a traceable standard at regular intervals. Use of the indirect method of power measurement avoids this requirement. The FCC is considering a change in the Rules that would permit the use of the transmitter power output meter directly, if it is periodically calibrated by comparison with the indirect method, instead of with a dummy load and standard wattmeter.

Using the indirect method, the output power is calculated from a measurement of the DC input power multiplied by the efficiency factor of the final amplifier stage. The efficiency factor is provided by the transmitter manufacturer on the final test data sheet or in the instruction manual and must be applicable to the particular frequency and power level in use. The power input to the final amplifier stage is normally defined as the product of plate voltage and plate current to this stage. Multiple output stages which are combined for the total power, must have their individual DC power inputs arithmetically summed to obtain the total power input.

The directional wattmeter can be used as a check when compared to the power output calculated by the indirect method to determine if the efficiency factor has changed due to incorrect tuning, changing antenna conditions, or a weak output device.

Logging of Transmitter Operating Parameters

Although the FCC has deleted specific logging requirements, FM stations may still wish to log certain transmitter parameters at three-hour intervals, in order to track equipment performance trends. The minimum suggested entries are:

- Final amplifier plate voltage
- Final amplifier plate current
- RF transmission line current, voltage, or power

The carrier frequency, stereo pilot frequency, and SCA subcarrier frequency require less frequent measurement and logging. Microprocessor based control systems often provide automatic logging of all transmitter parameters; including overloads and tolerance flagging.

Proof-of-Performance Measurements

While the FCC no longer requires proof of performance tests, it is advisable to conduct such tests periodically to ensure the equipment is operating properly. These tests should include:

- Audio frequency response
- Audio frequency harmonic distortion
- FM signal-to-noise ratio
- AM noise level

Fig. 39 is a block diagram of a typical test set-up for proof-of-performance measurements.

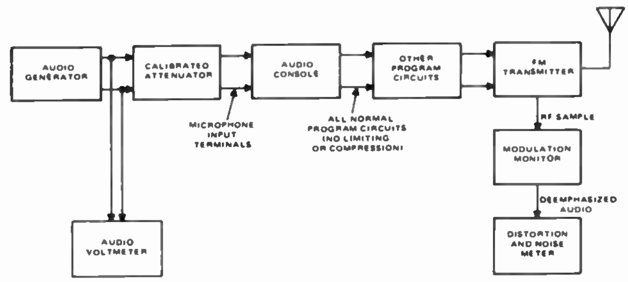

Figure 39. Block diagram of test set-up for audio performance measurements.

Measurement of Audio Frequency Response

The audio frequency response of the system is measured in reverse, that is, a constant percentage of modulation is maintained for all modulating frequencies by adjusting the amount of attenuation between the audio generator and the microphone input terminals. This is necessary because of the rising response due to preemphasis. Frequency response data is taken at three levels of modulation: 25%, 50%, and 100%. The audio voltmeter which measures the audio generator output voltage is used to maintain a constant voltage level versus frequency at the generator output terminals. The precision attenuator dials are adjusted for each modulating frequency to maintain the desired modulating level and the attenuator readings, in decibels, are recorded. Readings should be taken for the following modulating frequencies: 50, 100, 400, 1000, 5000, 7500, 10000, and 15000 Hz. Measurements at 7500 Hz are not required by the FCC Rules and Regulations, but are helpful when the data is plotted within the preemphasis curve limits.

When the attenuation, in decibels, is plotted versus frequency, the 75 microsecond preemphasis curve is obtained if the system frequency response is perfect. Deviations from the ideal response are permitted to an extent which allows the measured curve to be fitted between the upper and lower limit curves shown in Fig. 8. The procedure for doing this is to offset the measured curve by subtracting or adding the same number of decibels from each of the measured values. This process may be repeated until a fit is obtained. If it is impossible to obtain a fit within the limits by subtracting or adding the same value of attenuation from all measured values, the system frequency response is inadequate and corrections must be made.

Measurement of Audio Harmonic Distortion

Total harmonic distortion (THD) of the system from microphone input terminals to transmitter output is measured by modulating the transmitter with sinusoidal modulating signals having low distortion, and observing the harmonic content at the output of the modulation monitor. For this measurement, preemphasis is used in the transmitter and deemphasis is used in the monitor. The distortion analyzer must respond to de-emphasized harmonics through 30 kHz.

The type of distortion meter normally used in this test reads not only harmonic distortion but also noise in the audio passband. For this reason, THD measurements above 5 kHz may be noise limited due to the effect of deemphasis. A more accurate method of distortion measurement in the presence of noise is to use an audio frequency spectrum analyzer to determine the total root mean square (RMS) value of the individual distortion products.

The THD is often measured under the following conditions:

- For modulating frequencies of 50, 100, 400, 1000 and 5000 Hz at modulating levels of 25, 50, and 100% modulation
- For modulating frequencies of 10 kHz and 15 kHz at a modulating level of 100%

The preceding measurements must show that the system THD is less than 3.5% for modulating frequencies between 50 and 100 Hz, less than 2.5% for modulating frequencies between 100 and 7500 Hz, and less than 3.0% for modulating frequencies between 7500 and 15000 Hz. Most modern equipment will pass these tests by a wide margin. If distortion levels greater than these are measured, the system requires adjustment or repair. Tuning the transmitter for minimum even order harmonic distortion will result in a symmetrical group delay response and optimum FM modulation performance. This can be accomplished either by observing the even order harmonics in the demodulated baseband, or by placing an audio bandpass filter tuned to the second harmonic or other even order harmonic of the modulating frequency ahead of the audio distortion analyzer.

Measurement of Two-Tone Intermodulation Distortion

Audio intermodulation distortion (IMD) measurements are a quick and accurate way to evaluate the system performance before a complete set of THD measurements are made. If the system will pass a single 60 Hz/7 kHz, 4:1 (SMPTE-IMD) measurement at 100% modulation, it will probably pass all of the THD measurements up to 10 kHz. (This dual frequency test signal (SMPTE-IMD) is on track 30 of the *NAB Broadcast and Audio System Test CD*.)

Other types of difference-tone, swept two-tone, and sinewave/squarewave IMD measurements can reveal more subtle problems in the system such as transient IMD due to insufficient audio feedback bandwidth in the audio amplifier stages.

Measurement of FM Signal-To-Noise Ratio

The FM signal-to-noise ratio of the system is also measured from the microphone input terminals to the transmitter output. The residual noise level at the monitor output is measured with an audio voltmeter. For this measurement, preemphasis is employed in the transmitter and deemphasis in the monitor. The residual audio noise level is referenced to the signal level produced by 400 Hz (L + R, mono) modulation at the 100% level (75 kHz deviation).

The procedure for making the FM signal-to-noise ratio measurement is as follows:

1. Modulate the transmitter with a 400 Hz sine wave applied at the microphone input terminals of the console and set the level for 100% modulation.
2. Read and record the audio signal level appearing at the modulation monitor output terminals. If the monitor has audio metering capability, the meter gain should be set for a 0.0 dB reference level according to the manufacturer's instructions.
3. Remove the modulation and terminate the console audio input terminals with a resistor equal to the normal microphone output impedance.
4. Read and record the residual audio noise voltage in decibels below the 400 Hz reference signal level. The measured signal-to-noise ratio must be at least 60 dB. State of the art equipment can provide a signal-to-noise ratio of better than 90 dB, so it is relatively easy to meet the FCC requirement of 60 dB.

Measurement of AM Signal-To-Noise Ratios

The perfect FM transmitter will have an absolutely constant output, regardless of FM modulation or power supply variations. In practice, there is always some residual amplitude modulation of the FM transmitter. There are two types of AM signal-to-noise ratios that are of interest to the FM broadcast engineer:

1. *Asynchronous AM signal-to-noise ratio* measured without FM modulation is required by the FCC Rules and Regulations, and is primarily related to power supply ripple.
2. *Synchronous AM signal-to-noise ratio*, or ICAM (incidental carrier AM), measured with FM modulation is *not* required by the FCC Rules and Regulations and *is* related to the tuning and overall bandwidth of the system.

Asynchronous AM

Residual amplitude modulation of the transmitter output without FM modulation, due primarily to power supply ripple, is measured with an AM envelope detector. Most FM modulation monitors include an AM detector for this purpose. The detector must include 75 microsecond deemphasis of its output. AM noise measurements must be made directly at the transmitter output (or an accurate sample of its output). No amplifying or limiting equipment may be used between the transmitter output and the AM detector, since this equipment would modify the residual AM noise level present. The FCC Rules and Regulations require residual AM noise to be 50 dB below the level which would represent 100% amplitude modulation of the carrier. Since the transmitter cannot be amplitude modulated, this reference must be established indirectly by a measurement of the RF carrier voltage. Refer to the instructions of the detector manufacturer to determine the reference level. Generally, the reference level is determined by setting a carrier level meter to a specified reading. If the transmitter is unable to meet the 50 dB requirement, the problem can usually be traced to a power supply component or to line imbalance in a three-phase system.

Synchronous AM

Synchronous AM is a measure of the amount of incidental amplitude modulation introduced onto the carrier by the presence of FM modulation. Although this measurement is not required by the FCC Rules and Regulations, it provides information about the amplitude response and tuning of the transmitter. Measurement of synchronous AM also gives the station engineer an idea of the overall system bandwidth and whether the passband is positioned correctly. Since all transmitters have limited bandwidth, there will be a slight drop-off in power output as the carrier frequency is swept to either side of the center frequency. This slight change in RF output level follows the waveform of the signal being applied to the FM modulator, causing AM modulation in synchronization with the FM modulation. The concept is similar to the slope detection of FM by an AM detector used in conjunction with a tuned circuit.

Synchronous AM measurements are made directly at the transmitter output (or an accurate sample of its output). No amplifying or limiting equipment may be used between the transmitter output and the AM detector since nonlinearities in this equipment could modify the synchronous AM level present. Since the transmitter cannot be fully amplitude modulated, an equivalent reference level must be established indirectly by a measurement of the RF carrier voltage. Refer to the instructions of the detector manufacturer to determine this reference level. Generally, the reference level is determined by setting a carrier level meter to a specified reading, or to obtain a specific DC voltage level at the output of the detector diode without modulation. Care must be taken when making these measurements that the test setup does not introduce synchronous AM and give erroneous readings, which would cause the operator to mistune the transmitter to compensate for errors in the measuring equipment.

The input impedance of the envelope detector must provide a nearly perfect match so that there is a very low VSWR on the sampling line. Any significant VSWR on the sampling line will produce synchronous AM at the detector because the position of the voltage peak caused by the standing wave moves along this line with FM modulation. A thru-line type of directional coupler, normally used to drive the wattmeter movement, has the envelope detector diode built into the sampling element; and provides a DC component that the meter movement responds to, plus the demodulated synchronous AM component that the meter movement does not respond to. If the thru-line element output is fed to an oscilloscope instead of the wattmeter movement, the synchronous AM waveform can be accurately measured. This approach eliminates the errors due to VSWR on the sampling line, since the detector is located at the sampling point. The manufacturer of the thru-line coupler can supply the special connectors and/or cables to connect its output to the oscilloscope. Care must be taken to avoid hum pick-up from AC ground loops while making these low level measurements. Both the thru-line element detector and the precision envelope detectors have some residual RF on their DC output, so an RF filter network may be required between the detector and the input of the oscilloscope.

Most FM demodulators cannot be relied upon to make accurate synchronous AM noise measurements, so it is a good idea to cross-check the demodulator reading directly against the demodulated output of a precision envelope detector. This can be done by first measuring the DC component of the waveform with a voltmeter, or by DC coupling the scope input. The scope is then AC coupled and the input sensitivity is increased until an accurate peak-to-peak measurement of the AC modulation component can be made. The peak-to-peak AC voltage is then divided by twice the DC component to obtain the *voltage ratio*. Twenty times the LOG (base 10) of the voltage ratio is the actual synchronous AM noise level in dB below equivalent 100% AM modulation. Multiplying the voltage ratio by 100 yields the percent of AM modulation. Note that the *peak* detected value of the carrier must be doubled to convert it to the *peak-to-peak* value of the carrier. The ratio of the peak-to-peak modulation component to the peak-to-peak carrier is then used to calculate the percentage of synchronous AM modulation.

Built-In AM Noise Measurement Capability

Some FM transmitters feature a built-in precision envelope detector incorporated into the automatic power control (APC) system. A calibrated front panel AM noise test jack allows observation of the synchronous AM waveforms or direct measurement of the synchronous AM noise level on a standard audio voltmeter.

How Good Should Synchronous AM Be?

Synchronous AM of 35 dB or more below equivalent 100% AM, is considered to be acceptable since the limited bandwidth of the IF filter in the receiver will reintroduce higher levels of synchronous AM to the FM signal before demodulation. Higher levels of synchronous AM can cause increased "chopping" of the signal at the receiver near limiting threshold under weak signal "fringe area" conditions and can exacerbate multipath problems. Excessive synchronous AM is also an indirect indication of passband induced distortion problems that degrade stereo performance and SCA crosstalk.

Many of the older multi-tube transmitter designs presently in use will have as much as 6% (−30 dB)

TABLE 1
Synchronous AM versus bandwith.

SYNCHRONOUS AM (below 100% AM) (±75 kHz @ 1 kHz FM)	APPROXIMATE BANDWIDTH OF TRANSMITTER (−3 dB)	RF LEVEL VARIATION AT RECEIVER LIMITER (%)	(dB)
−30 dB	410 kHz	6.32%	0.57 dB
−35 dB	550 kHz	3.54%	0.31 dB
−40 dB	730 kHz	2.00%	0.18 dB
−45 dB	1.00 MHz	1.12%	0.10 dB
−50 dB	1.34 MHz	0.64%	0.06 dB
−55 dB	1.82 MHz	0.36%	0.03 dB
−60 dB	2.46 MHz	0.20%	0.02 dB

synchronous AM when simply tuned for best power output and efficiency, even though the asynchronous AM (without modulation) may be better than −50 dB. Some of the newer single-tube transmitters can be adjusted for 50 dB or more suppression of synchronous AM. The synchronous AM level of virtually any FM transmitter can be improved by proper tuning techniques. An approximation to the overall system bandwidth can be related to the synchronous AM as shown in Table 1.

Limitations of Synchronous AM Measurements

Synchronous AM measurements are an indirect way of evaluating and optimizing FM performance. Even though synchronous AM measurements are a helpful aid to correctly tune an FM transmitter, these measurements tell only (the amplitude response) half of the total story. Transmitter tuning also affects the group delay (time) response which in turn affects the relative time delays of the higher order FM sidebands. Even though the amplitude response appears flattened when the grid is heavily driven, the group delay (time) response still has a serious effect on the higher order FM sidebands.

Synchronous AM versus Symmetrical Group Delay Response

Recent research using computer simulations,[23] as well as empirical measurements made on FM transmitters, showed that group delay asymmetry results in much more distortion than asymmetrical amplitude response. As long as the group delay response is symmetrical, the amount of synchronous AM will have little effect on the FM modulation performance and distortion. Most FM transmitters will exhibit a significant increase in synchronous AM when tuned for symmetrical group delay response, even though this results in best FM modulation performance. Tuning for minimum synchronous AM is a good starting point, but it is more desirable to finish tuning at the symmetrical group delay point.

Fine tuning the input and output for minimum even order harmonic distortion will optimize the group delay (time) response. Transmitters that utilize wideband solid-state intermediate power amplifiers (IPA) will add less distortion to the FM signal because both the amplitude and group delay (time) response will be better than systems utilizing several tuned stages.

TUNING THE TRANSMITTER FOR BEST MODULATION PERFORMANCE

The modern power amplifiers which have been discussed in the preceding sections, can operate with high reliability and power efficiency without compromising subcarrier performance, if they are properly adjusted. All optimization should be done with any automatic power control (APC) system disabled so that the APC will not chase the adjustment in an attempt to keep the output power constant. The transmitter should be connected to the normal antenna system rather than to a dummy load. This is because the resistance and reactance of the antenna will be different from the dummy load and the optimum tuning point of the transmitter will shift between the two different loads. The tuning sequence is:

Initial Tuning and Loading

The transmitter is first tuned for normal output power and proper efficiency according to the manufacturer's instruction manual. The meter readings should closely agree with those listed on the manufacturer's final test data sheet if the transmitter is being operated at the same frequency and power level into an acceptable load.

Input Tuning and Matching

The input tuning control should first be adjusted for maximum grid current and then fine tuned interactively with the input matching control for minimum reflected power to the driver stage. Note that the point of maximum grid current may not coincide with the minimum reflected power to a solid-state driver. This is because a solid state driver may actually output more power at certain complex load impedances than into a 50 ohm resistive load. The main objective during input tuning is to obtain adequate grid current while providing a good match (minimum reflected power) to the coaxial transmission line from the driver. In the case of an older transmitter with a tube driver integrated into the grid circuit of the final amplifier, the driver plate tuning and the final grid tuning will be combined into one control; which is adjusted for maximum grid current.

Output Tuning

The output tuning control adjusts the resonant frequency of the output circuit to match the carrier frequency. As resonance is reached, the plate current will drop while both the output power and screen current rise together. Under heavily loaded conditions this "dip" in plate current is not very pronounced, so tuning for a peak in screen current is often a more sensitive indicator of resonance.

Amplifiers utilizing a folded halfwave cavity will display little interaction between output tuning and output loading, because the output coupling loop is located at the RF voltage null point on the resonant line. Quarter-wave cavities will require interactive adjustment of output tuning and output loading controls, since changes in loading will also affect the frequency of the resonant line.

Output Loading

There is a delicate balance between screen voltage and output loading for amplifiers utilizing a tetrode tube. Generally there is one combination of screen voltage and output loading where peak efficiency occurs. At a given screen voltage, increasing the amplifier loading will result in a decrease in screen current, while a decrease in loading will result in an increase in screen current. As the screen voltage is increased to get more output power, the loading must also be increased to prevent the screen current from reaching excessive levels. Further increases in screen voltage without increased loading will result in a screen overload without an increase in output power.

Automatic Power Control Headroom

Automatic power control (APC) feedback systems are utilized in many transmitters to regulate the power output around a predetermined setpoint with variations in AC line voltage or changes in other operating parameters. Most modern FM broadcast transmitters utilize a high gain tetrode as the final amplifier stage with adjustment of the screen voltage providing fine adjustment of the output power.

For each power output level there is one unique combination of screen voltage and output loading that will provide peak operating efficiency. If the screen voltage is raised above this point without a corresponding increase in loading, there will be no further increase in power output with rising screen voltage and screen current. If the screen voltage is raised without sufficient loading, a screen current overload will occur before the upward adjustment in power output is obtained. To avoid this problem, it is a good idea to tune the transmitter with slightly heavier loading than necessary to achieve the desired power output level in order to allow for about 5% headroom in adjustment range. The output loading can be adjusted for a peak in output power of 5% over the desired level and then the screen voltage can be reduced enough to return to the desired level. This procedure will allow headroom for an APC system controlling screen voltage and will result in about a 1% compromise in efficiency, but it will assure the ability to increase power output up to 5% without encountering a screen overload.

Centering the Passband

A simple method for centering the transmitter passband on the carrier frequency involves adjustment for minimum synchronous AM. If the bandpass is narrow or skewed, increasing synchronous amplitude modulation of the carrier will result. A typical adjustment

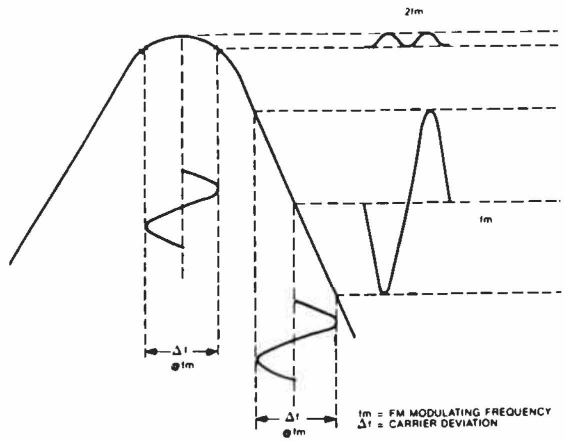

Figure 40. Synchronous AM waveforms.

procedure is to FM modulate 100% at 1 kHz, and fine-adjust the transmitter's grid tuning and output tuning controls for minimum 1 kHz AM modulation as detected by a wideband envelope detector (diode and line probe). 1 kHz is used as the FM modulating frequency rather than 400 Hz so that the audio high-pass filter in the audio analyzer can be used to eliminate the AC line frequency related asynchronous component from the synchronous AM component. It is helpful to display the demodulated output from the AM detector on an oscilloscope while making this adjustment. Note that as the minimum point of synchronous AM is reached, the demodulated output from the AM detector will double in frequency to 2 kHz, because the fall-off in output power is symmetrical about the center frequency causing the amplitude variations to go through two complete cycles for every one FM sweep cycle. This effect is illustrated in Fig. 40. It should be possible to minimize synchronous AM while maintaining output power and efficiency in a properly designed power amplifier.

Effect of Transmitter Tuning on the FM Sidebands

The higher order FM sidebands will be slightly attenuated in amplitude and shifted in time (group delay) as they pass through the final amplifier stage. These alterations in the sideband structure that are introduced by the amplifier passband, result in distortion after FM demodulation at the receiver. The amount of distortion is dependent on the available bandwidth versus the modulation index being transmitted. For a given bandwidth limitation, the distortion can be minimized by centering the passband of the amplifier around the signal being transmitted. This will cause the amplitude and group delay errors to affect both the upper and lower sidebands equally or symmetrically. Tuning an amplifier for minimum plate current or for best efficiency does not necessarily result in a centered passband. One way to center the amplitude passband is to tune the amplifier for minimum synchronous AM modulation while applying FM modulation to the transmitter. Since the circuit topology of most transmitters exhibit a difference in tuning between the symmetrical amplitude response and the symmetrical group delay response, FM modulation performance can be further improved by tuning for symmetrical group delay rather than for minimum synchronous AM. The symmetrical group delay tuning point usually does not coincide exactly with the symmetrical amplitude tuning point, and falls between the point of minimum synchronous AM and the point of maximum efficiency.

The transmitter may be tuned for minimum intermodulation distortion in left-only or right-only stereo transmissions. Stereo separation will also vary with tuning. For stations employing a 67 kHz SCA, transmitter tuning becomes very critical to minimizing crosstalk into the SCA. Modulate one channel only on the stereo generator to 100% with a 4.5 kHz tone. This will place the lower second harmonic (L-R) stereo sideband on top of 67 kHz SCA. Activate the SCA at normal injection level without modulation on the SCA. Tune the transmitter for minimum output from the SCA demodulator. This adjustment can also be made by listening to the residual SCA audio while normal stereo programming is being broadcast.

A more sensitive test is to tune for minimum even order harmonic distortion; which will result in a symmetrical group delay response and will optimize distortion, separation, and crosstalk.

The latest generation of power amplifiers has been designed to operate without compromising subcarrier performance. By providing broadband matching circuits, adjustment of these transmitters for optimum FM modulation performance (minimum distortion, minimum crosstalk, maximum separation, etc.) is very repeatable and stable.

The field adjustment techniques are listed below in ascending order of sensitivity:

1. Tune for minimum synchronous AM noise.
2. Tune for minimum IMD in the left or right channel only.
3. Tune for minimum crosstalk into the unmodulated SCA subcarrier.
4. Tune for minimum even order harmonic distortion (symmetrical group delay).

In any of these tests, the grid tuning is frequently more critical than the plate tuning. This is because the impedance match into the input capacitance of the grid becomes the bandwidth limiting factor. Even though the amplitude response appears flattened when the grid is heavily driven, the group delay (time) response has a serious effect on the higher order FM sidebands.

For more information about tuning an FM transmitter for optimum performance, see Refs. 14, 15, 20, and 22 at the end of this chapter.

OPTIMUM TUNING VERSUS EFFICIENCY

VHF amplifiers often exhibit a somewhat unusual characteristic when tuning for maximum efficiency. The highest efficiency operating point does not exactly coincide with the lowest plate current, because the power output continues to rise on the inductive side of resonance coming out of the dip in plate current. If the amplifier is tuned exactly to resonance, the plate load impedance will be purely resistive and the load line will be linear. As the output circuit is tuned to the inductive side of resonance, the plate load impedance becomes complex and the load line becomes elliptic instead of linear since the plate current and plate voltage are no longer in phase. Best efficiency occurs when the phase of the instantaneous plate voltage slightly leads the plate current. This effect is believed to be caused by the nonlinear gain characteristics of the power amplifier tube operating on an elliptic load line.

INSTALLATION CONSIDERATIONS

Adequate planning and care in the installation of an FM broadcast transmitter and associated equipment will help avoid many problems that may be difficult and expensive to correct later. For example, poor grounds and ground loops may cause high noise levels.

Wiring the Transmitter Plant

Separate metallic shielded conduits or troughs should be provided for the audio and the AC wiring. A third conduit should be used if computer logic levels are employed for equipment control. These conduits or wiring troughs may be either overhead or below the cabinets. The AC wiring should be well separated from the audio pairs to prevent the induction of unwanted hum and noise into the audio circuits.

Audio shields should be grounded at only one point to prevent ground loops in the shields. This point may have to be found experimentally to give the lowest noise pickup. The equipment racks and transmitter should be connected together by copper straps at least two inches wide, tied to a good earth ground at one point. If a good ground screen is not available, a satisfactory ground can be provided by driving four or five copper ground rods eight to ten feet long into the ground with a spacing of about three feet. These ground rods should be tied together with a wide copper strap. The straps connecting the equipment to the earth ground should be as short and direct as practical.

It is often difficult to remove VHF-RF from the equipment by grounding, because at FM carrier frequencies, nearly any connection to an earth ground has an appreciable impedance. The best way to keep RF out of sensitive low-level circuits is by keeping them enclosed within an RF shield, and by filtering leads that enter the shielded unit when necessary. Filters in the audio lines may be made up of small bifilar RF chokes and disc capacitors.

For stereo transmission, it is necessary to keep the L and R audio lines phased properly. To insure proper monaural compatibility, correct audio polarity must be maintained throughout the station from the microphones, tape machines, and turntables through all of the audio equipment to the stereo generator audio input terminals. Stereo phone line pairs or separate RF studio-to-transmitter links (STL) should also be checked for proper polarity and equal phase delay.

The transmitter equipment should be located and arranged to provide sufficient room around the front, sides, and rear for easy access during servicing and maintenance. Servicing of certain components may be easier by removing a side panel from the transmitter.

Transmitter Cooling

Almost all FM broadcast transmitters require forced air cooling, to remove heat from the output stage and other assemblies within the cabinet. A very important consideration in locating the transmitter is the provision for adequate cooling air. As a rough approximation, it can be assumed that the overall efficiency of the transmitter is about 50%. In other words, it will generate about the same number of kilowatts of heat as it does RF power output.

Fig. 41A shows a transmitter located in an air-conditioned room. This type of closed-loop system requires no special ducting and has the advantage that the transmitter intake air is usually much cleaner than outside air. The transmitter exhaust air places a substantial heat load on the air-conditioner during the summer, but it becomes a source of heat in the winter. The transmitter manufacturer can usually supply data on the number of cooling BTU's required, so that the proper size air-conditioner can be selected. This method is used frequently with the lower power transmitters. A protective system should be provided to prevent over-heating of the transmitter if the air conditioner fails.

Fig. 41B shows a transmitter located in a wall separating an air conditioned room and a ventilated, but not air-conditioned room. A large exhaust fan is provided in the ceiling to remove the rising hot air while an adequate cool air intake is provided in the lower portion of an outside wall. Adequate air filtering is required to keep the transmitter interior clean.

Fig. 41C shows a transmitter located in an air-conditioned room with intake and exhaust air ducts to the outside. An auxiliary blower or fan is normally required to overcome pressure drop in the ducting. This type of system requires careful design to make sure that the air flow through the transmitter is not impeded by the duct work. Additional air interlocks may be required to protect the transmitter from a failure of the external fan. The air intake and exhaust openings to the outside should be provided with rain shields, insect screens, and dust filters as dictated by the environment. The location of the air intake and exhaust openings should be arranged so that wind pressure will not impede the air flow.

Air filters should be periodically cleaned or replaced according to the transmitter manufacturer's instructions. This is very important because dust or insect clogged air filters may reduce the cooling air flow enough to cause overheating of some of the components. The probability of component failure increases very rapidly when cooling is insufficient. Particular attention should be paid to removing dirt and dust from high voltage components during regular maintenance after all power is removed and all components are discharged.

Dust should be cleaned from the transmitter by means of a suitable brush and vacuum cleaner or as otherwise recommended by the transmitter manufacturer. Usually weekly cleaning is sufficient.

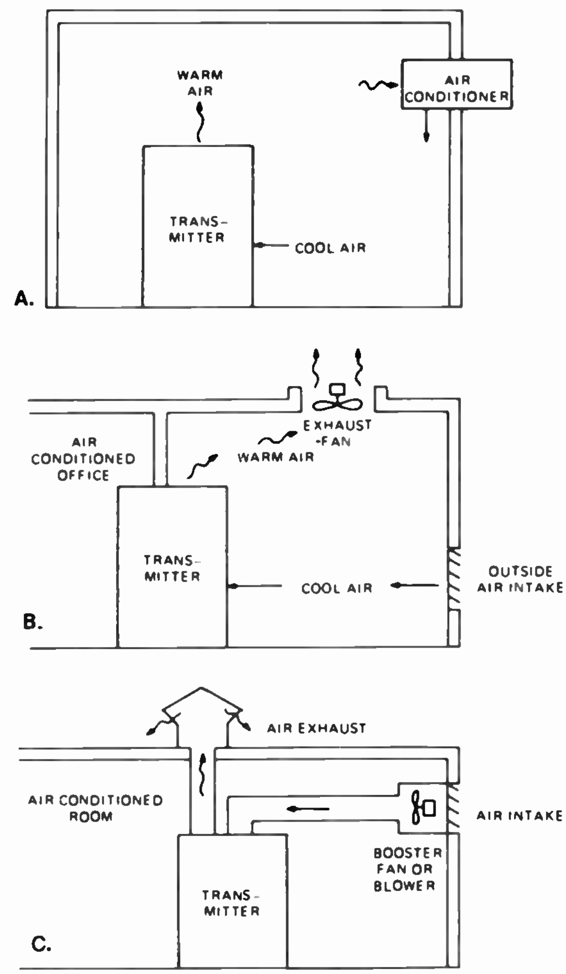

Figure 41. Three methods of providing cooling air for the transmitter.

FM TRANSMITTER PLANT MAINTENANCE

Care of Power Tubes

The operating life of high-power vacuum tubes can be extended by proper care. Most high power tubes utilize a directly heated cathode composed of a thoriated tungsten filament structure.

The key points to extending the life of RF power tubes are:

1. Store tubes upright (upside-down or right-side-up) along the axis of symmetry, not on their side. This will help to keep the internal elements concentrically aligned.
2. Use care when handling tubes to prevent mechanical shocks to the delicate internal structure. Do not set a tube on a hard surface without padding.
3. Keep the tube seals and anode cooler free of dust and dirt by cleaning once each week even in a clean environment.
4. Keep a spare tube on hand and rotate the tubes every few months to help keep the chemical "gas-getter" active so that the tubes remain gas free.
5. Keep a regular record of all tube operating parameters so that any trend of changes will be noticeable. In the event of a tube failure during the warranty period, this data will be essential to receiving credit on a replacement tube.
6. Monitor the filament voltage on a true RMS responding instrument and log any changes for future reference. The sampling point for this voltage measurement should be located as close to the tube's filament contacts as possible to minimize errors due to voltage drops in the filament wiring.

A tube that has been properly operated should gradually lose emission from the cathode until it is no longer useful, because the emissive material is gradually consumed. The carcass of the tube can then be rebuilt with a new cathode and recycled back into service. Tube life is not directly related to plate dissipation (within the ratings), but is related to the filament operating temperature (i.e., filament voltage) and the current density (milliamperes per heater watt) emitted by a given size filament. This means that operating a given tube type at a lower filament voltage and plate current will proportionately increase the life of the tube. For directly heated, thoriated tungsten filaments the plate current should be less than four milliamperes per watt of heater power for extended life.

Normally a new tube will deliver full output at a reduced filament voltage. By operating the tube at the optimum filament voltage, the filament life can be significantly extended. The optimum value may be found by slowly reducing the filament voltage from the manufacturer's rated value until the RF power output drops about 2% and then increasing the filament voltage until the RF power increases back up 1%. Recent informational bulletins[26] on extending tube life from tube manufacturers permit the filament voltage to be reduced more than 5% below the manufacturer's rating, as long as operation is closely monitored to stay above the point where there is a 1% drop in power output. A brand new tube should be operated at the full rated filament voltage for the first 200 hours before the voltage is reduced to the optimum value for long life. This will assure that the "gas-getter" is properly activated. As the tube ages, the filament voltage will have to be increased to stay at the optimum value, until RF output power cannot be maintained at or above the rated value of filament voltage. At this point, the tube's useful life comes to an end. Check the manufacturer's data sheets and most recent application notes which are often enclosed with the tube for detailed information. An excellent guide to the proper care of power tubes is listed in Refs. 10 and 26 at the end of this chapter. Ref. 17 gives detailed information about how to specify a proper forced-air cooling system for power tubes.

Preventive Maintenance

Preventive maintenance is equipment inspection and maintenance performed at regular intervals before an operational problem develops. The long term benefits are great because potential problems are discovered and solved while they are still easily manageable. A check-list of a few typical preventive maintenance items for an FM transmitter plant might include:

1. Weekly overall internal and external cleaning and inspection for damage or excessive wear.
2. Lubricate motors, tuning gears, and other moving parts at intervals recommended by the manufacturer.
3. Check and log all meter readings, including filament voltage, daily. Then compare these readings with the previous set of readings as an aid to diagnosing a developing problem.
4. Regularly exercise the automatic power control and any other servo systems.
5. Check the antenna lighting and deicer systems.
6. Check the transmission line pressurization and VSWR.
7. Check all air filters in the transmitter plant and clean or replace as required.
8. Check the proper operation of all monitoring and remote control equipment.
9. Good overall housekeeping will pay big dividends in the long run by keeping the equipment clean and free of problems that would otherwise be caused by dirt build-up.

Maintenance Systems

The key to making any maintenance program work is to set up formal check-list, logging, parts inventory management, and repair scheduling systems. These systems provide the conscience and discipline required to keep the maintenance routine accurate and complete. Each station should develop a system suited for the particular physical plant involved. Often there will be more maintenance and repair work needing attention than there is time to do it all. In this case, the maintenance system should set the priorities for completing each item, and assure that no item gets forgotten. Accurate notebooks describing all installation and maintenance work are a very helpful part of any maintenance system when working on the equipment years after the human memory has faded.

3.4 Subcarrier Transmissions and Stereophonic Broadcasting

John Kean
Moffet, Larson & Johnson, Inc., Falls Church, Virginia

Stereophonic sound FM broadcasting and Subsidiary Communications Authorization (SCA) services are a form of multiplexing that had its origins fifty years ago, when high-fidelity audio and facsimile messages were simultaneously transmitted from the Empire State Building in New York City to experimental receive sites in New Jersey.[1] Those historic multiplexing efforts demonstrated the value of wideband frequency *modulation*, allowing modern FM broadcasting to provide services to the public of both quality and variety.

Despite its illustrious start, FM broadcasting in the 1950s was a marginal business. The number of operating FM's declined annually from about 700 in 1947 to slightly over 500 in 1957. Many depended on additional income from their SCA services, which offered background music and other programs to stores and offices over medium-fidelity audio subcarriers. The FCC gave the then struggling industry a boost by granting something AM and TV didn't have: stereo. The FCC's April, 1961 Report and Order authorized transmission of a stereophonic sound system that combined the system proposals of Zenith Radio Corp., Chicago, IL, and General Electric Co., Syracuse, NY.

FM broadcasters did not show much excitement for their new capability, but the growing availability of stereophonic LP records and home stereo equipment created a natural market for FM stereo. Most agree that FM's resurgence and eventual dominance as an audio medium was due in large part to stereophonic transmission. SCA, as well, is still actively employed by FM licensees.

THE COMPOSITE BASEBAND

This section contains definitions of the terms commonly used in the FM stereo and SCA systems.[2] Since some of these terms are misused or ambiguous, the intention here is to establish meanings that will be used in the rest of this chapter.[3] The list was selected to clarify certain terms and is not a complete glossary.

Glossary of Terms For Stereo and SCA

Multiplexing. In its simplest sense, multiplexing implies that two or more independent sources of information are combined for carriage over a single medium (namely, the radio frequency carrier), and then are separated at the receiving end. In stereophonic broadcasting, for example, program information consisting of left and right audio signals are multiplexed onto an FM carrier for transmission to receivers, which subsequently recover the original audio signals.

Channel. A transmission path. The usage herein distinguishes between the concept of a channel (i.e., main channel, stereophonic subchannel, etc.), and left and right audio signals.

Composite Baseband Signal. A signal which is the sum of all signals that frequency modulate the main carrier. The signal includes the main channel signal, the modulated stereophonic subcarrier, the pilot subcarrier, and the SCA subcarrier(s).

FM Baseband. The frequency band from 0 hertz (Hz) to a specified upper frequency which contains the composite baseband signal.

Main Channel. The band of frequencies from 50 (or less) Hz to 15000 Hz on the FM baseband which contains the main channel signal.

Main Channel Signal. A specified combination of the monophonic, or left and right audio signals, which frequency modulates the main carrier.

Stereophonic Sound. The audio information carried by plurality of channels arranged to afford the listener a sense of the spatial distribution of sound sources. Stereophonic sound includes, but is not limited to, biphonic (two channel), triphonic (three channel), and quadraphonic (four channel) services.

Stereophonic Sound Subchannel. The band of frequencies from 23 kHz to 99 kHz (53 kHz for two channel transmission) containing sound subcarriers and their associated sidebands.

Subchannel. A transmission path specified by a subchannel signal occupying a specified band of frequencies.

Subchannel Signal. Subcarrier(s) and associated sideband(s) which frequency modulate the main carrier. It is synonymous with subcarrier, as in the stereophonic subcarrier or SCA subcarrier.

Frequency Deviation. The peak difference between the instantaneous frequency of the modulated wave and the average carrier frequency.

Percentage Modulation. The ratio of the actual frequency swing of the carrier to the frequency swing defined as 100% modulation, expressed in percentage. Although current FCC rules conditionally permit greater than 100% modulation when SCAs are transmitted, a frequency swing of ±75 kHz is still defined as 100% modulation.

Injection. The ratio of the frequency swing of the FM carrier by a subchannel signal to the frequency swing defined as 100% modulation, expressed in percentage. The total injection of more than one subchannel signal is the arithmetic sum of each subchannel injection.

Crosstalk. An undesired signal occurring in one channel caused by an electrical signal in another channel.

Linear Crosstalk. A form of crosstalk in which the undesired signal(s) is created by phase or gain inequalities in another channel or channels. Such crosstalk may be due to causes external to the stereophonic generator; consequently it is sometimes referred to as system crosstalk.

Nonlinear Crosstalk. A form of crosstalk in which the undesired signal(s) is created by harmonic distortion or intermodulation of electrical signal(s) in another channel or channels. Such crosstalk may be due to distortion within the stereophonic generator or FM transmitter; consequently it is sometimes referred to as transmitter crosstalk.

Frequency Spectrum and Modulation Limits

The FCC's stereophonic transmission standards are contained in Section 73.322 of the FCC Rules, and the SCA transmission standards are contained in Section 73.319. The characteristics and methods of generating these signals are discussed below, but readers are also referred to the Commission's Rules for a listing of its standards.

The composite baseband extends to 99 kHz and may be used in support of either stereophonic or SCA multiplex services.. Stereophonic broadcasting includes, but is not limited to, biphonic (two channel) service. Within the frequency range of 23 kHz to 99 kHz, any form of amplitude modulation (DSB, SSB, etc.), angle modulation (FM or PM), or frequency shift keying of a multiplex subchannel is permitted.

The term SCA is an acronym for a "Subsidiary Communications Authorization," once required in order for a station to begin broadcasting a multiplex service. Although the familiar term "SCA" continues, the authorization is no longer required. Broadcast licensees may begin transmitting multiplex services without prior notification of or authorization from the FCC.

Under certain conditions when SCA multiplex subcarriers are operated, a total modulation of up to 110% is legal. Fig. 1 shows the baseband frequency ranges and modulation limits for various modes, from monophonic to stereophonic, plus fully-loaded SCA operation.

Fig. 1A represents the basic monophonic program mode, where the baseband width is limited to approximately 15 kHz and no other signals are multiplexed. In this case all the modulating energy is contributed by the main channel. Not more than 100% modulation is permitted in this case.

Fig. 1B shows the baseband with SCA operation in addition to monophonic main channel service. Total SCA injection up to 30% is permitted within the band from 20 kHz to 99 kHz. This injection figure may be contributed by one or more SCA subcarriers. To insure that the bandwidth of the main carrier (and its interference to other stations on adjacent and alternate channels) is not significantly increased, the arithmetic sum of all modulation must not exceed 100% plus one-half of the SCA injection. SCA injection between 75 kHz and 99 kHz may not exceed 10% under any conditions.

Note that the Commission Rules permit transmission of multiplex subcarriers when *no* broadcast program service is carried on the main channel, provided that the above modulation rules are met.

Fig. 1C shows the basic stereophonic sound program

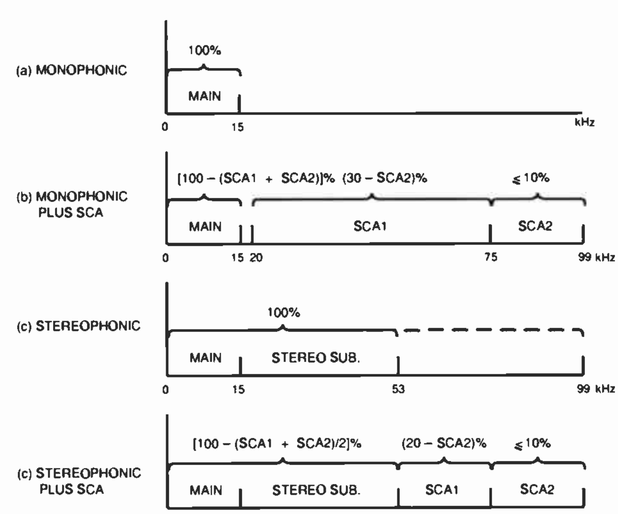

Figure 1. FM baseband scenarios with allowable modulation limits for monophonic, stereophonic, and SCA operation. Modulation percentages are referred to 75 kHz carrier deviation.

mode, without SCA operation. As is the case for monophonic program operation, the modulation must be limited to 100%. Frequencies up to 99 kHz are available for multichannel sound program transmission.

Fig. 1D adds a single band for SCA operation to the stereophonic mode. While total SCA injection may be up to 20%, no more than 20% total injection may be employed within the frequency bands from 53 kHz to 75 kHz, and 10% from 75 kHz to 99 kHz. (There is one exception to determining total SCA injection involving subcarriers that are multiples of and synchronous to the stereophonic pilot. This is discussed in the SCA multiplex section of the chapter.) The modulation contributed by the main channel and stereophonic subchannel signals must be no more than 100% minus one-half the total SCA injection. Since the total injection may be up to 20%, total modulation may be up to 110%.[4]

GENERATING THE STEREOPHONIC BASEBAND SIGNAL

Fig. 2 shows the composite baseband that modulates the FM carrier for biphonic broadcasting. (SCA multiplex subchannels are not part of this band and will be discussed later.)

The two-channel stereo baseband has a bandwidth of 53 kHz, and consists of:

1. A main channel which consists of the sum of left plus right audio signals $(L+R)$. This is the same signal broadcast by a monaural FM station, but is reduced by approximately 10% to allow for the stereo pilot injection.
2. A stereophonic sound subchannel $(L-R)$ is required, consisting of a double sideband amplitude modulated subcarrier with a 38 kHz center frequency. The modulating signal is equal to the instantaneous difference of the left and right audio signals. The subcarrier is suppressed to avoid wasting modulation capability. The pairs of AM sidebands have the same peak modulation potential as the main channel.
3. A 19 kHz subcarrier *pilot* which must be exactly one-half the frequency of the stereophonic subcarrier and very nearly in phase to it. It supplies the reference signal needed to synchronize the decoder circuitry in receivers. The frequency tolerance is ±2 Hz and the main carrier must be modulated between 8% and 10%.

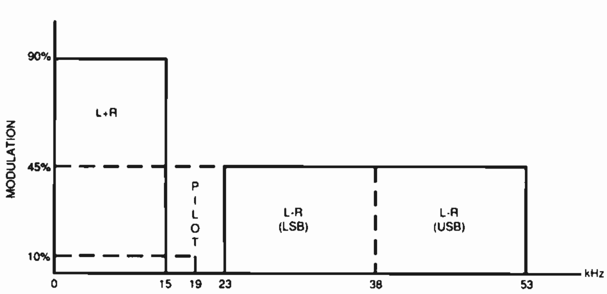

Figure 2. Biphonic (two-channel) stereo baseband.

In general two principles have been used to generate the stereophonic subchannel. The methods are called time division multiplex (TDM) or switching method and frequency division multiplexing (FDM) or matrix method.

Frequency Division Multiplexing

A basic method for generating the stereophonic baseband involves the direct generation of the double sideband suppressed $L-R$ subchannel along with the $L+R$ channel.

A simplified block diagram of the FDM system is shown in Fig. 3. Both left and right audio channels are preemphasized and low pass filtered. In the matrix the left and right audio signals are both added and subtracted. The audio signals are added to form the $L+R$ main channel which is also used as the monaural broadcast signal.

The subtracted signals are fed to a balanced modulator which generates the $L-R$ subchannel. Since a balanced modulator is used, the carrier at 38 kHz will be suppressed, leaving only the modulated sidebands.

The 38 kHz oscillator is divided by two to make the 19 kHz pilot tone. Finally, the main channel, stereophonic subchannel and pilot are combined in the proper proportions (45 + 45 + 10) to form the composite output.

An examination of the composite stereo waveform in the time domain, such as displayed by an oscilloscope, is helpful. First consider a 1 kHz sine wave applied equally to the L and R audio inputs. This is shown in Fig. 4A without a pilot signal. The only frequency present in the spectrum graph is 1 kHz, since the matrix produces no difference signal necessary to generate sidebands in the stereophonic subchannel.

Fig. 4B illustrates the ideal composite signal when the same 1 kHz tone is applied to the L and R inputs but exactly out of phase. With the pilot still off, two frequency components at 37 kHz and 39 kHz are generated. No $L+R$ signal appears from the matrix, thus only the sidebands of the modulated 38 kHz subchannel are present.

The symmetrical envelope shown represents a double-sideband suppressed carrier (DSBSC) AM signal. Note that the amplitude of each sideband is one-half that of the $L+R$ component in Fig. 4A. In the receiver's stereo decoder the sidebands are added together to produce an output equal to the full left signal.

Finally, consider the waveform in Fig. 4C, when the composite signal (still without pilot) is generated by applying a 1 kHz tone to the L input alone. The baseline of the waveform envelope will be a straight line if there is no amplitude or phase difference between the main channel and subchannel. Three frequency components

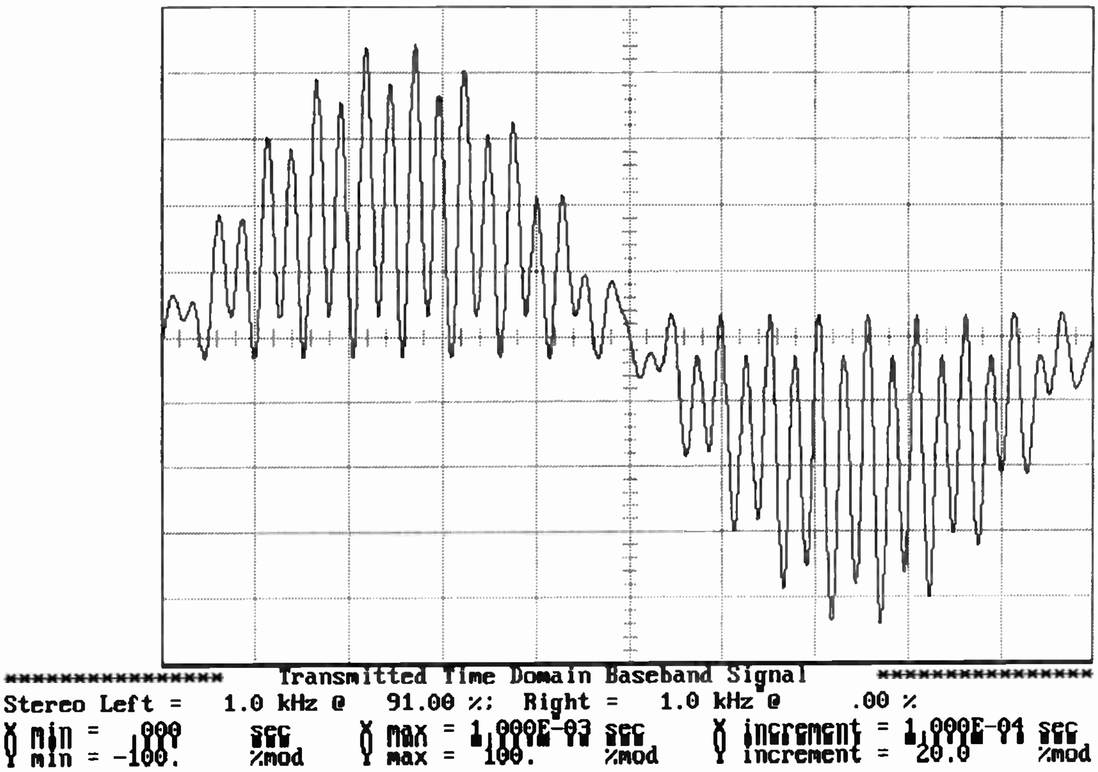

Figure 4E(2). Same modulation conditions as C, but with 19 kHz pilot at 9%. (Courtesy of Quantics.)

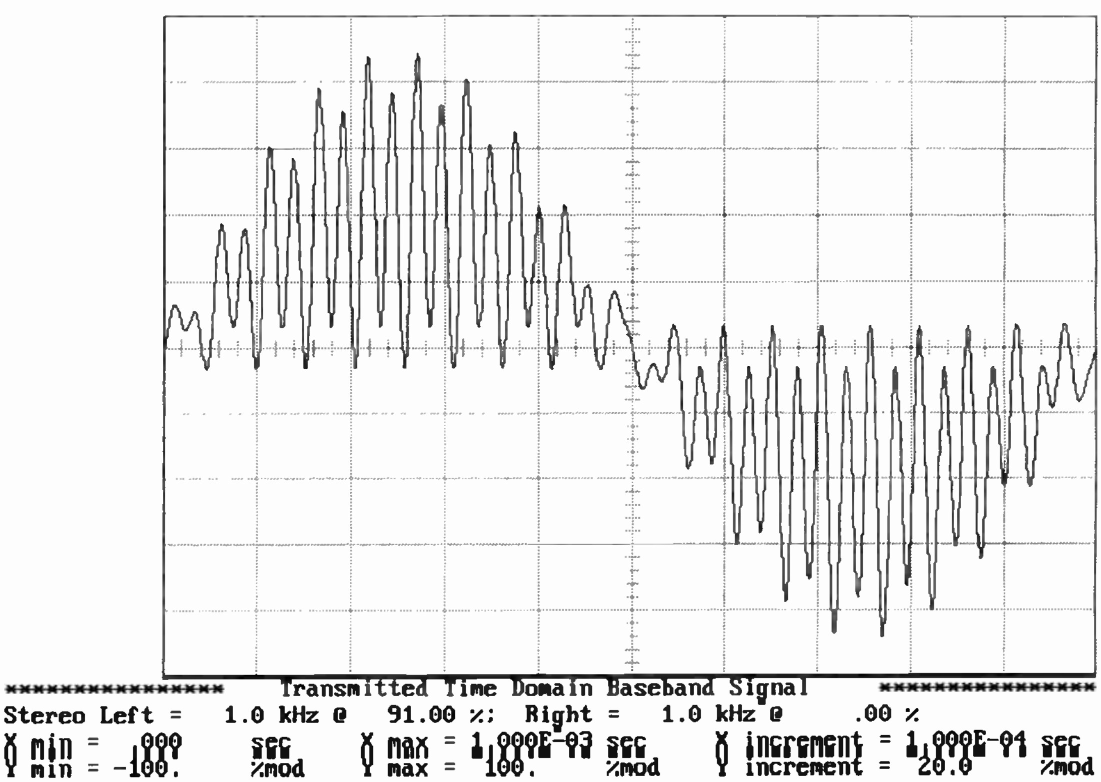

Figure 4F. Same modulation conditions as C, with 19 kHz pilot at 9%. (Courtesy of Quantics.)

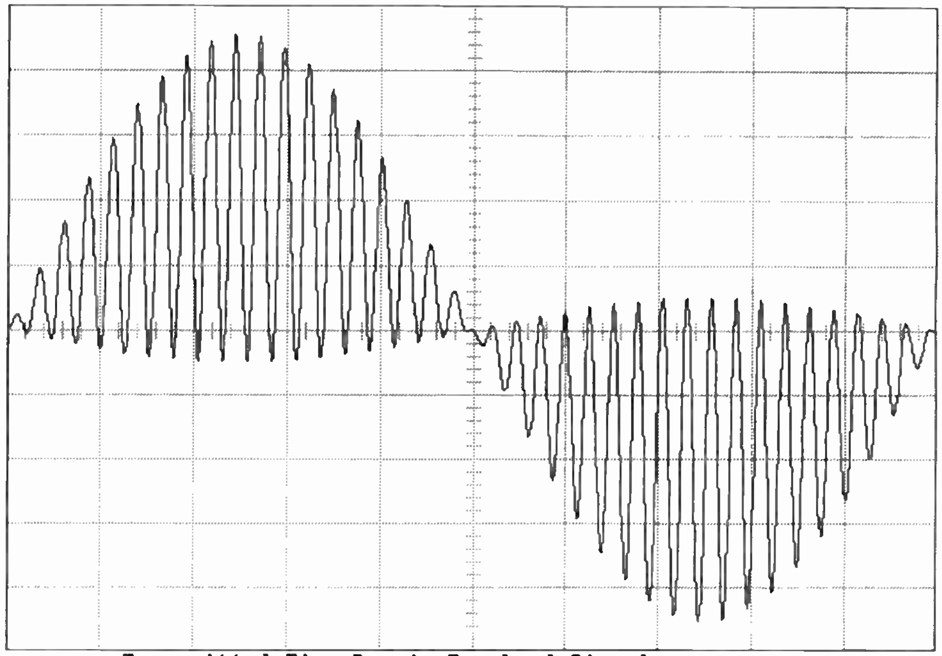

Figure 4G. Same modulation conditions as C, with mis-matched gain between Main Channel (L+R) and Subchannel (L−R). (Courtesy of Quantics.)

are present: 1 kHz, 37 kHz, and 39 kHz. These sidebands are each one-half the voltage amplitude of the 1 kHz signal in the main channel; together they equal the energy of the main channel in this instance. Figs. 4D-F show the same conditions as 4A-C with the pilot turned on. Fig 4G is an example of a possible degradation that can be caused by imbalance between the main channel and the subcarrier.

The last diagram looks the same when an *R*-only 1 kHz tone is applied, but the phase of the two sidebands would be reversed with respect to the 38 kHz subcarrier (and the pilot). Adding the pilot at 8% to 10% produces similar waveforms, but the oscilloscope display of the waveform baseline is fuzzier. For this reason, most stereo generators allow the pilot to be turned off for baseline measurements.

Time Division Multiplex

A different type of stereo generator is in use which produces a result similar to frequency division multiplexing by using a switching technique.

Generation of both the $L+R$ and $L-R$ channels is accomplished by an electronic switch that is toggled by a 38 kHz signal. The switch alternately samples one audio channel and then the other, as shown in Fig. 5. According to Nyquist criteria, the original signal can be reconstructed from periodic samples, provided that the samples are taken at a rate at least twice the frequency of the highest audio frequency component (approximately 15 kHz in broadcast FM).

The output waveform for the TDM generator shown in Fig. 6 is the time domain (as an oscilloscope would display the signal) for a sequence of input signals. The diagrams at the right of the waveform show the same signal in the frequency domain (as would be displayed on a spectrum analyzer).

In Fig. 6A, there are no input signals present. Ideally, no output signals are possible, and in practice only a small amount of leakage of the switching transients are present. Since the transfer time of the switching signal is extremely quick, harmonics of the fundamental 38 kHz are possible.

A 9 kHz audio tone is applied to the *L* and *R* inputs in Fig. 6B. The 9 kHz input signals are combined at full amplitude (90% modulation) and no subchannel sidebands are generated.

In Fig. 6C, only the left channel has a signal present. As the switch selects the *L* audio line, samples are passed along to the composite output. Therefore, the output waveform shows the same signal, chopped into segments of 1/38,000 of a second. Since the total area under the waveform has been divided in half, it should be apparent that the energy of the 9 kHz signal in the $L+R$ channel is only half the amplitude that it would be if an equal 9 kHz signal were also present at the right channel. The equation for the output signal (e) for an input signal (σ) at any instant (t) is

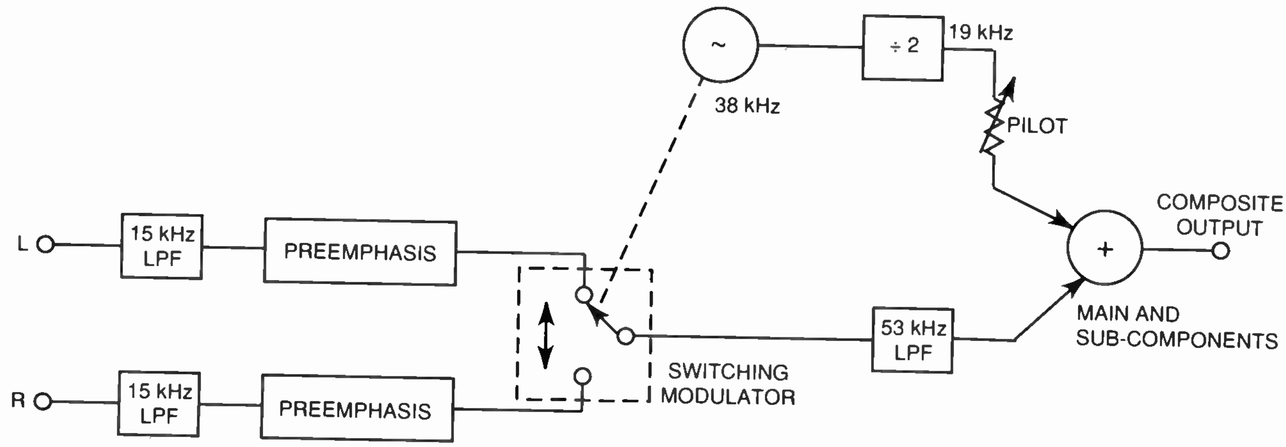

Figure 5. Functional blocks of a time division multiplex stereo generator.

$$
\begin{aligned}
e = {} & \tfrac{1}{2}\sin \sigma t + \\
& \text{(main ch. audio)} \\
& 1/\pi\,[\sin(\phi + \sigma) + \sin(\phi - \sigma)t] - \\
& \text{(DSBSC)} \qquad\qquad (1) \\
& \tfrac{1}{3}\pi\,[\sin(3\phi + \sigma)t + \sin(3\phi - \sigma)t] \\
& \text{(3rd harmonic)} \\
& \ldots \text{etc.} \quad \text{(higher harmonics)}
\end{aligned}
$$

Fig. 6C shows the original 9 kHz signal (at half amplitude), and a pair of sidebands centered about the 38 kHz switching frequency. No 38 kHz signal is generated if the switching waveform has perfect symmetry, that is, if the switch is connected to the left and right channels for precisely equal periods. Note that a harmonic of the stereophonic subcarrier is shown, centered around 114 kHz which is three times the switching frequency. Only one extra term was shown in the equation; however, other terms at the fifth, seventh, etc. are present.

In addition to the odd-order harmonics of the 38 kHz subchannel, asymmetry in the switching signal, or other circuit imbalances, can create some sidebands centered about the second harmonic at 76 kHz. All these harmonics must be removed by filtering, as shown in the diagram.

When the odd harmonics are filtered out, the proper DSBSC waveform results. However, it is slightly greater in amplitude than the $L+R$ signal because the fundamental component of the square wave is $4/\pi$ or 1.27 times larger than the square wave amplitude. This is easily corrected by adding enough of the L and R audio to the output to equalize the amplitude.

In Fig. 6D, the TDM signal is shown when the L and R signals are equal in amplitude and exactly reversed in phase. This waveform matches the composite stereo signal shown in Fig. 4C.

The composite lowpass filter must have very steep cutoff characteristics but should have flat amplitude response and linear phase shift with frequency (equal time delay at all frequencies) below 53 kHz. While this approach to stereophonic generation is simple and stable, the filter can degrade stereo separation, especially at higher audio frequencies.

The 19 kHz pilot square wave from the ÷2 digital divider must also be filtered to remove harmonics. This additional time delay (phase shift) of the pilot with respect to the 38 kHz information must be compensated to have optimum channel separation.

A significant improvement on the original switching concept is shown in Fig. 7. As mentioned earlier, the higher order terms of the square wave-driven switch are responsible for generating the harmonics of the 38 kHz subchannel which must be removed by filtering. By using a "soft switch" to connect back and forth between the L and R channels it is possible to eliminate the lowpass filter and its side-effects.

This is accomplished by using the electrical equivalent of a variable attenuator, shown in the diagram by a potentiometer. The slider is driven from end to end

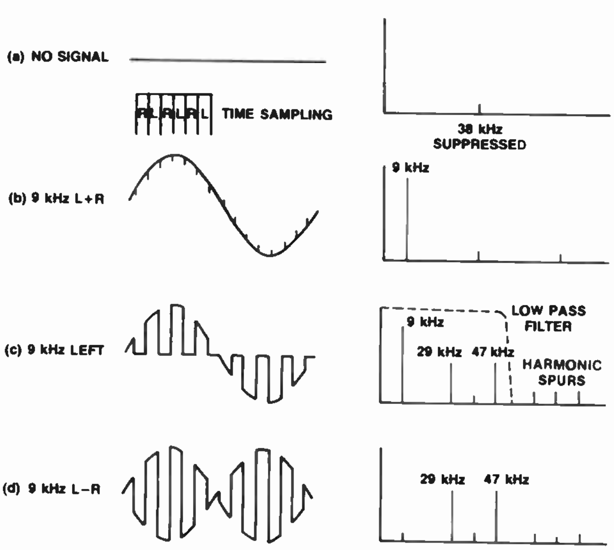

Figure 6. Time domain and frequency domain diagrams of stereo baseband signals.

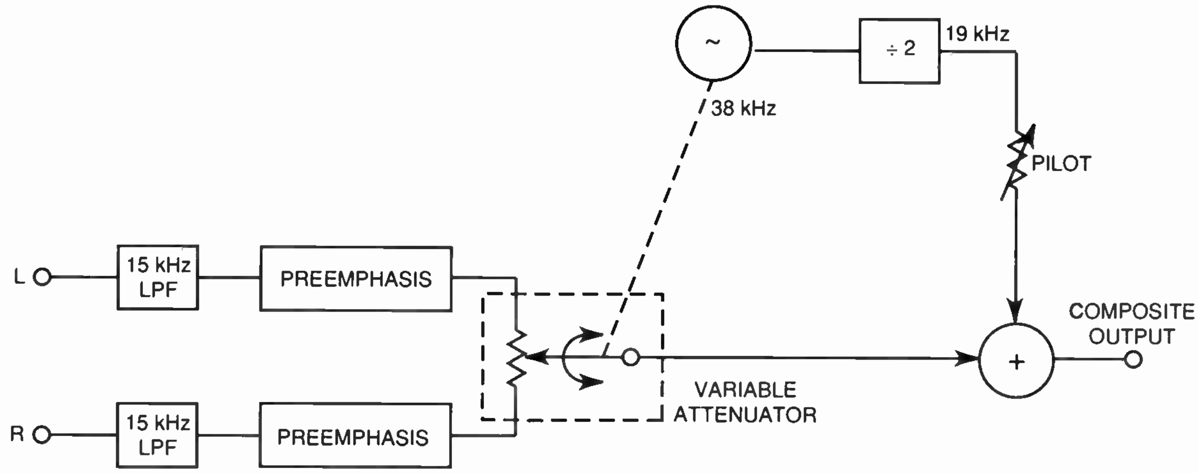

Figure 7. Functional blocks of a time division multiplex stereo generator using a variable attenuator.

of the potentiometer by a sine wave. Since a sine wave is represented only by a single, fundamental frequency, the signal output at the slider has the proper DSBSC characteristics without the harmonics. The equation for the composite signal generated in this way is

$$e = \tfrac{1}{2} \sin \sigma t \, (L + R \text{ audio}) +$$

$$1/\pi \, [\sin(\phi + \sigma)t + \sin(\phi - \sigma)t] \quad (2)$$
(38 kHz DSBSC)

As the equation shows, only the fundamental sidebands of 38 kHz are present in the sampled signal, along with the main channel component. Like the fast-switching TDM system, the $L+R$ and $L-R$ channels are generated in one operation so that the circuit remains relatively simple. No filter of the output is required, provided that the 38 kHz sinewave is free from harmonics and the variable attenuator has good linearity.

FMX™ Stereo Noise Reduction

The FMX™ system was developed to reduce the noise in stereo reception by compressing the stereo $L-R$ difference signal before transmission and expanding it to its original dynamic range at the receiver. The system utilizes the standard FM stereo composite format with the addition of a new subcarrier for the compressed signal. The added DSBSC subcarrier is in phase quadrature with the regular stereo subcarrier at 38 kHz, as shown in Figure 8A.

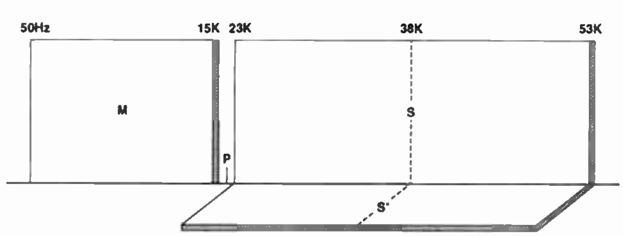

Figure 8A. Baseband spectrum.

The compression characteristic shown in Figure 8B provides linear operation at a fixed gain of 14 dB over much of the program dynamic range, while at the highest modulation levels the FMX program signals are attenuated to permit delivery of full modulation by the standard stereo composite signal. The FMX receiver has a quadrature channel demodulator, expander, and matrix that restores the compressed $L-R$ program to its original dynamic range and combines it with the $L+R$ signal to provide stereo with reduced noise.

Digital Stereo Generation

The major manufacturers of stereo generators have recently introduced all-digital composite generator designs. These units carry out the same functions as analog stereo generators, but with the flexibility and consistency commonly expected of digital audio sys-

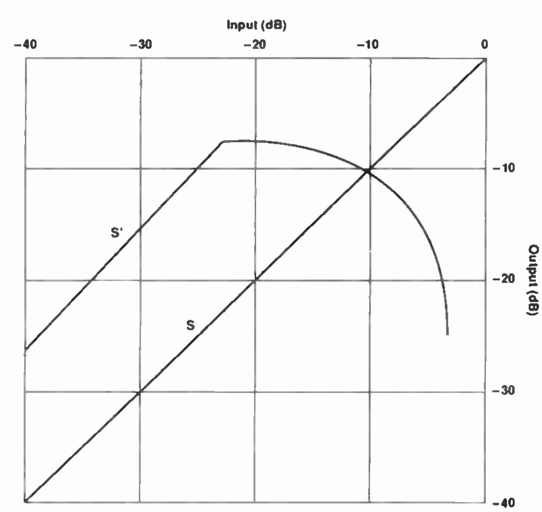

Figure 8B. Compression characteristic.

tems. Some generators also perform all the audio compression and peak limiting functions in the digital domain. This chapter is confined to a discussion of digital stereo generation techniques.

In a digital implementation it is made easier if the output sampling rate is a binary multiple of either of the two steady state vectors in the composite signal: the stereo pilot or the $L-R$ subcarrier. For example, an oversampling rate of 304 kHz is sometimes employed; this is eight times the subcarrier frequency (16 times the pilot).

The input sampling rate is also an important consideration. The reader will note that switching-type stereo generators, discussed earlier, operate at only 38 kHz. While higher rates do not yield any additional improvement in fidelity, it is desirable to use a higher rate throughout the generator system.

While Digital Compact Discs© are fixed at 16-bit quantization precision, most digital stereo generator designs use more bits per sample. This is because analog-to-digital (A/D) conversion devices do not perform to the theoretical limits of 16 bits, and because the mathematical precision of the processing architecture can produce rounding errors that contribute noise and distortion to the processed signal. Eighteen to 24 bit data paths are generally chosen.

Analog audio for each channel is passed through an anti-aliasing lowpass filter and is then A/D converted into digital data streams. At this point, generators with audio processing carry out algorithms that gain-control, preemphasize, limit and filter the digital audio stream. The dynamic effects are very similar to analog processors even though the treatment is entirely digital.

The processed L and R signals are then numerically matrixed using simple addition into $L+R$ and $L-R$ channels. The digitized 38 kHz sinewave is derived from a look-up table and digitally multiplied by the $L-R$ channel to produce the 38 kHz double-sideband suppressed carrier (DSBSC) subchannel. The 19 kHz pilot is generated by another look-up table that is locked via software control so that the phasing relative to the 38 kHz subchannel is perfect. The pilot and 38 kHz subchannel are finally summed and applied to a digital-to-analog converter to form the complete composite stereo signal. Some manufacturers provide a separate digital output port for future digital FM exciters.

Stereo Decoder Circuits

Stereo FM receivers include a circuit to convert the multiplexed composite signal at the FM detector into the original left and right audio channels transmitted by the FM station. There are at least as many ways to decode the stereophonic signal as there are ways to encode (generate) the composite signal. In practice, only one type of decoder is commonly used: the so-called phase-locked loop (PLL) integrated circuit.

The circuit in Fig. 9A is seldom used, but is shown for comparison. It is the closest complement to stereo generators using frequency division multiplexing. At the input, the composite signal is split with three equal time-delay filters into the main $(L+R)$ channel, pilot signal, and stereo $(L-R)$ subchannel. Next, the pilot is doubled to 38 kHz. This regenerated carrier is reinserted into the double-sideband AM signal from the subchannel filter. The AM signal is demodulated to yield the $L-R$ (difference) audio. Finally, the $L+R$ and $L-R$ signals are combined in a sum and difference matrix to produce the original left and right audio channels.

Because of the costly filters needed to separate the composite spectrum, the frequency division multiplex circuit is not used in consumer equipment. Similar circuits have been used in broadcast modulation monitors, where metering of the separate channels is required.

The circuit shown in Fig. 9B is universally used due to its simplicity, high performance, and low cost. While this stereo decoder is commonly referred to by its internal phase-locked loop (PLL), its performance is really distinguished by its time division demultiplexer (shown in the dashed box as a toggle switch).

Following a buffer amplifier, the composite baseband signal is sampled by a phase-locked loop within the integrated circuit (IC). A voltage controlled oscillator, usually running at 76 kHz (four times the pilot frequency), is held in phase with the pilot by a reference signal from the phase comparator and loop filter. When divided by two, the result is a square wave at 38 kHz having nearly perfect duty cycle (high and low states have equal timing) and very fast rise and fall times. This signal is ideal for driving the output audio switcher (demultiplexer). This stage is a transistor matrix designed to rapidly transfer the composite baseband to the left and right audio output in time with the switch in the station's stereo generator. Fast, clean audio switches are relatively easy to make and do not drift.

Because PLL stereo decoders normally use square wave switching, the circuit is able to demodulate baseband signals that are odd harmonics of 38 kHz. The third harmonic (114 kHz) is most troublesome, since noise and spurious signals near this frequency are shifted to the audio baseband, as is the 38 kHz stereophonic subchannel. Engineers should be watchful of the frequency band centered on 114 kHz in their transmitted signal since audible noise may occur in consumer receivers.

Recent stereo decoder designs have reduced sensitivity to energy outside the composite baseband. One approach utilizes a second composite audio toggle switch operated at 114 kHz. The demodulated product is inverted and mixed equally with the 38 kHz switching outputs, canceling the response to signals in the 114 kHz range. The other approach, called a Walsh demodulator, applies a properly timed stair step imitation of a sinusoid to a digital multiplier in the output signal path.[5] This reduces sensitivity to third and fifth harmonics, as well as adjacent channel noise and interference, by up to 20 dB.

FM SCA TRANSMISSION

Background

From its beginning as a broadcast service, people have recognized the potential of FM for multiplexed services. As early as 1940, the FCC permitted multiplex facsimile transmission on FM stations, but not until much later did auxiliary FM services attain a wide acceptance among FM broadcasters.

In 1955 the FCC established the Subsidiary Communications Authorization and created an entirely new industry. The original intent of the authorization was to permit programming of background music to offices, stores, restaurants, etc., where it was uneconomical to provide this service via telephone lines. For many commercial FM stations, the SCA operation became a major source of revenue which enabled them to survive in the 1950s.

By the early 1980s, improvements in transmitter and receiver technology and the desire for new revenue prompted commercial and noncommercial broadcasters to seek changes in the SCA rules. In a series of rulemakings in 1982 and 1983 the Commission made numerous changes to expand technical opportunities and reduce legal regulation.[6] These changes extended the baseband frequency limit from 75 kHz to 99 kHz, allowed any type of subcarrier modulation to be used, changed the subcarrier injection requirements to permit multiple services, and increased limits for the total modulation during SCA multiplex operation to reduce main channel modulation loss.

FCC Rule Requirements For SCA Operation

Section 73.319 of the FCC Rules sets forth the technical standards for FM multiplex subcarriers. Users should note, however, that the Commission does not set standards for minimum SCA subcarrier performance. This is left for the broadcaster or lessee of the service to determine. In its rules, the Commission defines the transmission conditions under which subcarriers may be operated, to minimize interference to

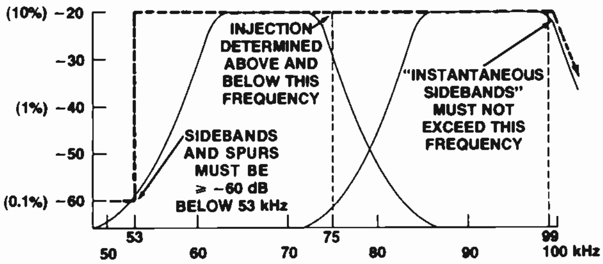

Figure 10. Injection, channel bandwidths and spurs limits for SCA operation when stereo is transmitted. Two possible subcarriers (at 67 and 92 kHz) are shown.

the main channel, the stereophonic subchannel, and to other FM stations.

Subcarrier injection and bandwidth are considered here only with stereophonic operation, since this is by far the most common FM mode. Fig. 10 shows the upper portion of the composite baseband, from approximately 50 kHz to 100 kHz. This is the same as the upper portion of Fig. 2 with the addition of two hypothetical subcarriers centered at 67 kHz and 92 kHz. Any number of SCA subcarriers may be operated in this frequency range provided that total bandwidth and injection limits are met.

On the baseline are several frequency markers at the upper and lower frequency limits of the two subcarrier ranges. The actual frequencies of the subcarriers are not specified, but are referred to as "*fc1*" and "*fc2*".

Alongside each subcarrier are arrows marking the level in dB below 100% modulation of the main carrier. For example, −20 dB marks the injection at the center frequency of both subcarriers. Since 10% is the maximum injection permitted under the Commission Rules within each SCA subchannel,

$$\text{Injection} = 20 \times \log_{10}(0.1) = 20(-1) = -20\,\text{dB} \qquad (3)$$

At 53 kHz, an arrow marks a level of −60 dB. The FCC requires that any frequency modulation of the main carrier due to the SCA operation shall be at least 60 dB below 100% modulation in the frequency range of 50 Hz to 53 kHz when stereo is transmitted. This figure must include spurious and intermodulation products as well as subcarrier sideband energy.

At 99 kHz, the level of −20 dB is marked, denoting the FCC requirement that "instantaneous sidebands" be restricted within this frequency limit. The Commission has not officially defined instantaneous sidebands, but it is normally considered to be the instantaneous frequency of the subcarrier at its peak deviation (for frequency modulated subcarriers) or the highest sideband frequency (for amplitude modulated subcarriers).

Interference Between FM SCA Subcarriers

In practice, two subcarriers should be separated as far apart in frequency as possible, while observing the limit of spurious energy below 53 kHz and the instantaneous sidebands at 99 kHz. While the FCC Rules are silent on the choice of SCA frequencies, 67 kHz and 92 kHz have become the defacto standards for FM subcarriers. The first frequency was adopted when the original stereophonic standards restricted the subcarrier spectrum between 53 kHz and 75 kHz. The second frequency was recommended to situate the instantaneous sidebands below 99 kHz while maintaining a safe separation from a 67 kHz subcarrier.[7]

Some overlap of the subcarrier sidebands does occur, as depicted in Fig. 11. This does not cause significant interference between the two SCA subchannels when the systems use frequency modulation. The following is a list of bench test results of a standard table model SCA receiver:

1. Unweighted 67 kHz SCA SNR at 65 dBf, referred to 5 kHz deviation: 57.5 dB.
2. Same, with 4 kHz tone modulation of 92 kHz subcarrier at 7 kHz deviation: 56.5 dB.
3. Same as first case with tone modulation of main channel at 67.5 deviation: 52.5 dB.

The above data show that crosstalk is greater from main-to-subchannel than from a 92 kHz subcarrier into the 67 kHz subchannel demodulator.

Other Types of Analog Subcarrier Modulation

Other frequencies and total number of subchannels are permissible, according to the occupied bandwidths and interference margins required. A hypothetical SCA baseband spectrum combining five amplitude-modulated subcarriers is shown in Fig. 10. Here, a variety of bandwidths and injection levels are used.

In Fig. 12 note that single-sideband suppressed carrier (SSBSC) AM systems are used for the four

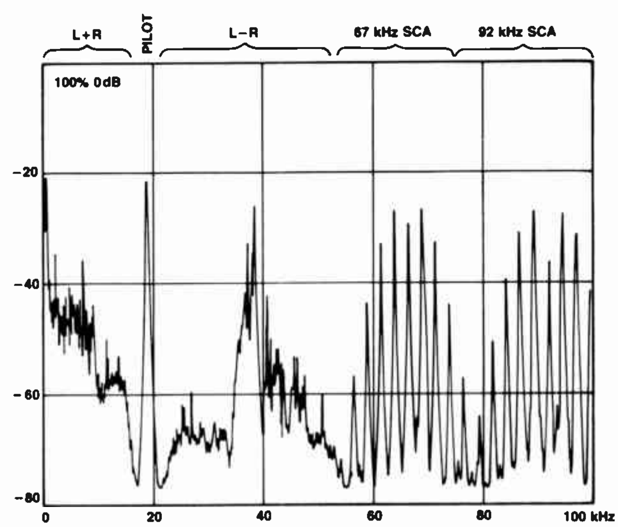

Figure 11. Composite baseband of FM station with 67 kHz and 92 kHz FM-SCAs, modulated with 2.5 kHz tone at 5 kHz and 7 kHz peak deviation, respectively. Note overlap of sidebands between subcarriers. Station is carrying stereo programming.

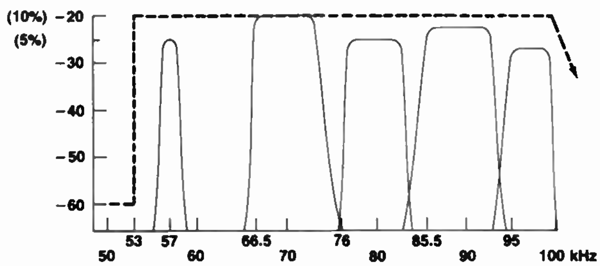

Figure 12. Carrier envelope spectrum, DSB-AM and SSB-AM SCA subcarriers. Vertical markings are dB referred to 75 kHz deviation.

other subchannels. On the first (at 66.5 kHz), 10% peak envelope injection is being used, while the other three use levels which bring the total to 20%.

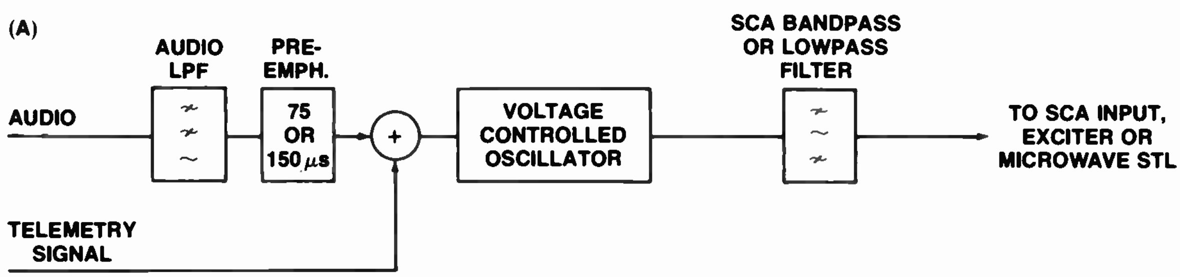
At 57 kHz, the envelope of a narrow subcarrier is shown. Actually, standards exist to interleave two subcarriers within the same channel. One is called the Radio Data System (RDS) and is in use by a large number of Western European countries for personal paging, station and program identification, emergency alerting, etc. This 57 kHz system is currently used for subcarrier paging in the U.S. The modulated carrier spectrum resembles suppressed-carrier double sideband AM that is locked to the third harmonic of the pilot. Digital data rate is 1187.5 bits/second and nominal deviation of the carrier is 2.67% (±2.0 kHz).

Another 57 kHz system was also developed in Europe for Automotive Road Information (ARI). It is used to identify stations that broadcast traffic information and to activate specially-equipped FM car radios during traffic announcements. ARI is a slow-rate signaling system with very narrow bandwidth. The 57 kHz ARI carrier is centered within the suppressed-carrier region of the RDS signal (if RDS is transmitted).

Examples of Analog SCA Operation

Fig. 13A shows the functional blocks of a standard aural SCA generator using frequency modulation. At the input, audio is lowpass filtered to limit the modulation sidebands that could interfere with the stereophonic subchannel or an upper SCA subchannel.

A 5 kHz audio cutoff is frequently used so that fidelity compares favorably to unequalized telephone service. Using a Bessel function analysis one can determine the peak deviation which may be used to maintain FM sidebands below 53 kHz within FCC limits.



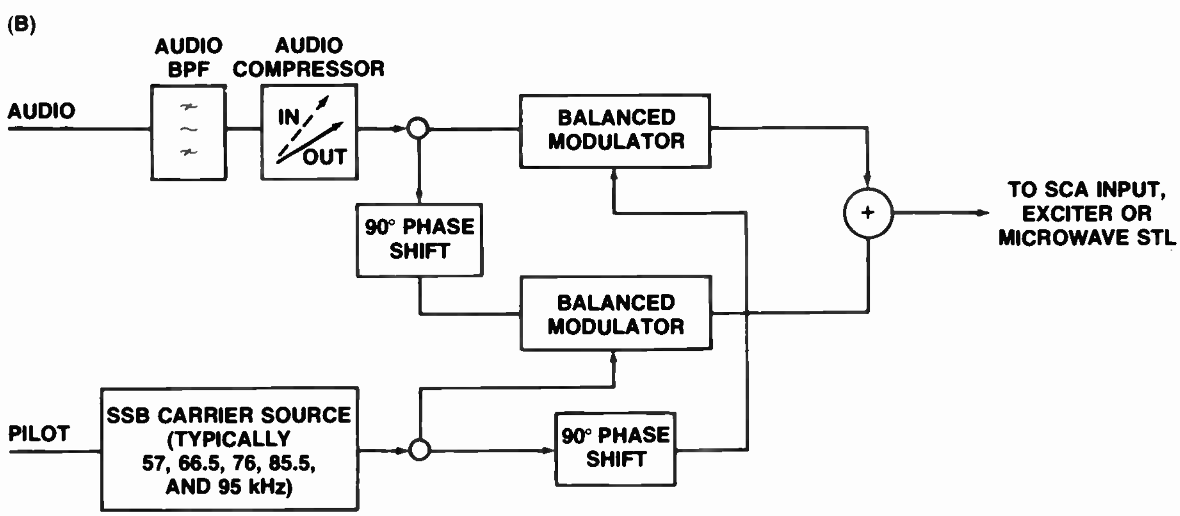


Figure 13. Functional blocks of (A) a frequency-modulated SCA subcarrier generator, and (B) a single-sideband AM subcarrier generator.

TABLE 1

Sinusoidal SCA Modulating Frequency	Maximum SCA Peak Deviation
3.5 kHz	5.0 kHz
5.0 kHz	3.5 kHz
7.5 kHz	2.0 kHz

For the above protection requirements, equipment manufacturers often recommend 3.5 kHz or 4.0 kHz peak deviation with a 5 kHz low-pass filter when stereo is transmitted. In practice, slightly higher deviation may be used since the calculations assume single tone modulation which has greater modulation power than program audio.

Preemphasis follows the low-pass filter in the sample FM SCA generator. A value of 150 μSec is commonly used to combat the rising high-frequency noise characteristic in the FM SCA channel. Unfortunately, this extreme boost (almost 17 dB at 5 kHz, compared to 400 Hz) requires substantial amounts of peak limiting to allow full modulation at low and middle audio frequencies.

The processed audio signal is fed to the FM modulator, usually with a provision for subaudible (less than 30 Hz) channel for telemetering return. The telemetry channel takes advantage of the extended low frequency response capability of FM subcarriers by sending tone signals in the 10 Hz to 30 Hz range at a level of 15 dB to 25 dB below reference peak deviation. A high-pass filter is inserted ahead of the audio input when subaudible telemetry is used to avoid interference to the low frequency channel.[8]

Ideally, no filtering of the frequency-modulated subchannel is required. However, some of the FM generator circuits produce spurious or harmonic energy. For this reason, a bandpass or low-pass filter is used which passes all the significant sidebands but suppresses spurious signals to acceptable levels. The modulated subchannel signal is amplified to a level required by the subcarrier input of the FM exciter or studio transmitter link equipment.

A simplified block diagram of a SSBSC AM subchannel generator is shown in Fig. 13B. The input audio is bandpass filtered to control subchannel bandwidth (to 5 kHz, for example), and may be compressed according to specific amplitude and spectral standards. A complementary expander circuit in the receiver restores the original program dynamics and reduces noise in the channel. Large amounts of preemphasis are not as important since the spectral characteristic of the noise is flat with a linear modulation system, not rising with frequency as in angular modulation systems.

The processed audio signal is fed to a pair of balanced modulators, one path going through an allpass filter which shifts the audio phase 90° throughout the required audio range. The balanced modulators are driven by a subcarrier frequency source which may be frequency-locked to a harmonic of the stereophonic pilot (and its half-frequency of 9.5 kHz, as shown). One of the modulators is driven by a carrier signal which is shifted 90°. When the two modulated carriers are summed, cancellation of the lower (or upper) sidebands creates the desired single-sideband signal.

Since SSBSC AM requires a carrier for detection, the pilot provides an excellent source for reinsertion at the receiver. With monophonic audio, no pilot is transmitted, so another carrier reference must be used. One approach is to carry the 19 kHz reference at a reduced level which will not trigger the stereophonic decoders in FM receivers.

SCA DATA SYSTEMS

SCA subchannels have characteristics that are quite favorable for transmitting data: while the channels are noisy for high fidelity audio services, they can provide good to excellent data error performance; and moderately fast data rates are possible without complicated or expensive receivers. Combined with the high power and elevation of FM broadcast stations, SCA data systems may be operated over large service areas.

There are many methods of putting data on an SCA subchannel, the simplest being connection of a telephone-type data MODEM to the audio terminals of the SCA generator. This method is commonly called *audio-frequency-shift keying* (AFSK).

The cost and complexity of this form of SCA data broadcasting is low. However, this technique occupies the bandwidth of a standard audio subcarrier and the highest practical speed is about 2,400 bits/second. This may be acceptable where the hardware must be "off the shelf" and data capacity of baseband spectrum efficiency is not a consideration.

Direct Data Modulation

Direct data modulation eliminates the intermediate steps that convert the data into audio signals, allowing the subcarrier to be directly modulated by the binary data. This efficiency allows a greater amount of data to transmitted within the available SCA subchannel bandwidth.

In *non-return-to-zero frequency-shift keying* (NRZ/FSK), the two binary states are represented by two different subcarrier frequencies. For example, a "0" could be 65 kHz and a "1" 69 kHz. FSK is the most popular form of direct data modulation at this writing, probably because of its robust performance, simplicity and low cost. Using careful design, a modulated bandwidth similar to that of background music services (i.e., about ±16 kHz at −25 dB below subcarrier injection) maximum speed 19 Kbits/second are currently possible.[9]

Data FSK systems must use filtering methods to control occupied bandwidth, since the rapid frequency transitions generate high-order sidebands that could interfere with adjacent subchannels. Filtering is accomplished by either or both of the following ways, shown in Fig. 14:

1. Where a pair of oscillators are alternately toggled by the data states, filtering must be done to

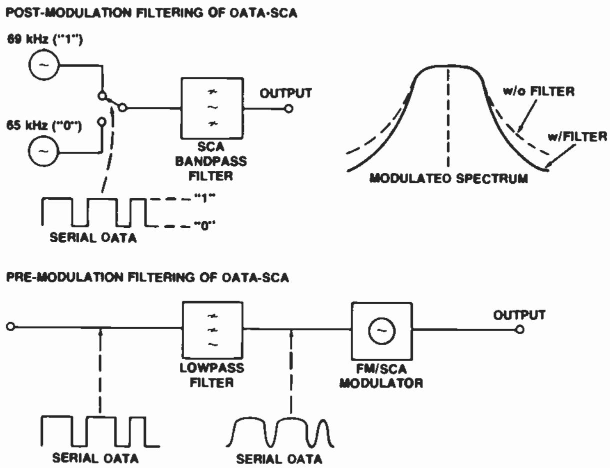

Figure 14. Two basic methods for generating and controlling the bandwidth of data subcarriers used for SCA.

the output spectrum to directly reduce occupied bandwidth.

2. Where analog FM modulators are used, filtering the slew rate of the switching signal tends to reduce high-order sidebands indirectly.

The spectrum of the composite baseband of a Washington, D.C. FM station is shown in Fig. 15, carrying a 4800 baud data signal. The spectrum was generated by a specially designed SCA generator employing both pre- and post-modulation filtering.

Phase-shift keying (PSK) is another technique for transmitting high-speed data. With PSK, one phase of the carrier represents one binary state and a second phase (usually 180° apart) is used for the second state. High speed data transmission is possible, up to 56,000 bits/second, although most of the 53 kHz to 99 kHz bandwidth might be required and receiver/decoders would be much more expensive than those for moderate speed FSK systems.

MONOPHONIC, STEREOPHONIC, AND SCA PERFORMANCE

While monophonic, stereophonic and various SCA services are conveyed by the same FM carrier, performance varies considerably due to the relative carrier deviation of each and the particular frequency span occupied within the composite baseband. The performance of a channel may be expressed in terms of demodulated signal to noise ratio for a given radio frequency carrier level, or, conversely, coverage range for a given signal-to-noise ratio. The purpose of this section is to summarize and illustrate these relations but not present the lengthy derivations for the equations.

The performance of a conventional FM receiver in the presence of random (thermal) noise is commonly judged on the basis of the variation of the output signal-to-noise power ratio as a function of the carrier-to-noise power ratio contained within the receiver bandwidth, usually determined by the IF bandwidth. An estimate of the IF bandwidth required for transmission of (monophonic) broadcast FM is given by[10]

$$\beta_{IF} = 2(F_{dev} + 2f_m) \tag{4}$$

where: F_{dev} = The peak frequency deviation (75 kHz)
f_m = The highest baseband modulating frequency (15 kHz)

This β_{IF} figure is rounded to 200 kHz for later use.

The equivalent input noise power in a bandwidth β launched into a noise-free (cool) receiver is

$$rB = 4 \times 10^{-21}\,\beta f_N \tag{5}$$
$$= 8 \times 10^{-16} f_N \quad \text{(Watt)}$$

where: f_N = The receiver noise figure
β = Nominal noise bandwidth in Hz

The carrier power is

$$C = (V_{\mu V^2}/R) \times 10^{-2} \quad \text{(Watt)} \tag{6}$$

where: $V_{\mu V^2}$ = the RMS input voltage in microvolts
R = the receiver r.f. input resistance

For R = 75 ohms the carrier to noise ratio in decibels is

$$CNR = 10\log_{10}(C/rB) \tag{7}$$
$$= 12.2 + 20\log_{10} V_{\mu V} - 10\log_{10} f_N$$

For example, for a 10 dB noise figure the carrier-to-noise ratio (CNR) is 0 dB for an input voltage of 0.77 μV over 75 ohms (1.55 μV over 300 ohms).

For a half-wave dipole antenna matched to a 75 ohm receiver, the input voltage is related to the field strength as

$$V_{\mu V} = 48.5\, E_{\mu V}/f_{MHz} \tag{8}$$

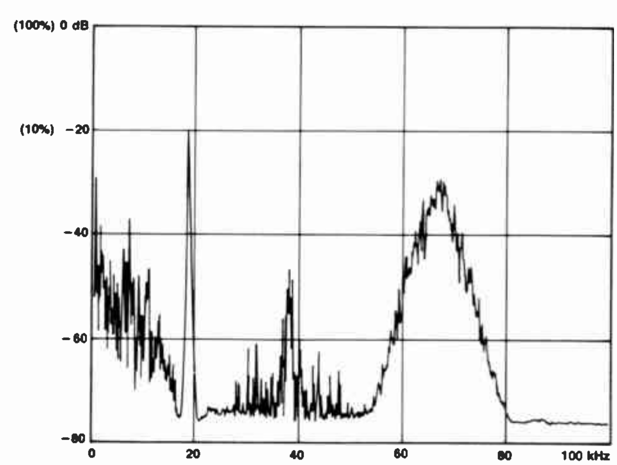

Figure 15. Composite baseband of an FM station carrying a 4800 baud frequency-shift-keyed data subcarrier. Center frequency of the subcarrier is 67 kHz, with an injection of 9%. Station is carrying stereo programming.

where: $E_{\mu V}$ = The field strength in microvolts
f_{MHz} = The carrier frequency in MHz[11]

Thus, for 98 MHz (middle of the FM band)

$$V_{\mu V} = \frac{E_{\mu V}}{2} \quad (9)$$

With the FCC F(50,50) field strength curves, it is possible to relate $E_{\mu VV}$ to the distance to the transmitter, effective radiated power, and antenna heights. Ultimately, it is possible to predict the carrier-to-noise ratio for a given broadcast system. For a 200 kHz nominal bandwidth, the CNR in dB can be shown to be

$$CNR = E_o + P + G - F + 20\log_{10}(h/30 \times 98/f) + 6 \quad (10)$$

where: E_o = Field strength for 1 kW ERP at 1000′ HAAT, in dBμ V/m
P = ERP in dBkW
G = Receiver antenna gain relative to dipole, in dB
h = Receiving antenna height above ground, in feet
F = Receiver noise figure in dB
f = Frequency in MHz

For example, if $F = 10$, $P = 10$, $G = 0$, $h = 30$, and $f = 98$, then $CNR = E_o + 6$.

Next, the signal-to-noise ratio is established by the carrier-to-noise ratio

$$SNR = 40 + 10\log_{10} CNR\ dB \quad (11)$$

This expression assumes a peak deviation of 75 kHz, a deemphasis corner frequency of 2.1 kHz (75 μS) and a nominal intermediate frequency noise bandwidth of 200 kHz.[12]

From the above, a carrier-to-noise ratio of 0 dB would result in a signal-to-noise ratio of 40 dB. However, standard FM demodulators typically exhibit a "threshold" at about 12 dB CNR, below which the noise floor changes from a "hiss" to a raspy kind of noise with noticeable "clicks" jutting above the noise. For this reason, the monophonic channel actually deteriorates below a signal-to-noise ratio of about 52 dB.

A well-known effect of FM demodulation is that the noise voltage in a narrow band (for example, 1 Hz) increases with frequency. This has important implications for systems which employ subchannels, since both the bandwidth and center frequency affect the signal-to-noise ratios. For example, the stereophonic $(L-R)$ subchannel shown in Fig. 2 extends nominally from 23 kHz to 53 kHz and occupies twice the bandwidth of the main $(L+R)$ channel. When the noise of the $L-R$ subchannel is combined during stereo decoding, the unweighted noise floor is 23.1 dB higher than the monophonic system under the same conditions.[13]

The signal-to-noise ratio of an SCA subcarrier, relative to the main channel, is a function of a number of variables and is

$$N_s/N_o = (2f_c^2/m^2D^2)\frac{f_1^3(b_1 - \arctan b_1)}{(f_o^3(b_o - \arctan b_o)} \quad (12)$$

where: f_c = Subcarrier frequency
m = Injection level as a percent of 75 kHz
D = Deviation of FM subcarrier
f_o = −3 dB frequency of deemphasis in main audio channel (2.12 kHz)
f_1 = −3 dB frequency of deemphasis in SCA audio channel (1.06 kHz)
b_o = Main channel audio output bandwidth (15 kHz)/f_o
b_1 = SCA channel audio output bandwidth (5 kHz)/f_1

An example of the excess noise in the 5 kHz SCA audio channel compared to the 15 kHz main channel is given below, if $m = 0.1$ (10%). Note that the noise level of a 67 kHz subcarrier with 5 kHz deviation and 92 kHz subcarrier with 7 kHz deviation are nearly equal. Comparative tests by the author have indicated that susceptibility to impulse noise, e.g., gasoline engine ignition radiation, is greater at the higher subcarrier frequency even though gaussian noise levels are approximately the same. This may be due to a higher noise threshold in the 92 kHz demodulator (due to a wider predetection bandwidth than the 67 kHz demodulator) or to differences in the spectral distribution of impulse noise compared to gaussian noise in the IF (composite) demodulator.[14]

f_c	(SCA freq., kHz)	67	92	92
D	(deviation, kHz)	5	5	7
N_s/N_o	(above main, dB)	36.4	39.2	36.2

Fig. 16 graphs the relative subcarrier noise level against increasing frequency of a subcarrier, compared

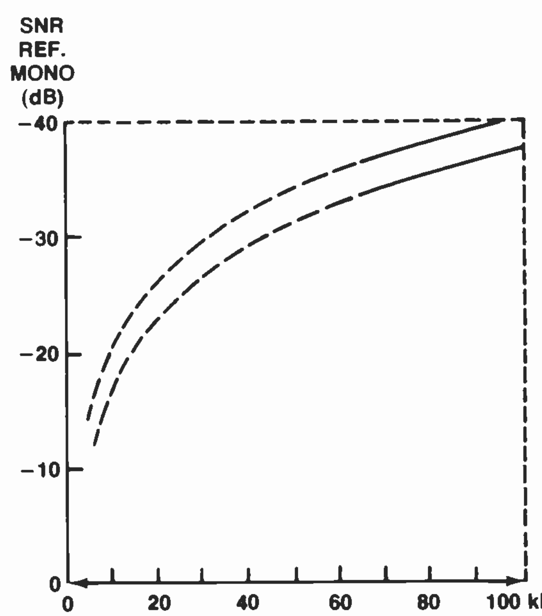

Figure 16. SNR of FM/SCA audio (5 kHz bandwidth) versus subcarrier frequency, compared to monophonic reception, referred to 5 kHz and 7 kHz deviation.

to the main (monophonic) channel for the same receive conditions. Shown are two peak deviations (5 kHz and 7 kHz) for FM SCA, and SSBSC AM SCA with 10% peak envelope injection. The graph segment representing 7 kHz deviation is dashed below 70 kHz since excessive interference to the $L-R$ subchannel is possible in this frequency range when stereo is transmitted.

Single Sideband AM Subcarriers

The conditions under which standard SCA subcarriers are operated are quite close to those existing with narrow band frequency modulation. For example, when a maximum audio bandwidth f_m of 5 kHz and peak deviation f_d of 5 kHz are used, the modulation index is 1.

$$i = f_d/f_m = 5/5 = 1 \qquad (13)$$

After frequency demodulation, the signal-to-noise power ratio (SNR) will be[15]

$$SNR = \frac{3 \cdot i^2}{CNR} = \frac{3 \cdot 1^2}{CNR} \qquad (14)$$

where CNR is the carrier-to-noise power ratio in the bandwidth occupied by the modulated signal. The noise power bandwidth B_n is difficult to predict for two reasons. First, the (usually) inexpensive SCA predetection filter has sloping skirt selectivity, thus departing from the ideal rectangular shape assumed in the calculation. Second, the actual bandwidth may vary, depending on the amount of audio distortion to be tolerated. The extremes of choice may be:

$$i \le 1, \quad B_n = 2f_m = 10\,\text{kHz} \qquad (15)$$

$$i > 1, \quad B_n = 2(f_d + f_m) = 20\,\text{kHz} \qquad (16)$$

A noise power bandwidth of 15 kHz is a compromise value that happens to represent the measured performance in some common FM SCA receivers.

In single sideband systems, one is simply frequency-shifting the modulation passband to a particular frequency in the composite baseband. There is no inherent noise reduction effect; the recovered audio signal-to-noise ratio is approximately equivalent to the noise contained within the subchannel bandwidth.

While the FM subcarrier system improves SNR, its greater bandwidth admits about three times the noise power. At a modulation index of one, FM improvement is approximately 10 log(1) or 0 dB for an ideal detector. The use of preemphasis and deemphasis improves the FM system SNR without significantly affecting the subcarrier's occupied bandwidth. The use of 150 µS deemphasis, common in FM subcarrier demodulators, reduces RMS noise in a 5 kHz channel by 8.8 dB. The practical improvement in signal-to-noise ratio measured by the author is more typically 4 dB. This is because the extreme high-frequency boost is not a good fit to the program material.[16]

Since single sideband modulation is spectrally efficient, even when compared to narrow band FM, it is practical to divide the 53–99 kHz range into a number of independent subchannels. In the one system, five subchannels each having a 5 kHz baseband are operated at 57 kHz, 66.5 kHz, 76 kHz, 85.5 kHz and 95 kHz. These are shown in Fig. 12.

20% peak injection is the maximum permitted by the FCC Rules when stereo is transmitted, therefore, each subchannel would receive 4% injection (20/5 = 4). It is reasonable to assume that slightly higher injection could be permitted for each subchannel due to the random interleaving of the total subchannel injection. If 5% were employed, then, the SNR would be lower than that for a channel using 10% peak injection.

$$\text{change in } SNR = 20\log(10/5) = -6\,\text{dB} \qquad (17)$$

Assuming an approximated improvement of 4 dB for a standard FM subchannel, and a reduction of 6 dB for one of five single sideband subchannels, there is an estimated difference in SNR, assuming the same center frequency of both subchannels and flat noise density over this spectrum.

$$SNR_{FM} - SNR_{SSB} = 4 - (-6) \approx 10\,\text{dB} \qquad (18)$$

The power density from an AM demodulator remains uniform across the baseband (unlike FM demodulators, in which noise density rises in proportion to frequency). Therefore, preemphasis/deemphasis is not as necessary to combat noise. The use of a complementary noise reduction system (compandor) can significantly improve the signal-to-noise ratio of either system.

Using the above estimates, the performance of the (uncompandored) single sideband and (deemphasized) FM subchannels is compared to main channel and stereo in Fig. 17. The coverage radii are based on the FCC F(50,50) field strength predictions for an FM station having 10 kW ERP, 1,000 feet height above average terrain, and a dipole receiving antenna at 30 feet above ground level into a receiver having a 10 dB noise figure.

SCA-To-Stereo Interference Considerations

Introduction of new signals into the modulating baseband of an FM station requires attention to their possible interactions with existing baseband signals, as well as its chosen performance characteristics. Several findings regarding the potential for perceptible interference (crosstalk) are summarized below.

FM stereo receivers having stereo decoders with diode switching bridges driven by a high-level 38 kHz sinusoid (usually identified by discrete component construction and tuned transformer stages) were responsible for the original "birdie" or beat-note interference in early SCA/Stereo broadcast systems. For historical perspective, the sources of this interference were:

- Nonlinearity in the diode bridge due to the conduction characteristics of the diodes and the sinusoidal drive signal
- Imbalance in the center-tapped transformer driving

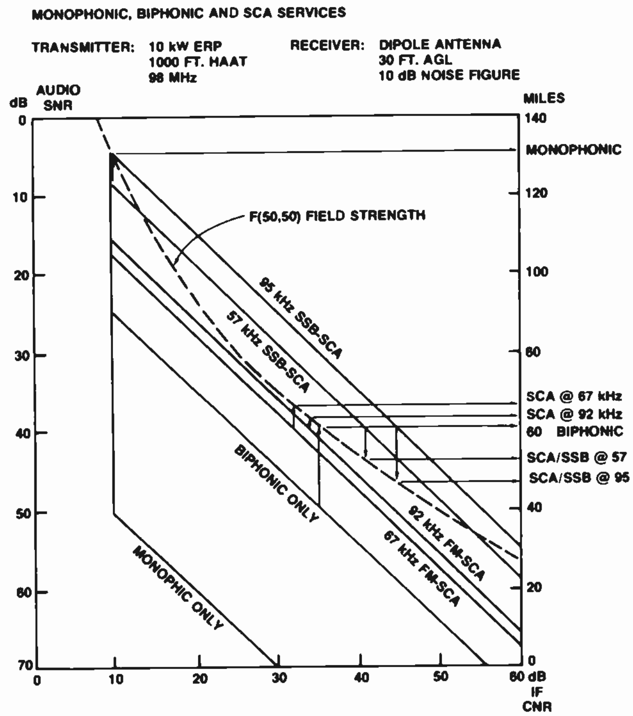

Figure 17. Predicted service distances for 50 dB monophonic and biphonic SNR, and 40 dB SCA SNR. To use, find intersection of desired SNR with service (diagonal) line; next move up (or down) to F(50,50) dashed line; then read across to mileage scale.

the diode bridge and second harmonics of the 38 kHz sinusoid at this point

The result caused a second-order intermodulation (mixing) of twice the 38 kHz switching frequency minus the instantaneous frequency of the SCA subcarrier as

$$9\,\text{kHz} = 76\,\text{kHz}\,[38\,\text{kHz} \times 2] - 67\,\text{kHz} \qquad (19)$$

The product is not 10 kHz as was often believed. Today, the small amount of beat-note interference that results from a 67 kHz subcarrier is 10 kHz, but due to an entirely different mechanism.

Over the past decade these receivers have been entirely replaced by sets with integrated circuit decoders, which have virtually no internally-generated beat-note problem. As a result, the interference to stereo service from SCA operation has dropped significantly.

Contemporary receivers create very little beat-note interference from SCA operation because of the type of stereo decoding done within the integrated circuit. The fact that the circuit contains a phase-locked loop (PLL) has little to do with this improvement. Modern decoders derive their 38 kHz signal by a digital technique, which is well-suited to circuit integration. This results in a 38 kHz square wave of fast rise time and balanced duty cycle (equal time in high and low states). The output circuit is usually a differential transistor pair configured as a balanced demodulator. When driven by the 38 kHz square wave (which has virtually no even-order harmonics), very little mixing is possible which can result in the product shown in Eq. 19.

If SCA beat-notes created within stereo receivers were the only source of interference, there would be virtually no problem with SCA operation. However, experience shows that a minor source of interference remains when certain SCA frequencies are used. The source of this interference is *external* to the receiver: multipath distortion of the radio frequency signal itself.

Large obstructions such as mountains, hills, and tall buildings can reflect VHF broadcast waves well enough to create the simultaneous reception of a direct and one or more reflected-path signals. Upon demodulation the baseband signals will include a combination of linear, second- and third-order distortion products, as shown in Fig. 17. Higher order distortions are negligible when the distortion is small.[17] Hence, these products take the form

$$2A,\ 2B,\ 2C,\ \text{etc.}$$
(where A, B, and C are the fundamentals)
$$A+B,\ A-B,\ A+C,\ A-C,\ B+C,\ B-C,\ \ldots\text{etc.}$$
$$2A+B,\ 2A-B,\ 2B+A,\ 2B-A,\ \ldots\text{etc.}$$

Second-order distortion (frequency sum and difference) is the most troublesome, because new product frequencies are created which may fall within the main and stereophonic channels where they can become audible. This is illustrated in Fig. 18, which shows the baseband of an actual FM station. The only modulation present in the transmitter is the stereo pilot and unmodulated SCA subcarriers at 67 kHz and 92 kHz, plus a small amount of noise from the audio chain which can be seen from zero to 15 kHz and centered around 38 kHz in the $L-R$ subchannel.

Several second-order products are visible in the spectrum graph. This distortion takes the form:

$$f_{SCA1} \pm f_{SCA2} = f_{IM}\ product \qquad (20)$$

OR

$$f_{SCA} \pm pilot = f_{IM}\ product$$

In the case of 67 kHz and 92 kHz subcarriers, significant products are

$$92 - 67 = 25\,\text{kHz}$$
$$67 - 19 = 48\,\text{kHz}$$
$$92 - 19 = 73\,\text{kHz}$$
$$67 + 19 = 86\,\text{kHz}$$
$$92 + 19 = 111\,\text{kHz}$$

While these IM products are not directly audible, some may be once they are demodulated by a stereo decoder:

$$38 - 25 = 13\,\text{kHz}$$
$$48 - 38 = 10\,\text{kHz}$$
$$114 - 111 = 3\,\text{kHz}$$

(The last product could be demodulated by IC stereo decoders using a 38 kHz square wave switching signal. However, sensitivity to a 111 kHz product is rare.)

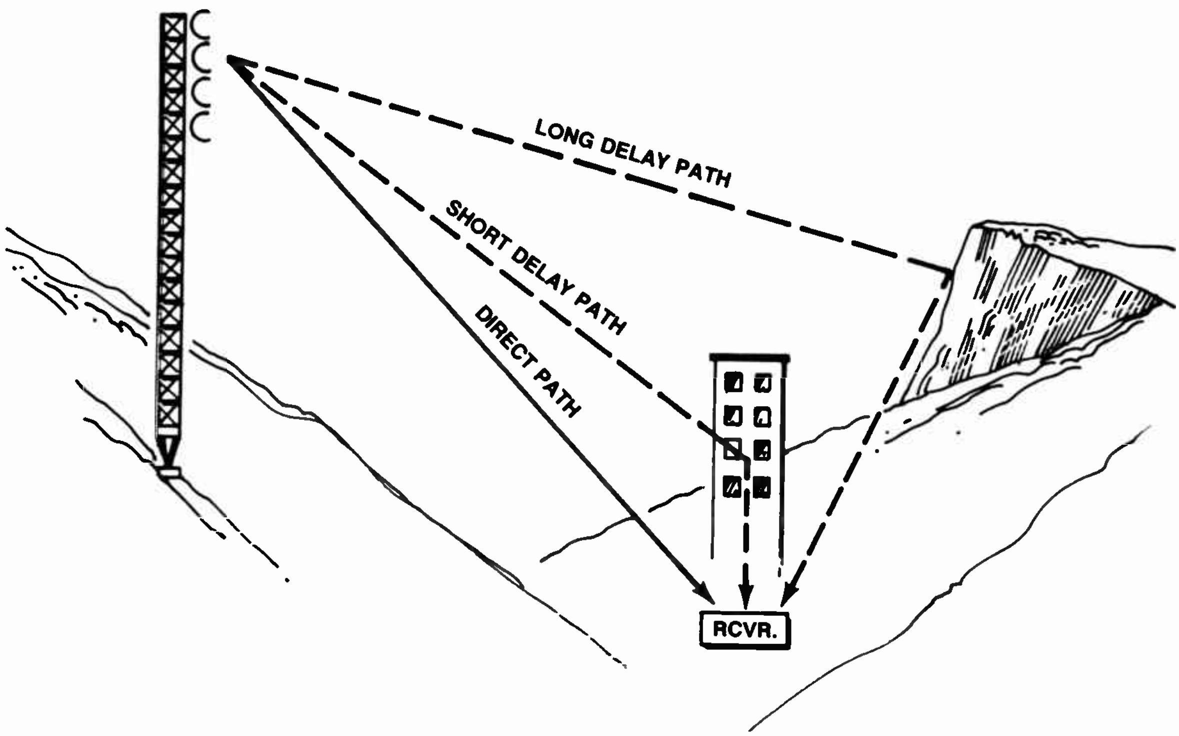

Figure 18. Examples of reflected signals arriving at an FM receiver, along with a direct path RF signal. Distortion of the demodulated FM signal is related to both the direct/reflected signal ratio and delay time of the reflected signal; distortion increases as the signal ratio approaches 1:1 and as the secondary path delay time rises.

Some other general findings about multipath effects are[18]

1. Multipath distortion is almost inversely proportional to the DU (desired-to-undesired path signal ratio) if the ratio is greater than about 10 dB.
2. Baseband signal distortion increases almost proportionally to the delay time up to about 10 μS, then increases with delay time at a slower rate.
3. A high DU ratio is required to suppress the beat-note interference to stereo program reception from an SCA subcarrier (about 20 dB at a delay time of around 5 μS and about 30 dB at around 20 μS).

It should be emphasized that the perceptibility of this form of beat-note interference depends on the loudness and consistency of main channel programming, (i.e., program audio in most broadcast FM stations is capable of masking the beat-note). Generally, only stations which do light amounts of audio processing and broadcast programming with wide dynamic range are even aware of an occasional case of interference.

The *type* of SCA modulation or the subcarrier frequency may significantly affect the perceptibility of any beat-note. For example, properly encoded high-speed data subcarriers using FSK or PSK spread the carrier energy in such a way that it sounds like faint, band-limited noise which is most easily masked. Furthermore, higher subcarrier frequencies will shift the beat-note image out of the audible range: experience has shown that 92 kHz to 95 kHz subcarriers have little problem in this regard.

Crosstalk From Main Channel Program Into SCA Subchannels

Crosstalk remains a problem for audio SCA services, despite the development of low-distortion receivers for

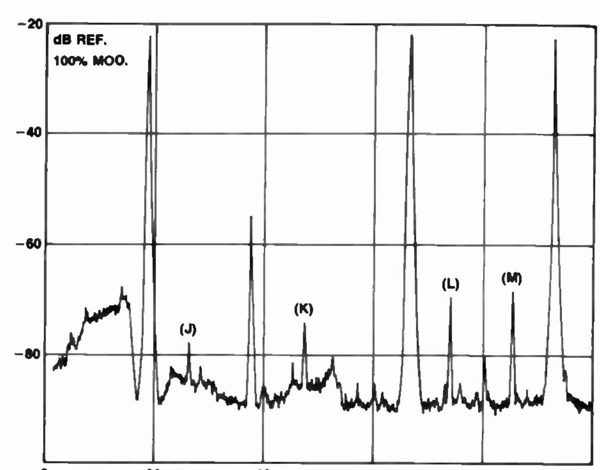

Figure 19. Composite baseband of an FM transmitter system with pilot, 67 kHz, and 92 kHz SCAs at 9 percent injection. IM products are identified by letters and are described in the text.

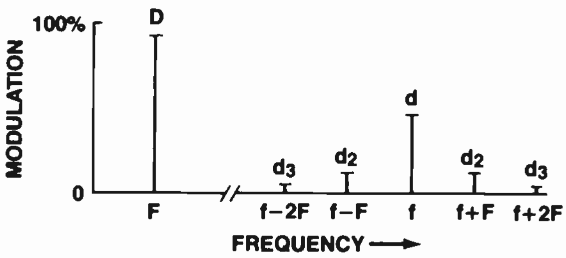

Figure 20. Spectrum of a subcarrier "f" shown with second and third order distortion products resulting from low frequency modulation "f".

SCA use. The cause is the same as SCA-to-stereo beat-notes: multipath distortion.

In the reference case illustrated in Fig. 20, the baseband signal consists of one low-frequency sine wave of frequency F, i.e., 1 kHz, which modulates the main carrier by a deviation D (95% or 71.25 kHz for broadcast FM), and a sine wave subcarrier at a variable frequency f Hz which modulates the main carrier with a very small deviation d, having a modulation index less than 0.3.

Second-order distortion will cause sidebands at frequencies of $f-F$ and $f+F$ with an output injection $d_2(f-F)$ and $d_2(f+F)$. The sum of the sideband amplitudes is

$$d_2(f) = d_2(f-F) + d_2(f+F) \tag{21}$$

The distortion is defined as the ratio of the sum of the sidebands to the amplitude of the subcarrier d_1 is

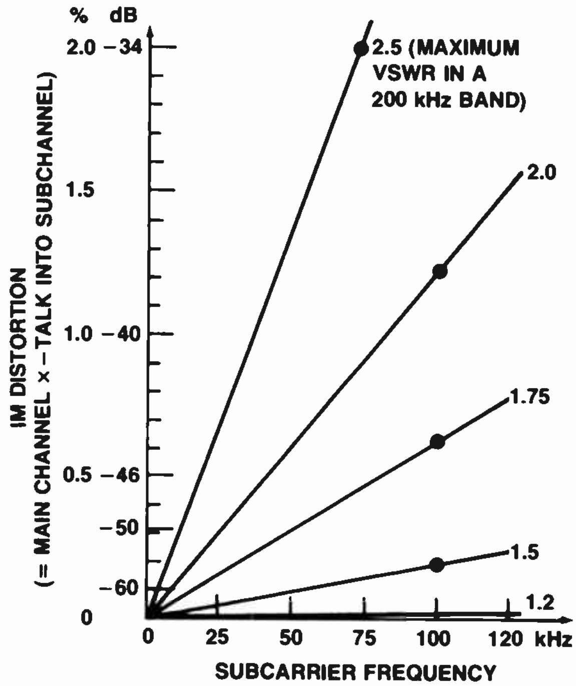
$$\delta = \frac{d_2(f)}{d_1(f)} \tag{22}$$

This distortion is easily measured as a function of the subcarrier frequency f with a spectrum analyzer. If the sidebands are equal, they may, in the extreme, either amplitude-modulate or phase-modulate the subcarrier. In general there is a combination of amplitude- and phase-modulation.

Third-order distortion is similarly defined by the sidebands created at frequencies $f-2F$ and $f+2F$.

While FM SCA detectors usually include amplitude limiting, they are intended to convert any angular modulation, whether program audio or not, into an output signal. Thus any phase nonlinearity in the RF system or multipath will generate second-and higher-order sidebands around the subcarrier, causing main-to-SCA crosstalk at audio modulating frequencies.

Fig. 21 shows the relationship between main-to-SCA crosstalk, subcarrier frequency, and maximum antenna VSWR in a 200 kHz band. It is evident that higher frequency subcarriers require somewhat larger, but not very much larger bandwidth. It has also been determined that antenna matching must be improved as the transmission line becomes longer. This is especially important for higher frequency subcarriers since the phase error is compounded rapidly with an increase in



NOTE: ANTENNA IS MATCHED TO TRANSMISSION LINE AT THE CENTER FREQUENCY.

Figure 21. Distortion due to limited antenna bandwidth vs frequency of subcarrier with max VSWR in 200 kHz band as parameter.

subcarrier frequency. Distortion is proportional to the subcarrier frequency. Thus, for equal distortion, doubling the subcarrier frequency requires halving the reflection coefficient.[19]

3.5 TV Transmitters

Robert R. Weirather, Gregory L. Best, Robert Plonka
Harris Corporation, Quincy, Illinois

INTRODUCTION

Significant advances have been made in TV transmitter technology in recent years. New technology and ideas have been introduced in order to continue to provide high quality TV signal transmission while improving reliability, reducing maintenance, and lowering overall cost of ownership. These new technologies fall primarily into the following areas: solid-state high-power amplifiers, efficiency improvements for UHF transmitters, and transmitter combiners which eliminate off-air switching. Each will be covered in this chapter.

Further, the FCC continued its policy of technical deregulation which has served to allow more flexibility in transmitter design and system operation.

VISUAL EXCITER

The visual exciter has the purpose of receiving a video baseband signal, processing it, and converting it to a fully modulated vestigial sideband on-channel signal. Since intermediate frequency (IF) modulation has become a standard within the industry, most of the signal processing occurs either in the video stages or in the IF stages. The basic block diagram of an IF modulated transmitter is shown in Fig. 1. We will discuss each basic block diagram in greater detail.

Video Processing

For the TV transmitter's goal of becoming transparent to the incoming signal, it is of utmost importance to make sure that the incoming signal is optimized. It is often difficult to define exactly where the station video processing of a signal ends and the transmitter video processing begins. Typically some video processing is done external to the transmitter at the station plant by a *proc amp*. Different manufacturers of transmitters employ various means of accomplishing the same purpose and therefore, may use different approaches to solve the same problem. The main functions of the exciter video processing circuitry are:

- Obtain proper sync to video ratio
- Remove any common mode signal
- Provide overall video level control
- DC restoration
- Overmodulation prevention
- Frequency response correction for the signal applied to the transmitter

Quite often precorrection, used to compensate for some transmitter distortions, is included in the video processing section. Types of transmitter precorrection which are sometimes included are differential gain,

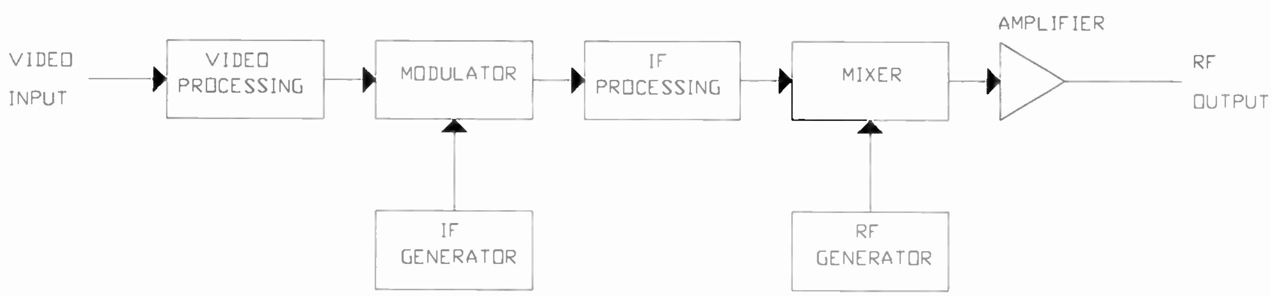

Figure 1. IF modulated transmitter.

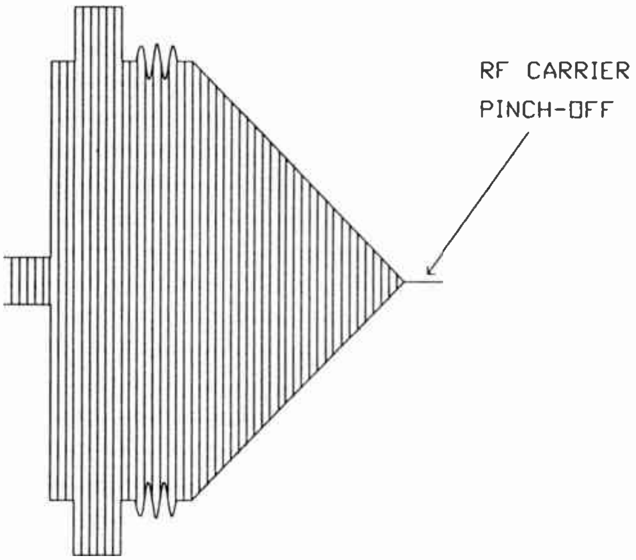

Figure 2. RF carrier pinch-off.

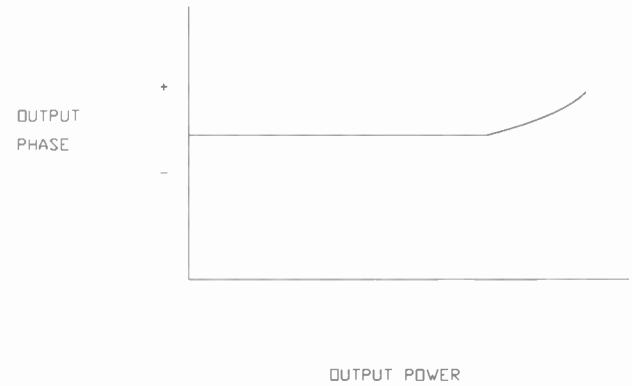

Figure 4. Phase transfer curve.

differential phase, and group delay compensation (for transmitter and/or for the notch diplexer, if used).

DC restoration, (clamping) is important because picture brightness information is contained in the DC component of the video signal. If AC coupling is used anywhere in the video circuitry, the DC level will tend to vary as the capacitors in the coupling circuits charge and discharge. AC coupling is convenient since differences in AC and DC grounds can be allowed without introducing waveform distortion. By clamping a consistent part (such as sync tip or "back porch") of a TV waveform during each TV line to a fixed voltage which does not vary, the correct DC level is applied to the modulator.

Common mode signals such as noise or AC hum can be removed by using a differential input mode for the video signal input stage. It is desireable to use an RF choke at the video input stages also to prevent rectification of ambient RF and remodulation of the main signal from that rectified RF.

White peak limiting is used to prevent modulation from reaching 0% or in other words, to keep the carrier from being "pinched off" as shown in Fig. 2. When an intercarrier TV receiver encounters a carrier that has been pinched off, it temporarily has no signal to receive, its automatic gain control circuits increase to maximum gain, and since there is nothing but noise available when the carrier is pinched off, that noise is greatly amplified, transferred to the aural intercarrier and becomes audible as a buzz in the receiver.

High frequency peaking circuits in a transmitter's video processing circuitry are often used to compensate for long video signal runs in a transmitter plant.

In UHF exciters, often the horizontal and vertical sync portions of the TV signal are detected and sent to klystron pulsers.

When a transmitter is adjusted for maximum efficiency, its transfer characteristic is not ideal. Typical transmitter amplitude and phase transfer curves are shown in Figs. 3 and 4. Often the video signal is predistorted in the opposite direction of the errors in amplitude and phase produced by the nonlinear transfer curve of the transmitter. An example of this predistortion is given by Fig. 5.

Nonlinear chroma gain at different luminance levels that exhibits a change in the saturation of the colors, is termed *differential gain*. Nonlinear chroma phase at

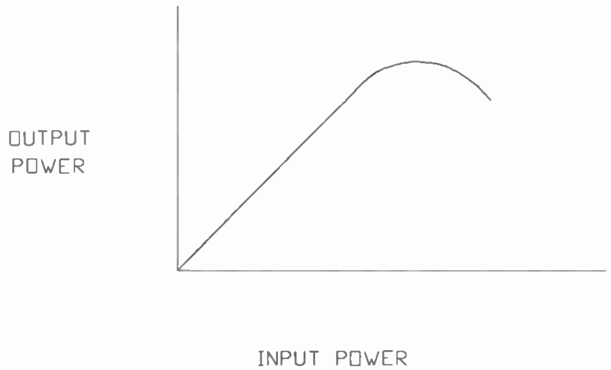

Figure 3. Amplitude transfer curve.

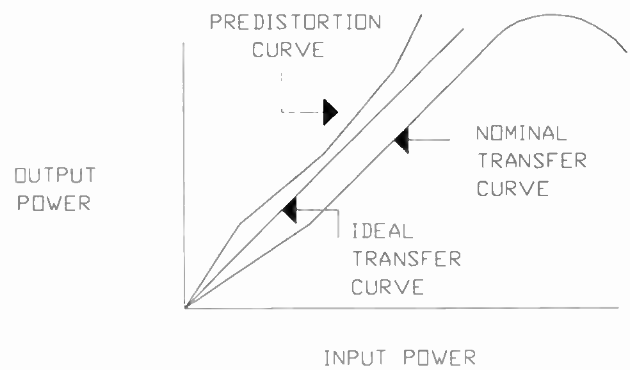

Figure 5. Sample predistortion curve.

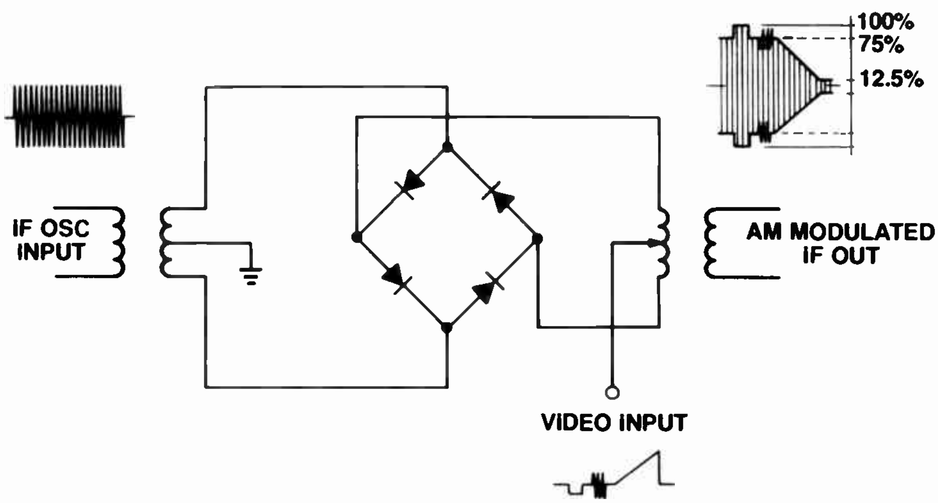

Figure 6. Balanced mixer.

different levels of luminance that exhibits a change in hue of the colors is termed *differential phase*. Differential gain and phase predistortion is often done in the exciter to compensate for nonlinearities in the transmitter.

Luminance nonlinearity is present when there is a change in luminance gain with different brightness levels.

Both luminance nonlinearity and differential gain are amplitude distortions. Precorrection can be accomplished by changing the gain of a video amplifier over a portion of the total video signal. The gain change is usually keyed by the video signal reaching a certain level. Differential phase can be corrected by splitting the video signal into two paths which are 90° different at the color subcarrier. By changing the gain of one path over a portion of the video waveform while not changing the other path phase changes can be obtained. Other methods can also produce the same result.

Modulator

With nearly all IF modulated transmitters, the modulator is a broadband, balanced, diode mixer. It is configured for maximum rejection of the local oscillator signal and biased so as to provide excellent linearity, low noise, and capability to achieve carrier cutoff. A schematic of a typical balanced mixer is shown in Fig. 6. The video signal is DC offset to provide the proper modulation level. The video signal is used to control the attenuation of the diodes. Peak of sync corresponds to maximum IF envelope output and white corresponds to minimum IF output. The output signal of the modulator is a double sideband AM signal having the proper depth of modulation (12.5%).

Group Delay Compensation

Waveform distortion can be caused by group delay inherent in RF amplifiers and tuned RF filters, combiners, and other output systems. Group delay distortion is the nonuniform delay of different frequencies over the bandwidth of the TV signal. Group delay distortion occurs in tube cavity amplifiers and notch diplexer combiners. In general, the closer the amplitude roll-off frequency is to the visual passband, the higher the group delay distortion.

IF and Video Delay Compensators

Group delay impairments show up in a picture as color smear and halo effects on edges. On a waveform monitor the effects may be seen using the 2T and modulated 12.5T contained in the composite test signal shown in Fig. 7. Pulse responses with unacceptable group delay may include exaggerated pre- or post-ringing on 2T and modulated 12.5T base line disturbance.

The multipulse signal shown in Fig. 8 may also be used to analyze group delay. The multipulse signal consists of a gray flag (80 IRE), 2T pulse, and five sine-squared pulses modulated with five discrete frequencies (consisting of one 25T pulse and four 12.5T

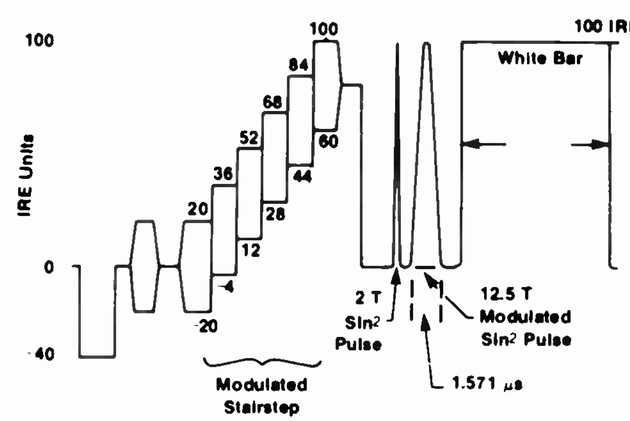

Figure 7. Composite test signal.

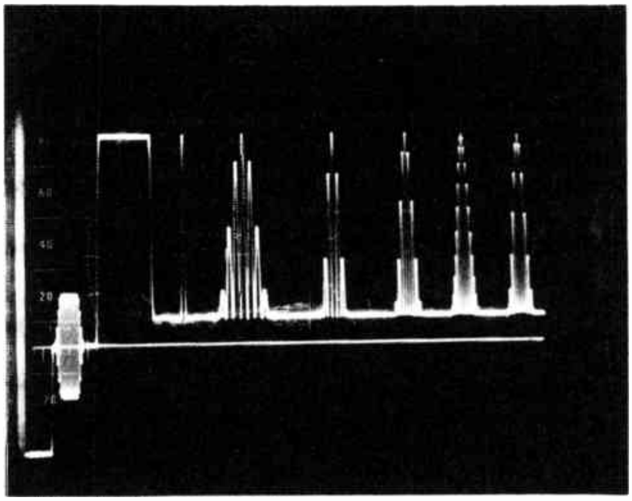

Figure 8. Multipulse.

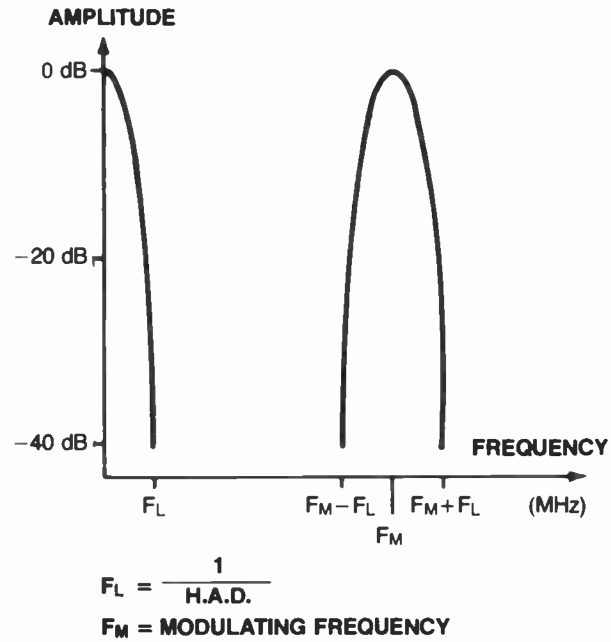

Figure 9. Energy spectrum for modulated pulses.

pulses). This signal may be used to measure linear distortion in TV systems such as amplitude versus frequency response and group delay distortion.

The modulated pulses contain two spectra of information, low frequency and high frequency, as illustrated in Fig. 9. These modulated pulses are useful for measuring group delay errors. If the low-frequency spectra and the high-frequency spectra are delayed equally, the results will be a symmetrical modulated pulse with the same shape as the input. The gain versus frequency distortion will alter the base line flatness but will not change pulse symmetry. Delay errors will result in an asymmetrical pulse baseline. Combinations of group delay and gain errors are shown in Fig. 10.

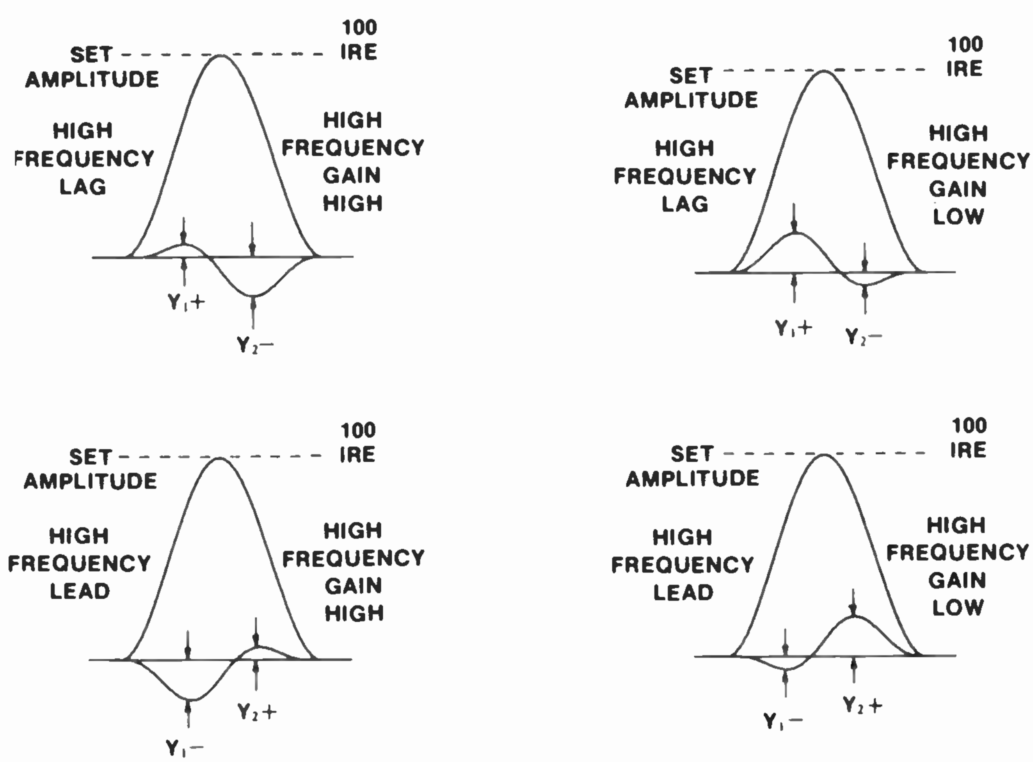

Figure 10. Modulated sine-squared pulses with gain and phase errors.

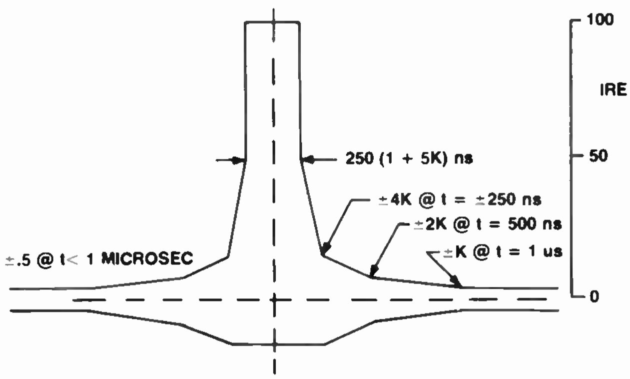

Figure 11. 2T sine-squared pulse graticule.

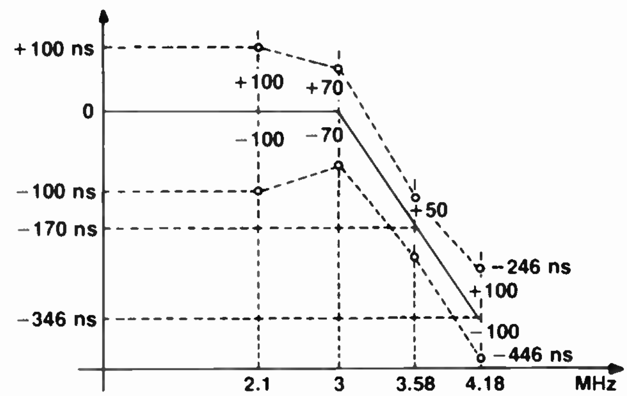

Figure 13. Predistorted group delay curve.

A method of quantifying these distortions uses the waveform graticule shown in Fig. 11. This graticule was arrived at empirically and represents constant perceptible distortion levels. This shows that overshoots closer to the desired pulse are not as perceptible as ringing further away.

The desired K factor graticule, i.e., 2%, is overlapped on a waveform monitor and the group delay corrector is adjusted until the 2T waveform lies entirely within the graticule. This technique is often preferred to swept group delay measurements because the results are in terms of perceptibility.

Low-frequency group delay and amplitude errors are referred to as short time waveform distortions. Fig. 12 shows typical distortions of a 2T pulse.

If the group delay error affects only the high frequency side of the passband, precorrection can be accomplished at video. This is the case for most visual-aural RF notch type diplexers and the FCC receiver equalizer curve. In the case of the notch diplexer, a pair of cavities resonant at the aural frequency are inserted between two 90° hybrid couplers. (Refer to Fig. 87.) The presence of the tuned circuits near the upper edge of the visual passband can cause a significant group delay error.

Another source of group delay is the tuned circuits of the high power tetrode or klystron amplifiers.

Finally the FCC requires the TV transmitter to predistort group delay according to the curve shown in Fig. 13.

The delay shown in Fig. 13 is a characteristic delay curve the FCC requires all visual transmitters to have. The purpose of it is to compensate for the delay error caused by discrete LC aural notch filters in early TV receivers. The reason this was done was that it would be far cheaper to group delay compensate one transmitter than every TV set. The notch filter in TV receivers is necessary to prevent the aural carrier from mixing with the detected video and chroma subcarrier signals and producing visible spurious beats.

Group delay predistortion may be accomplished at video baseband or IF. The techniques used are similar in concept. Both active and passive equalizers may be employed. IF group delay correction is necessary to correct group delay errors below visual carrier while not affecting the signal above visual carrier. Above visual carrier both IF and video correction is effective.

Passive Group Delay Equalizer

A common form of a passive group delay equalizer is shown in Fig. 14. It provides a flat frequency response and a nonlinear group delay which peaks at the resonant frequency of the circuit. This type of circuit is referred to as a passive all-pass network.

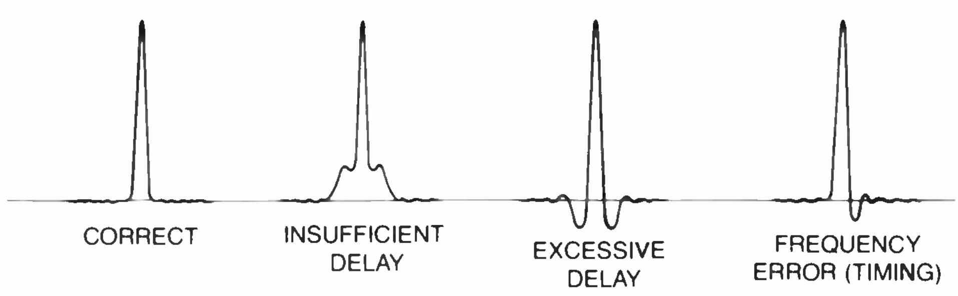

Figure 12. Typical distortion of a 2T pulse.

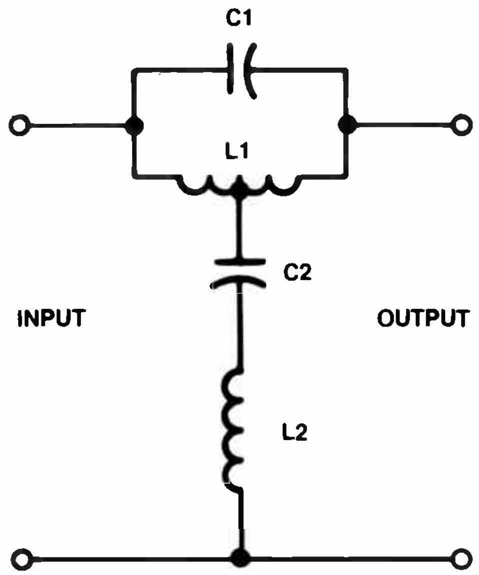

Figure 14. All-pass network.

Without going through a detailed analysis of the circuit, much can be understood by examining the circuit at frequencies well below and above resonance. At low frequency the network can be approximated by a low series inductive reactance due to L1. Here the output voltage leads in phase. At high frequency well above resonance the circuit can be approximated by a series capacitive reactance due to C1. At high frequencies the output voltage lags in phase. The output amplitude, however, is constant across the band. The phase of the network is plotted in Fig. 15. The slope of the phase is defined as group delay and is expressed as

$$\tau = (d\phi/d\omega)$$

where: ϕ = phase angle
ω = angular frequency

The steeper the phase slope the higher the maximum group delay. A plot of the group delay is shown in Fig. 16.

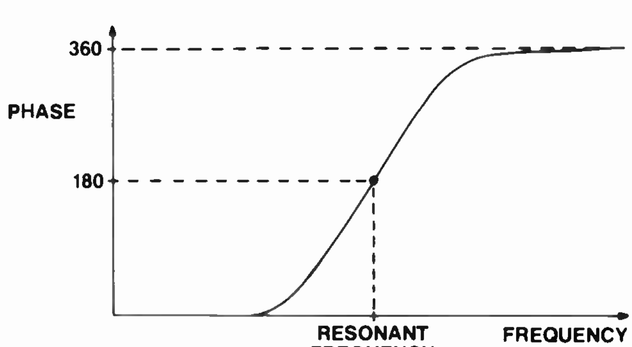

Figure 15. All-pass phase.

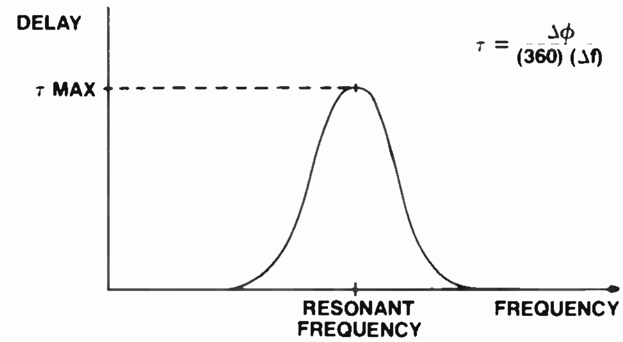

Figure 16. All-pass group delay.

Active Group Delay Equalizer

As in the passive type the network has a constant amplitude frequency response and a nonlinear phase response. The action of an active all-pass network can be best explained using the simplified schematic of Fig. 17. If the phase of voltage e_1 were plotted as a function of frequency, it would trace out a circle with maximum amplitude and zero phase at resonance. Voltage e_2 on the other hand has a constant amplitude and phase.

For the case when e_1 voltage is equal to twice e_2, the output voltage of the summing amplifier, e_3, has the characteristics of an ideal all-pass network. The output amplitude is constant and the resonator tuning determines the frequency of maximum group delay and the resonator Q determines the magnitude of delay.

For the case where voltage e_1 is larger than twice e_2, the output will have an amplitude peak at resonance and conversely if e1 is smaller, the output will have a dip at resonance.

Vestigial Sideband Filter

The FCC requires that the radiated TV signal have a major portion of the lower sideband (vestigial sideband) suppressed. In addition, the upper sideband signal must be contained within 4.75 MHz of the visual carrier. With the advent of IF modulation the filtering is at low-power stages and transmitter manufacturers have selected solid state filters using Surface Acoustic Wave technology to accomplish the stringent filtering requirements.

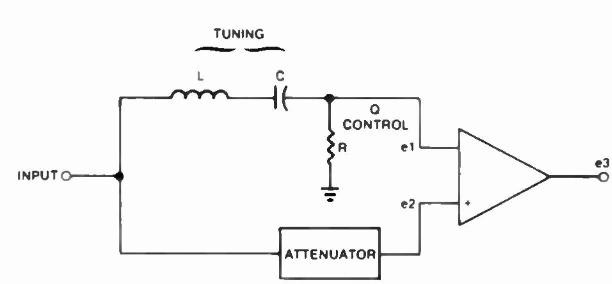

Figure 17. Active all-pass network.

The term *surface acoustic wave* (SAW) refers to the propagation of elastic waves on the surface of a piezoelectric crystal. The wave propagation is roughly the speed of sound, and therefore called acoustic. A time varying voltage on a metalized transducer is used to induce a deformation on the surface and produces a electromechanical wave. The deformations produce local electric fields which travel along with the mechanical wave, and interact with metal electrodes, which convert the mechanical wave back to a time varying voltage. The length, spacing, and the number of the electrodes determine the wave shaping properties of the filter.

The electrodes act like tapped delay lines, as illustrated in Fig. 18. The electrodes are designed to amplitude scale and delay the signal. The output is selectively attenuated depending on the time delay and signal frequency relationship. This type of filter is called transversal because the attenuation is controlled by delay lines rather than resonators. The transversal filter was invented in the early 1940s and used coax cables as delay lines. Today, surface acoustic wave transducers provide the same function. The wavelength of an IF acoustic signal is approximately 0.003".

This small wavelength allows the filter to be very small and compact. Because the transducers are only on the surface, photographic masks can be used to accurately control the physical dimensions of the transducers. The photographic mask lends itself to modern manufacturing techniques and insures a reproducible filter with a permanent amplitude versus frequency response and group delay.

A characteristic of a transversal filter is that group delay can be set independently of the amplitude characteristic. This is not true of discrete LC filters where basic physical laws couple group delay and amplitude.

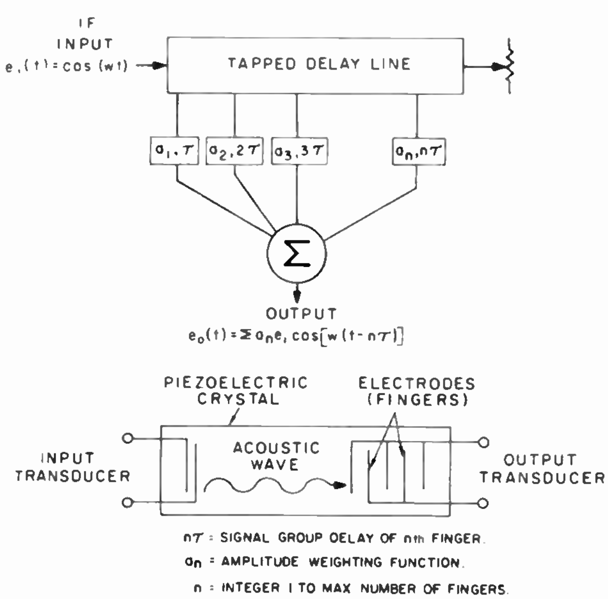

Figure 18. Saw filter.

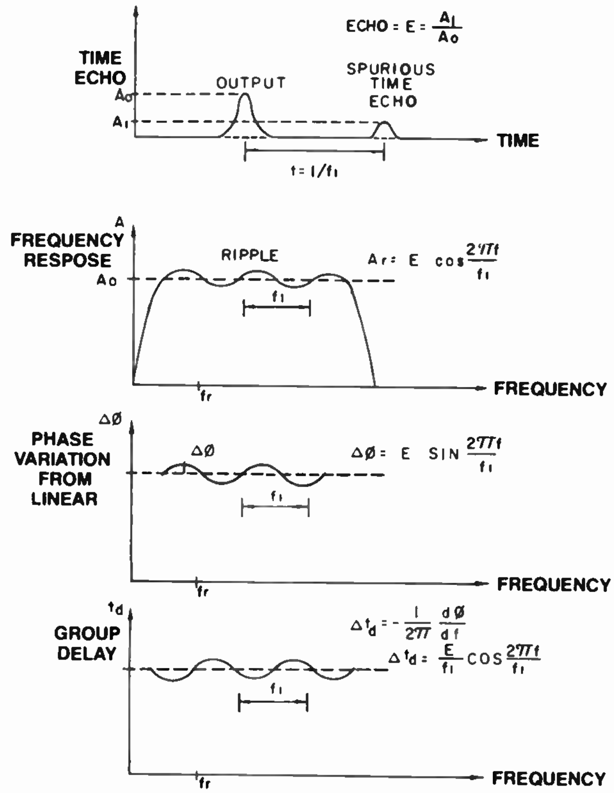

Figure 19. Response, phase, and delay ripples caused by time echoes.

The independent nature of group delay and amplitude allows a manufacturer to provide almost any type of group delay curve (such as a constant delay or the TV receiver group delay precorrection curve) across the passband.

Although the FCC does not require attenuation of visual signals in the aural passband, video signal components can cause interference called visual-to-aural crosstalk. Reduction of visual-to-aural crosstalk is essential to the proper transmission of stereo sound and other subcarrier broadcast services. High resolution cameras and character generators can produce spectral components at 4.5 MHz and beyond. Without sufficient attenuation these signals can cause distortion, especially in aural subcarriers which are more sensitive to visual crosstalk than the main aural signal. SAW filters thus are able to perform many functions simultaneously, i.e., bandwidth shaping, group delay equalization, and video to aural crosstalk reduction.

Distortion products that can be created by SAW filters are due to signal reflections (triple travel) and direct feedthrough. These distortions cause time echoes displaced either before or after the desired responses. In the frequency domain these echoes show up as ripples in the passband. (Fig. 19) A given time echo will contribute uniquely to the amplitude, phase and group delay characteristics by the addition of a ripple component of the waveform in the passband.

The amplitude of the ripple is proportional to the echo level, and its period is proportional to the reciprocal of the SAW time delay.

The SAW group delay characteristic will vary sinusoidally with the same period as the passband ripple. Its magnitude, however, is a function of both echo level and inversely proportional to time delay, and therefore not a sure test of signal distortion. The group delay ripple for long delayed echoes will give peak-to-peak values which have no correlation with conventional signal distortion estimates. For that reason, fast peak-to-peak group delay errors that occur closer than the reciprocal of the filter time delay can usually be ignored.

When pulse waveforms in Figs. 7 and 8 are used to measure group delay distortion, the 2T preshoot, overshoot, and asymmetry can be used to gauge low-frequency group delay error. Modulated pulse baseline "S" curve is a result of group delay and the peak excursions of the "S" curve can be used to quantify the amount of group delay distortion.

IF Linearity Precorrection

Amplitude and phase nonlinearities are sometimes corrected at video baseband. The alternative is to provide the correction at IF frequencies. There are advantages to correcting at IF in that, since most distortions are caused in the high power RF amplifiers after vestigial sideband filtering, a corrector placed after the vestigial sideband filter can more accurately predistort the modulated signal. Any precorrection spectra generated at IF after the VSB filter will produce energy components which can cancel intermodulation products generated in the final amplifier stage. This is particularly important in the case of a pulsed klystron transmitter.

Correction of distortion at IF is particularly helpful for chroma distortions. Chroma spectra at 3.58 MHz has only a single sideband information and thus has less energy than equivalent luminance signals. An ideal diode detector frequency response of the NTSC modulation signal is plotted in Fig. 20. Here it is seen

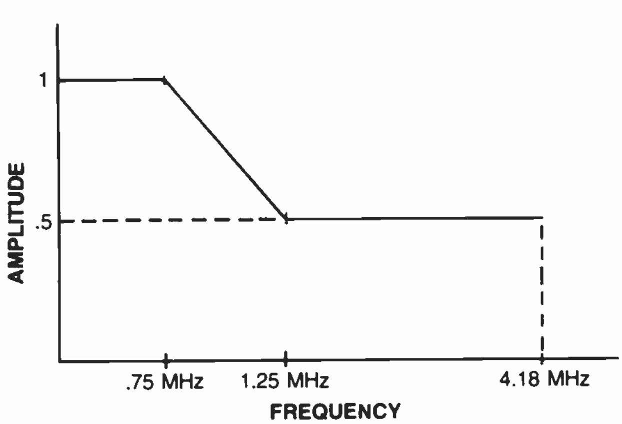

Figure 20. Frequency response using ideal diode detector.

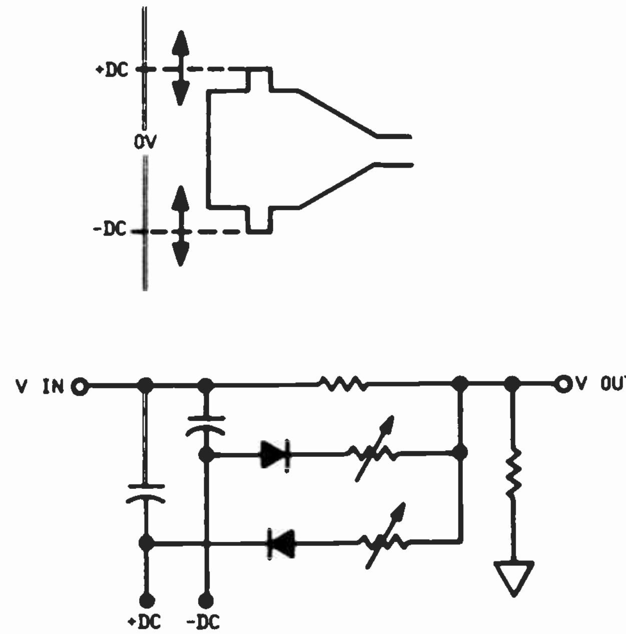

Figure 21. Basic gain expansion circuit.

that beginning at 0.75 MHz the video begins to fall to −6 dB. For video signals lower than 0.75 MHz, the RF spectrum is double sideband and has twice the peak RF voltage.

Intermodulation products are caused in high power amplifiers by nonlinear amplitude transfer characteristics. As the power output increases towards saturation, amplitude compression begins and in general the phase begins to lag as well. The nonlinear transfer characteristics give rise to mixing products which occur at sum and difference frequencies around the visual carrier. This process also creates the frequency spectra of what is called the lower sideband.

Correctors for amplitude distortion are usually similar in concept to video differential gain correctors. Linearity correctors generally use diodes which are keyed by the IF modulated signal. When the diodes conduct, the gain or attenuation is reduced as needed.

An example of a basic gain expansion circuit is shown in Fig. 21. The signal is normally attenuated a fixed amount by using a resistive L-pad. The diodes are normally reverse biased by equal, but opposite polarity, DC voltages. Reducing the DC voltage amplitude permits the diodes to conduct on the signal peaks. This inserts additional resistance in parallel with the series arm of the L-pad attenuator thereby decreasing the attenuation. Varying the resistance in series with the diodes provides for a variable gain expansion.

ICPM

Phase distortions in high power amplifiers produce incidental carrier phase modulation (ICPM), which are spectral components in quadrature with the modulation signal. Fast video amplitude changes such as a step or pulse will cause larger incidental phase spectral components than slow changes. Receivers make this condition worse by attenuating the lower sidebands below 0.75 MHz. The receiver then responds to the extra sidebands created by the phase modulation as if they were amplitude modulated single sidebands and produce spikes. The faster the rise time on the signal the more high frequency energy is present resulting in edge distortions in the displayed picture.

The picture impairment is similar to simultaneous group delay and differential phase errors in that edges are less sharp and color hue changes with brightness. On a waveform monitor, overshoots are visible as trailing edges and as rounding on leading edges. These overshoots vary in severity depending on how close the power amplifier is driven towards saturation.

Audio impairment is produced by ICPM in receivers employing intercarrier conversion. Intercarrier receivers use an AM or synchronous detector to produce a 4.5 MHz aural IF signal from the composite video IF. Any phase modulation present on the visual carrier is then transferred to the aural intercarrier. In the monaural baseband audio the increasing amplitude frequency effect of ICPM is nullified by de-emphasis to some degree. With multichannel sound, however, there is no de-emphasis applied to the baseband stereo signal, and thus the distortion is more pronounced at the stereo subchannel and pilot frequencies. To counteract the effects of ICPM and other noise sources on the stereo subchannel, an audio companding is employed that greatly reduces the potential interference. Although the audio companding process can reduce some of the effects of ICPM, ICPM correction is essential in delivering clear, low-noise audio to intercarrier receivers.

There is no defined level of ICPM for a given stereo performance level since the signal to buzz ratio is highly dependent on the picture spectral components.

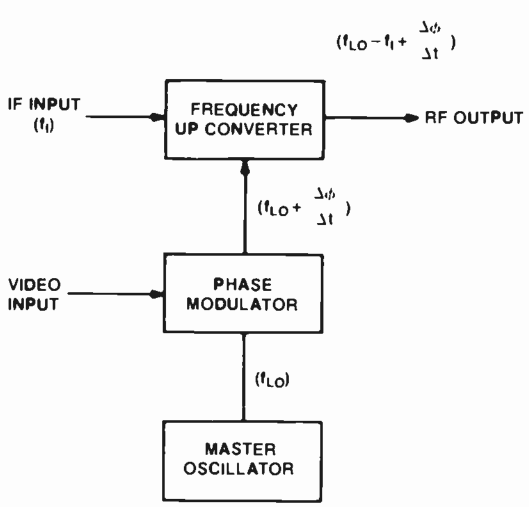

Figure 22. Master oscillator phase modulator block diagram.

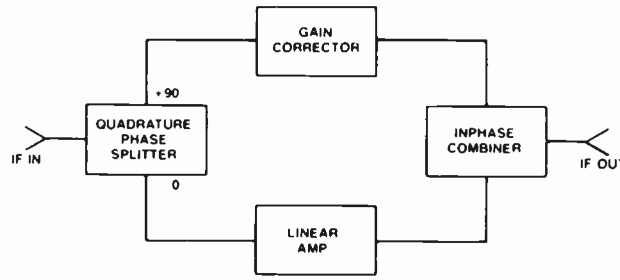

Figure 23. Direct IF ICPM corrector.

Refer to the EIA Recommended Practices for the current recommendations on ICPM limits.

ICPM precorrectors can be grouped into two types: ones using a phase modulator and the other operating on the signal directly. The phase modulator type uses video to vary the IF or master oscillator phase with the opposite phase characteristics of the nonlinear amplifiers. A phase modulator can also operate on the IF signal directly using a video signal to set the amount of modulation. A block diagram of a master oscillator phase modulator is shown in Fig. 22.

ICPM precorrectors operating directly on the IF signal can be implemented several ways. Direct precorrection at IF is similar in concept to baseband differential phase precorrection. See Fig. 23. In both cases, the visual signal is split into two paths which are in phase quadrature. In the IF corrector, the entire channel of frequencies is in quadrature, whereas in the video precorrector only the chroma band is in quadrature. One method of implementation is to modify the quadrature signal gain function with level dependent diode expansion or compression circuits. This can be done using the same techniques as in the linearity corrector.

RF Generator

Transmitters employing IF modulation generate the following frequencies; visual IF, modulated aural IF, and master oscillator signal(s) for translating visual and aural IF to the final carrier frequencies. These oscillators have been implemented with either digital synthesizer techniques or crystal oscillators. An advantage of the synthesizer is that only one crystal is needed and it operates at a single standard frequency for all TV channels. The crystal oscillator approach, however, may involve simpler circuitry.

The two commonly used IF frequencies are 37 MHz and 45.75 MHz. There are many reasons for selecting one IF frequency or the other. One advantage of 37 MHz is that the temperature drift sensitivity of most IF components such as the SAW filter is related directly to carrier frequency. Thus the lower IF has a 12% less drift sensitivity than components at 45.75 MHz. The second harmonic of 37 MHz falls in between channels 4 and 5 so as not to cause interference. On the other hand, 45.75 MHz is a common demodulator IF which can be useful for IF troubleshooting. Temperature drift may be minimized at either IF by maintaining the SAW filter at a stable temperature.

The important performance characteristics of an oscillator are: its phase noise, sensitivity to frequency drift with time and temperature, and susceptibility to mechanically induced phase and frequency shifts called microphonics.

In replacing a crystal, it is important to follow the recommendations of the oscillator manufacturer to insure proper operation. Synthesizer performance should be properly maintained to prevent inadvertent phase noise and spurious frequency generation.

OFFSET FREQUENCY CONTROL

The limited number of available channels for TV Broadcasting makes it necessary to assign the same carrier frequencies to many stations. To avoid interference between stations operating on the same frequency (co-channel interference) geographical separation and radiated powers are carefully selected.

Nevertheless, considerable co-channel interference was encountered in many locations. Investigation has shown that additional means were able to reduce co-channel interference by reducing optical or perceptive interference elements in the system. In other words, steps were taken not to alter the strength of the interfering carrier but to choose operating parameters to reduce the visibility of the interference.

Considerable investigative work was done to lay the scientific and physiological basis and to define the parameters which need to be controlled to reduce the visibility.

It turned out, with horizontal and vertical sweep ratios fixed, the visual carrier frequencies of the interfering stations was the parameter which needed to be controlled.

Co-channel interference between television stations appears to viewers as a horizontal pattern of alternating light and dark bars on the viewing screen—very much like the shadows cast by venetian blinds. It has been demonstrated for many years that the visibility of these bars varies cyclically as a function of the difference in frequency of the interfering carriers (Fig. 24). The interference is most visible when the carriers were offset by multiples of the line frequency (15734 kHz) and least visible when the carriers are offset by odd multiples of one-half the line frequency. In addition to the gross maxima and minima, fine grain maxima and minima occur when the frequency offset is a multiple of the frame frequency (29.97 Hz).

Ideally, stations would be offset by odd multiples of one-half the line frequency to provide minimum interference visibility. However, a third station in the same area would be offset from one of the other stations by an even multiple of the line frequency. Hence, maximum visibility of the interference would occur. Therefore, 10 kHz offsets currently used in the United States were chosen to provide approximately equal reduction of the interference patterns for any number of stations in geographical proximity. (See Fig. 25.)

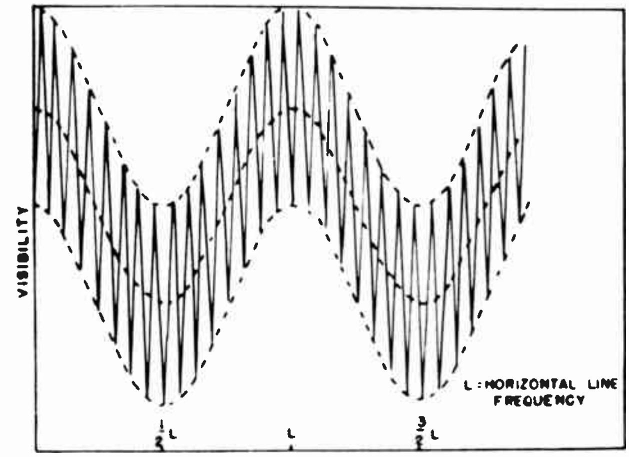

Figure 24. Co-channel interference.

Precise Frequency Offset

Although it is not practical to utilize the gross minima occurring at odd multiples of one-half the line frequency, it was determined experimentally that utilizing the fine grain minima, occurring at even multiples of the frame frequency, would be very advantageous in reducing the visibility of co-channel interference.

The nearest even multiple (334th) of the frame frequency to the 10 kHz offset is 10010 Hz. In a three station arrangement, one station will have zero offset, and the other two stations will be offset by ±10010 Hz. Experiments indicated that changes in the frequency differences of 5 Hz had a negligible effect on the reduction of the interference visibility.

To maintain the precision offset within 5 Hz requires maintaining each visual carrier frequency within 2 Hz or 3 Hz. Maintaining a television transmitter to such tight frequency tolerances requires some type of control system using an extremely stable frequency source.

In exciters using two independent oscillators (one for IF and one for the local oscillator), the visual carrier signal may be derived from mixing the oscillators together and comparing that signal to the reference signal in the comparator. That resultant error signal can be used to adjust one of the oscillators, preferably the local oscillator. For exciters using synthesizers, the sythesizer reference oscillator is compared to the precise frequency standard in the phase detector and the resultant error voltage is used to adjust the synthesizer oscillator.

By phase-locking the visual carrier to a stable reference oscillator, the master oscillator acquires the stability of the reference source. Sources which use an internal WWV Receiver/Comparator to self-correct or an Atomic Frequency Standard can easily provide the stable reference source required. These reference sources allow a transmitter to be maintained within a few hertz of a desired frequency indefinitely. Experimental results have indicated that frequency differences between transmitters can vary as much as 5 Hz

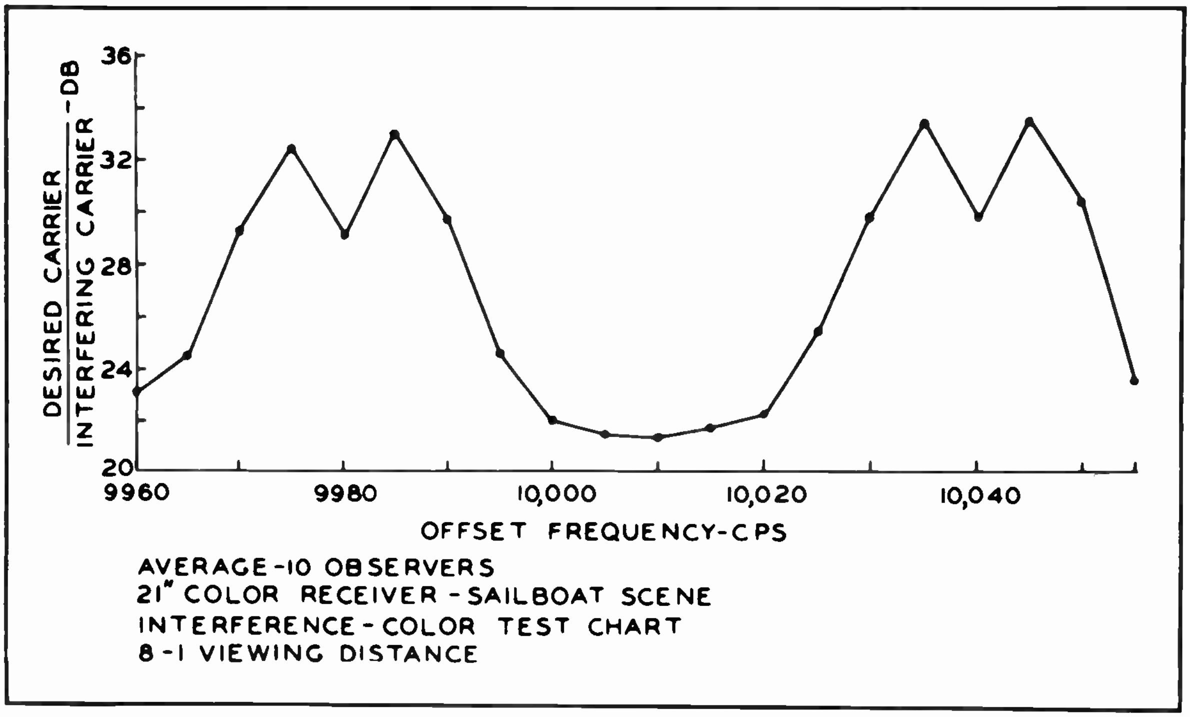

Figure 25. 10 kHz offset pattern.

from the precision offset before co-channel interference becomes noticeably worse. This means that two television stations can minimize their co-channel interference without the requirement to continuously adjust the transmitter frequency.

One word of caution when working with any frequency standard. If power is removed from the standard and no backup power supply is incorporated either internally or externally, ensure that the standard has stabilized before making any adjustments. Also ensure that after any adjustment has been made, a suitable time period has elapsed to allow the standard to settle before making any reading.

To ascertain the carrier frequency of a station operating under precision frequency control, assuming a measuring accuracy ten times better than the quantity to be measured, means measurement equipment must have the following accuracy requirements:

VHF Low Band	$+2.5 \times 10^{-9}$
VHF High Band	$+1 \times 10^{-9}$
UHF	$+3 \times 10^{-10}$

Frequency counters with the above accuracy and with National Institute for Standards and Technology (NIST) broadcasts, traceable calibration may be used for making measurements.

AURAL EXCITER

In its most basic form, the aural exciter consists of some audio processing, an FM modulated IF oscillator, and an up-converter to obtain the desired carrier signal as shown in Fig. 26.

Audio Processing Circuits

To ensure that the transmitter is not the limiting factor in audio (monaural and stereo reproduction), it is desired that the transmitter add as little distortion to the incoming signal as possible.

Baseband audio of the BTSC[1] MTS (Multi-channel Television Sound) system (including the mono, stereo, SAP, and profession channels) include frequency components to 105 kHz. Emphasis must be placed on phase linearity, low distortion, reduction of any amplitude ripples, or roll-off over the stereo (BTSC) passband to achieve good stereo separation and minimum crosstalk between the main stereo and the SAP channels.

While unbalanced coaxial inputs are used for the MTS input to the aural exciter, it is still necessary to use some form of common mode rejection to reduce the possibility of hum and noise from getting directly into the audio stages.

All errors in phase linearity and amplitude response within the audio circuitry contribute to stereo separation degradation. *As a general rule, amplitude roll-off*

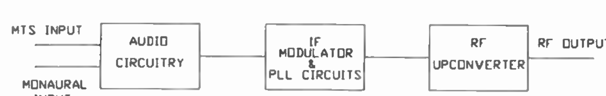

Figure 26. Aural exciter.

should be less than 0.1 dB and departure from phase linearity should be less than 1 degree for good quality stereo.

IF Modulation

All modern transmitters are IF modulated. To ensure low power stages do not contribute any group delay or amplitude roll-off, wideband amplifiers should be used. Modulated oscillator linearity requirements include flat modulation sensitivity versus frequency characteristics up to 47 kHz minimum, and typically out to 120 kHz.

With the advent of the MTS stereo system, intermodulation (IMD) and harmonic distortion (THD) products which, in monaural operation lie above 15 kHz (which would therefore be reduced by deemphasis in the receiver), now lie in the stereo channel or the SAP channel and will degrade stereo separation or will cause crosstalk into the SAP channel. In addition, IMD products generated in the stereo channel may now lie in the mono or SAP channel.

As the MTS signal is up-converted to the aural RF carrier frequency, the residual FM of the local oscillator signal becomes a determining factor. The level of FM produced by the local oscillator should be 10 dB lower than the modulated oscillator. Synthesized sources should be inspected for spurious frequencies which may show up as FM noise.

RF Amplifiers and Diplexers

All RF amplifiers are optimized (for stereo performance) when a flat, symmetric frequency response and a minimized variation in group delay across the modulation passband is achieved. Since FM modulation and demodulation is a nonlinear process there is not a one-to-one correspondence between RF amplitude/phase response and baseband stereo separation and crosstalk. Measurements indicate that a 1.5 MHz, 3 dB bandwidth will provide excellent stereo and SAP performance. RF amplifiers must be swept-frequency analyzed to insure the passband is sufficiently wide to pass the stereo signal and that its passband amplitude and group delay characteristics are symmetrical about the carrier frequency.

The diplexer is the last and possibly the most critical element in the aural chain with regard to stereo separation and crosstalk between stereo channel and SAP. However, hybrid diplexers, since they are broader bandwidth than notch diplexers, normally do not present any degradations to multichannel sound. If correct tuning of the notch diplexer itself and of any associated group delay compensation or amplitude correction is not properly maintained, stereo separation and crosstalk will be degraded. Low insertion loss at 4.18 MHz and proper aural bandwidth are both required for optimum visual and sound performance. Refer to the EIA Recommended Practices (Systems Bulletin #5) for other current recommendations.

Minimizing antenna reflections (VSWR) helps to keep the pilot signal from becoming distorted and the audio channel from losing separation or becoming noisy.

In summary, these characteristics have been incorporated into transmitters designed for MTS:

1. Wideband low distortion audio stages with excellent signal-to-noise ratio (SNR) are employed to insure negligible distortion in the baseband signal.
2. Low distortion wideband modulated oscillators with improved noise performance and phase locked loop (PLL) techniques are used so that the quality of TV multichannel sound will approach that of the FM broadcast service.
3. The bandwidth of IF and RF stages is wide. Power bandwidth tradeoffs may need to be made to achieve optimum stereo performance.

COMPENSATION OF AURAL PASSBAND FOR OPTIMUM STEREO PERFORMANCE

This section describes circuits that offer group delay equalization for a TV aural transmitter when operating through a notch diplexer. These circuits introduce group delay correction in the IF section of the aural exciter and after up-converting to the operating channel, the group delay precorrection effectively corrects the adverse group delay existing in the output diplexer circuit. The end result is improved TV stereo separation. In addition, precorrection of the FM bandpass can allow the use of lower cost, single-cavity notch diplexers. Stagger-tuned dual-cavity notch diplexers also have been utilized to provide a broad bandwidth desired for good stereo separation and negligible crosstalk between the different MTS components. However, dual-cavity notch diplexers introduce more group delay in the visual path, are more expensive, and should be tuned differently than single-cavity diplexers.

Many TV engineers have noticed a significant difference in the level of distortion when making performance measurements on an aural TV transmitter at points before the notch diplexer and after the notch diplexer. With the introduction of TV BTSC stereo broadcasting, the increase in THD distortion and stereo separation errors caused by the diplexer became a major problem which had to be solved.

The notch diplexer is a passive device and under first consideration it may seem strange that it can introduce nonlinear distortion and stereo separation errors. The basic problem is that the FM stereo signal is sensitive to the notch diplexer group delay and amplitude response over the occupied bandwidth of the FM signal.

The group delay and amplitude response of a single-cavity diplexer is shown in Fig. 27. The phrase, "single-cavity diplexer", means a single aural notch cavity is used in each branch of the diplexer. Dual-cavity notch diplexers use two aural notch cavities in each branch of the diplexer. The response curves shown in Fig. 27 are typical of a notch diplexer optimized for minimum aural reject power. The bandpass is somewhat narrow and the group delay is steep. Fortunately, the response

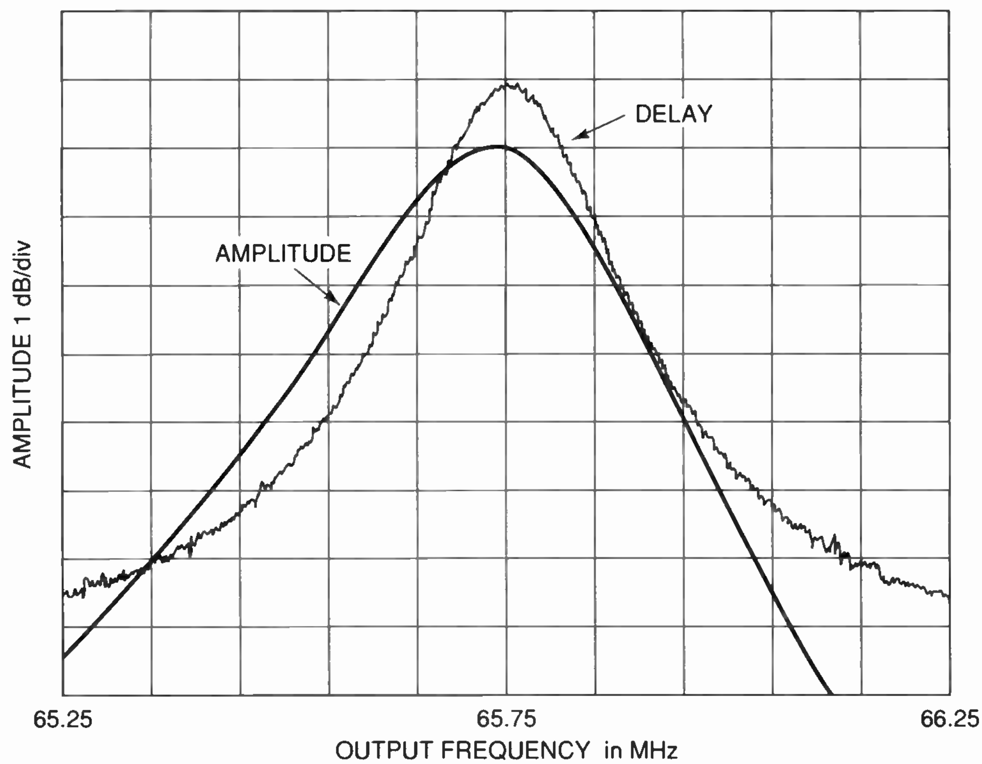

Figure 27. Typical single cavity diplexer amplitude and group delay.

curves in Fig. 27 show a high degree of symmetry which makes precorrection possible.

The group delay equalization concept as applied here to the FM modulated signal is essentially a feed-forward correction scheme. The phrase "feed-forward" is used here to describe the technique of generating correction signals early in the RF line up of a transmitter for the purpose of correcting distortions occurring downstream in the system.

Feed-forward correction signals are operated open loop (without feedback) and are manually adjusted for optimum operation and, once adjusted, left to operate in this manner.

IF Group Delay Correction

The equalization technique of adjusting the circuit to produce an inverse curve of that of the diplexer for correction is the same as that used on the visual transmitter.

There is however, a significant difference between group delay correction on a FM system versus an AM system. The aural transmitter must incorporate group delay correction at RF or IF to compensate for group delay distortions occurring in the output diplexer system. *Group delay correction before the FM modulation process is not effective for equalizing group delay occurring at RF.* The reason for this is that the occupied bandwidth of an FM signal increases or decreases as a function of baseband signal level. Fig. 28 shows the occupied bandwidth when the carrier is deviated 25 kHz and how it compares to a typical notch diplexer group delay curve. (Also note the precorrected group delay curve shown as an additional overlay.) When the baseband signal level is increased, the FM deviation will increase and a number of additional significant sidebands will be generated which will begin to extend beyond the acceptable group delay curvature region. The result is that distortion is observed in the demodulated FM signal.

In addition, as the baseband high frequency content increases, i.e., when switching from a mono to a stereo signal, significant sidebands extend even further outward increasing the demodulated distortion. Fig. 29 shows the spectral content of a TV stereo signal (with notch diplexer group delay curves, standard and precorrected, overlayed).

Simply put, there is not a direct relationship between the amount of group delay correction injected at baseband versus the amount of group delay correction achieved at the output of the RF system for a FM modulated signal.

To avoid the additional cost of extra cavities in the diplexer to achieve better stereo performance, an adjustable group delay circuit designed for the low power IF section of the aural exciter can provide the inverse group delay curve necessary to equalize the output. The corrector location in the aural transmitter system is shown in Fig. 30.

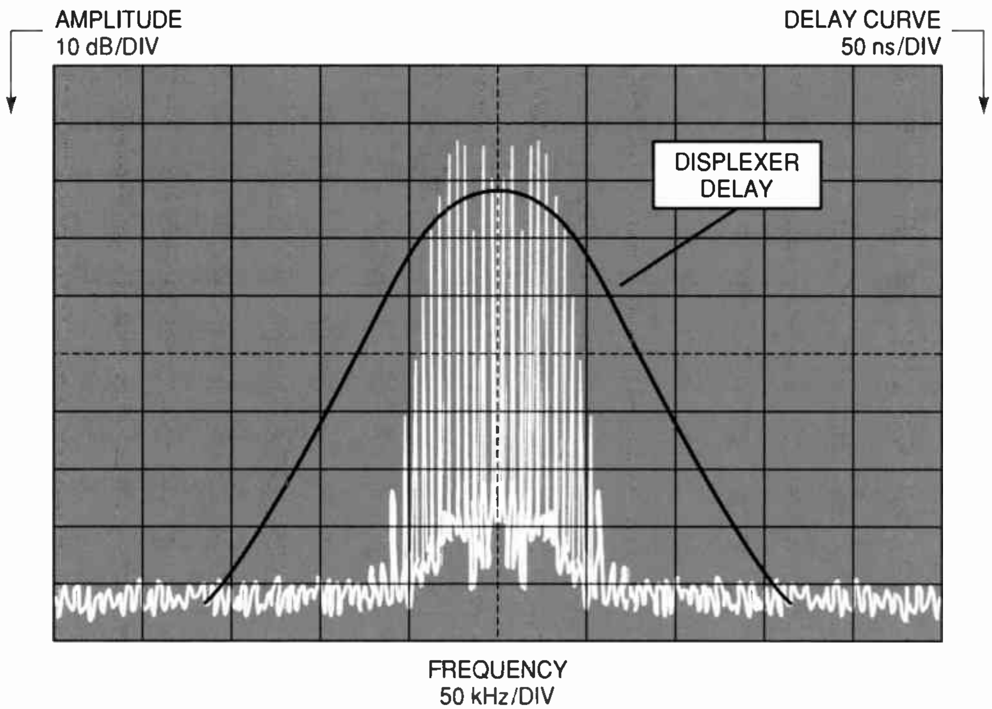

Figure 28. Occupied bandwidth with 25 kHz deviation with overlayed notch diplexer bandwidth.

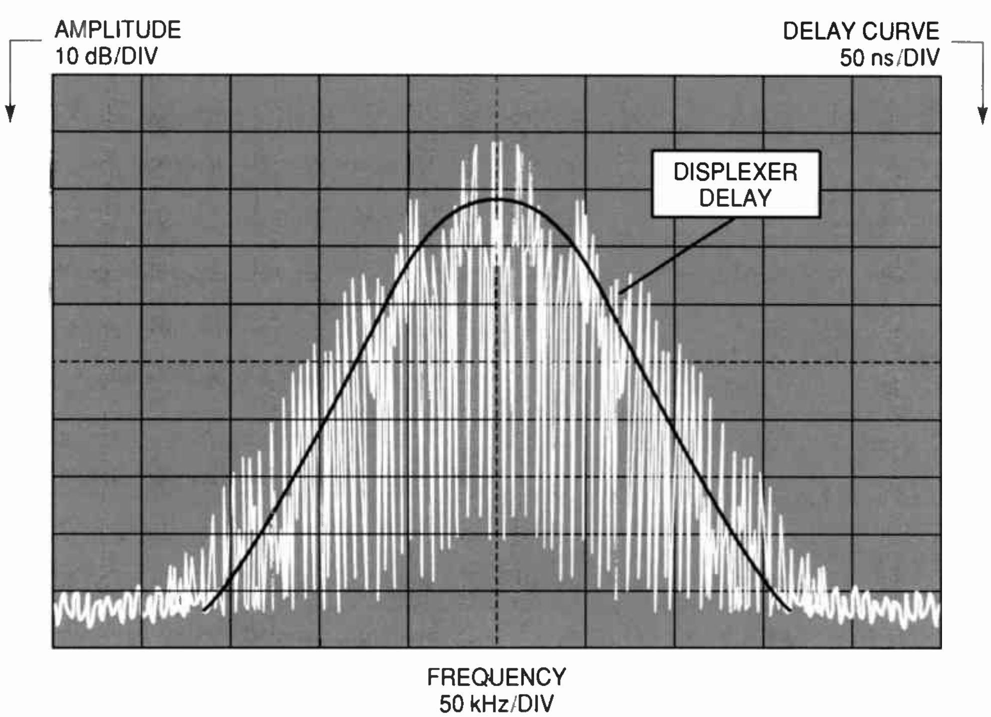

Figure 29. Occupied bandwidth of TV stereo signal with 55 kHz deviation and overlayed notch diplexer bandwidth.

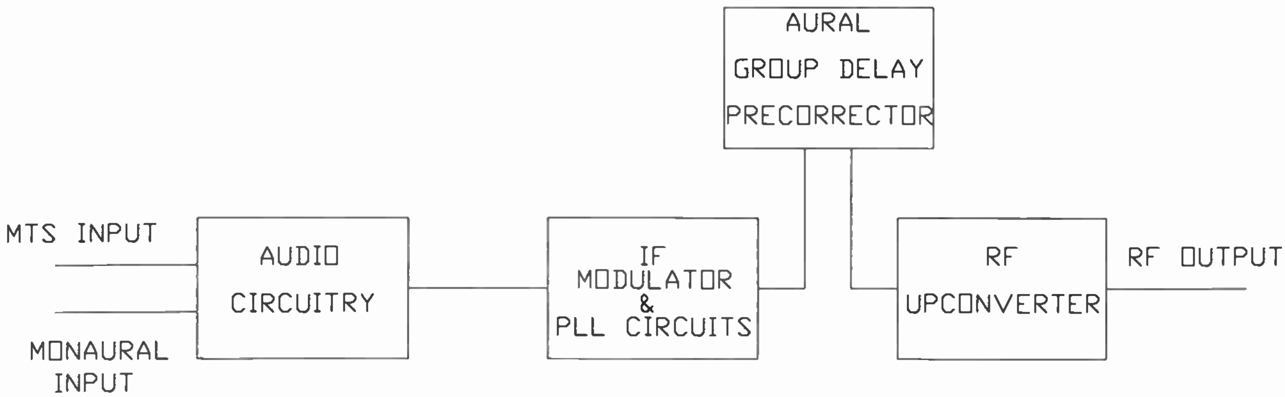

Figure 30. Aural exciter with group delay precorrector.

Equalization at IF frequency is effective because the up-conversion circuit uses a signal mixing process rather than a frequency multiplying process. In this manner, the precorrected sidebands are passed directly to the output for compensation.

Circuit Design

The circuit configuration is shown functionally in Fig. 31.

Results

The measured amplitude and group delay response of the group delay corrector is shown in Fig. 31. An ideal precorrection circuit without any circuit losses would have a flat response without a dip. The response dip shown in Fig. 32, however, is very useful because it also provides a first order correction to the notch diplexer amplitude response.

Fig. 33 shows the overall system equalization when the delay corrector is switched in and out of the circuit. The diplexer delay response contributes nearly all of the delay errors. The lower curve shows that a significant amount of equalization has been achieved over the occupied bandwidth of a stereo signal.

The effect on stereo separation is shown in Fig. 34 with the corrector switched in and out of the circuit. The curves generated in Fig. 34 are from measured data through the system with the response characteristics

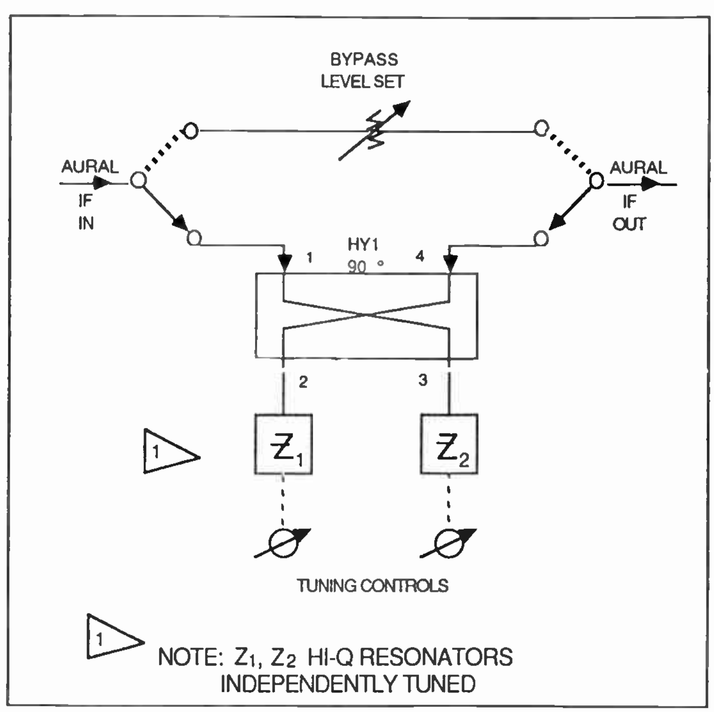

Figure 31. Aural group delay corrector functional block diagram.

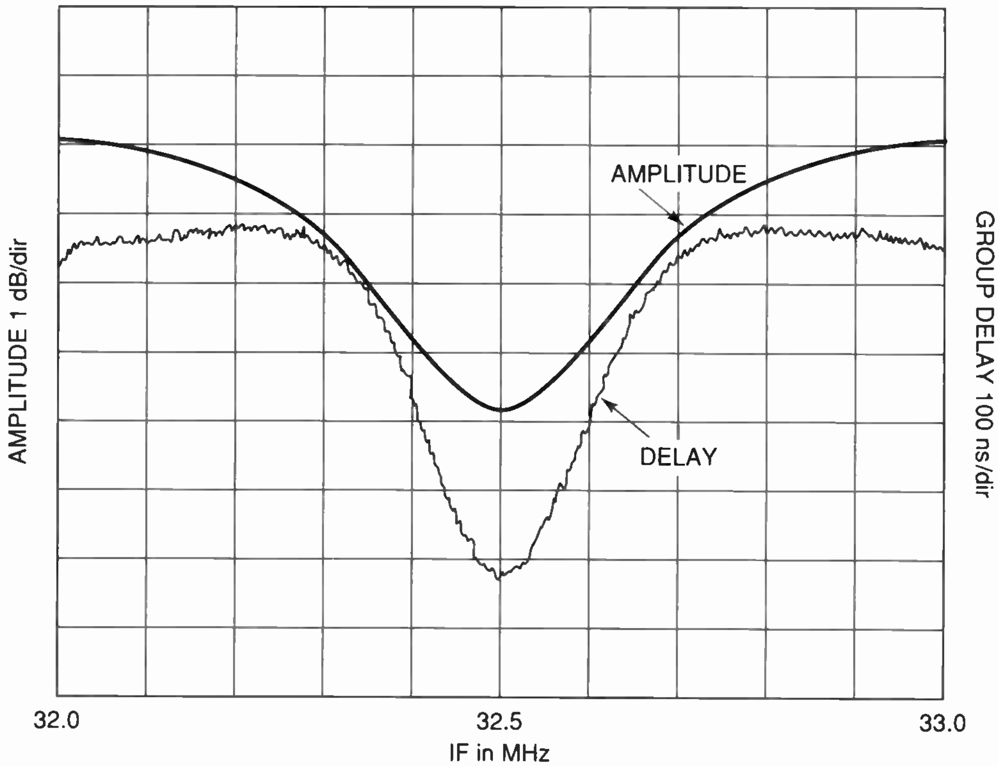

Figure 32. Aural group delay corrector measured results.

shown previously in Fig. 33. Fig. 34 shows that more than 10 dB stereo separation improvement can be obtained over midband audio frequencies.

SOLID-STATE TRANSMITTERS

More and more emphasis has been placed on maximizing the on-air time of TV transmitters. Recent technological advances in field effect transistors (FET) have made the development of solid state high power, linear amplifiers for TV applications both practical and cost effective.

Designing For Reliability

Because there are many factors which can affect the reliability of a TV transmitter, it must be understood that the application of solid-state high power technology in itself does not necessarily ensure a high reliability, low maintenance transmitter. Overall design philosophy, device technology, module design, control architecture, power supplies, cooling systems and cabinet design are some of the critical areas which also must be considered. By paying careful attention to the overall architecture and all of the subassemblies in the entire transmitter, a very reliable system results.

In a transmitter design which uses circuits in series with no system redundancy, it is clear that if one device fails then the entire transmitter will fail. Fig. 35 shows a system of three series devices with no redundancy.

If each device (a, b, c) has a probability of survival over a given period of time (P) of 0.5, then the overall probability of the system surviving P(s) over the same period of time is given by the formula:

$$\begin{aligned} P(s) &= P(a) \times P(b) \times P(c) \\ &= 0.5 \times 0.5 \times 0.5 \\ &= 0.125 \end{aligned}$$

If three identical devices are operated in parallel and only one is required for adequate operation of the system, the probability of the system surviving over the same time period is greatly enhanced. Fig. 36 shows this configuration.

The overall system reliability now becomes:

$$\begin{aligned} P(s) &= P(a) + P(b) + P(c) - P(a)P(b) - \\ &\quad P(a)P(c) - P(b)P(c) + P(a)P(b)P(c) \\ &= 1.5 - 0.25 - 0.25 - 0.25 + 0.125 \\ &= 0.875 \end{aligned}$$

System On-Air Availability

Related to reliability, but perhaps even more important to the broadcaster, is on-air availability. On-air availability is the percentage of time the transmitter

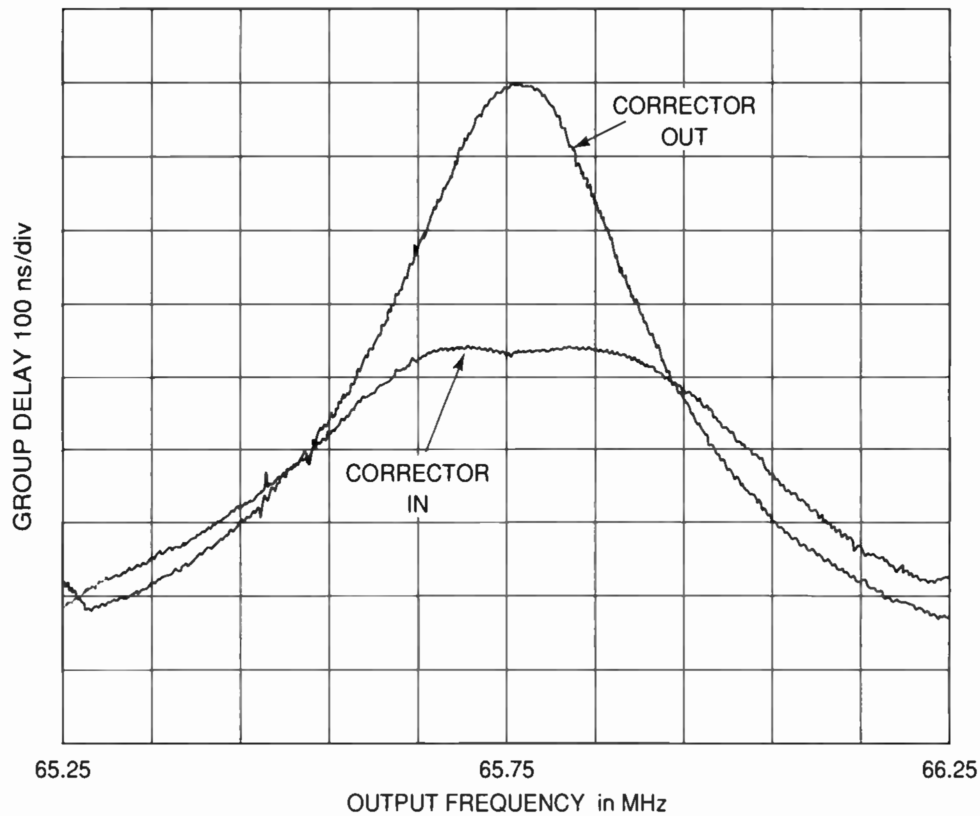

Figure 33. Overall transmitter delay with aural delay corrector switched in and out.

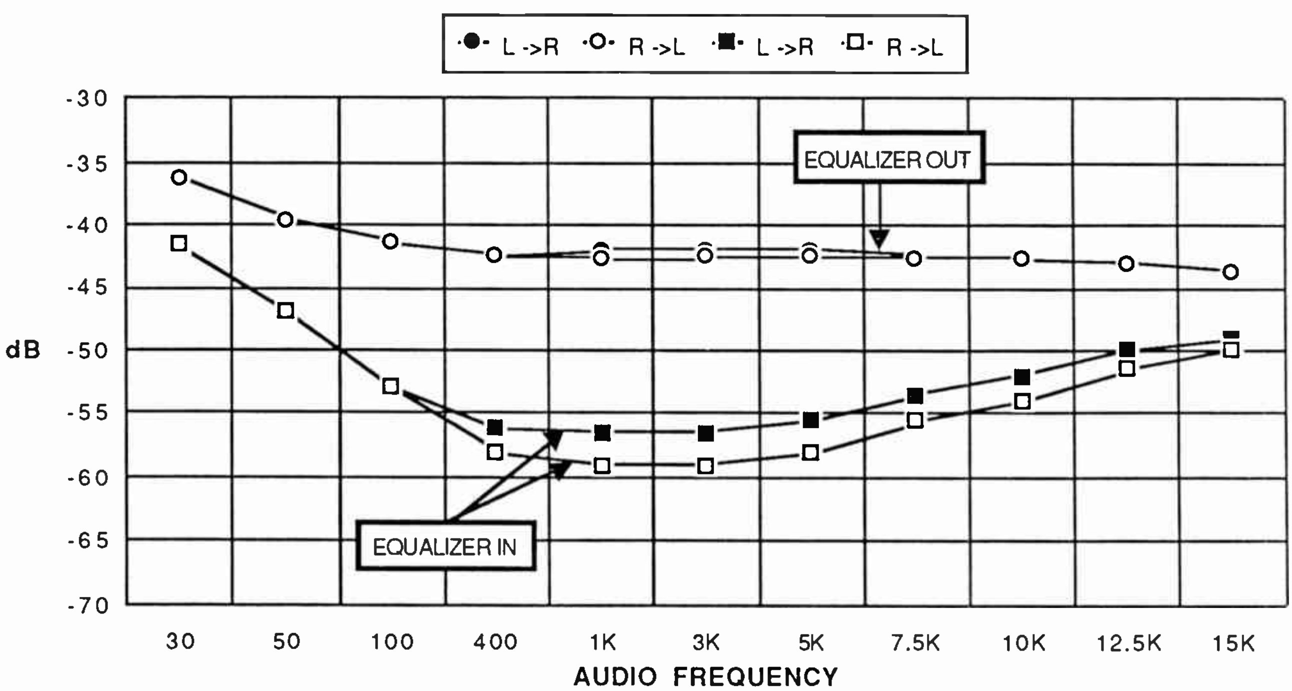

Figure 34. TV stereo separation with and without group delay equalizer.

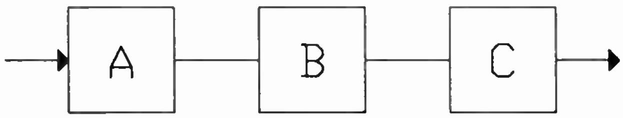

Figure 35. Circuits in series.

is in service, or could be in service. Availability is defined by the following equation:

$$\text{On-Air Availability} = \frac{\text{MTBF}}{\text{MTBF} + \text{MTTR} + \text{MPMT}} \times 100\%$$

where:

MTBF = Mean Time Between Failures (hours)
MTTR = Mean Time To Repair (hours)
MPMT = Mean Preventative Maintenance Time (hours)

From this equation, one can see that there is little point in designing a transmitter that has an extremely high MTBF figure if, due to poor design and mechanical packaging, it takes an inordinate length of time to make repairs, or the transmitter has to be shut down frequently for routine preventative maintenance.

Many stations have very short sign-off windows or operate 24 hours a day. This often results in a less-than-optimum maintenance schedule which can lead to premature failure or out-of-tolerance operation. One way to reduce the amount of off-air maintenance time is by making provisions for on-air maintenance or to have redundant transmissions. This significantly reduces the MPMT factor.

Several design factors should be considered for a transmitter for optimum on-air availability:

1. Very high reliability for the fundamental circuits.
2. Provision for fast and easy access to all modules and subassemblies.

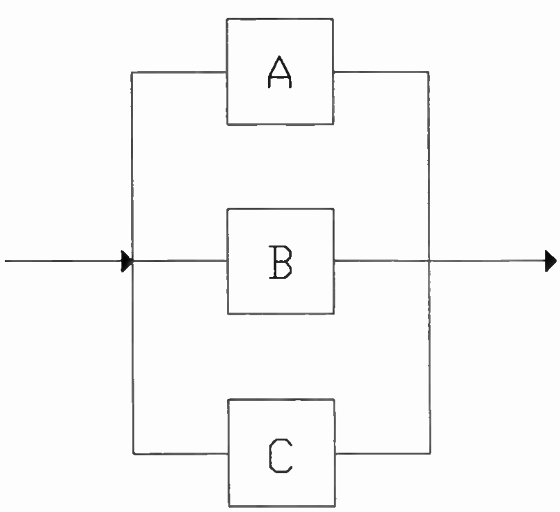

Figure 36. Circuits in parallel.

Figure 37. Modular VHF-TV transmitter (Model HT-30HS). (Photo courtesy of Harris corporation)

3. Maximum use of like part and subassemblies. Because only a few items would be needed, this allows most TV stations to maintain a full inventory of spares. If spares are on hand, it follows that the repair time will be much shorter.
4. Repair of transmitter at module or subassembly level. Modules which have been removed can then be repaired by station personnel or returned to the manufacturer for exchange.

Figs. 37 and 38 show two different modular solid state VHF-TV transmitters.

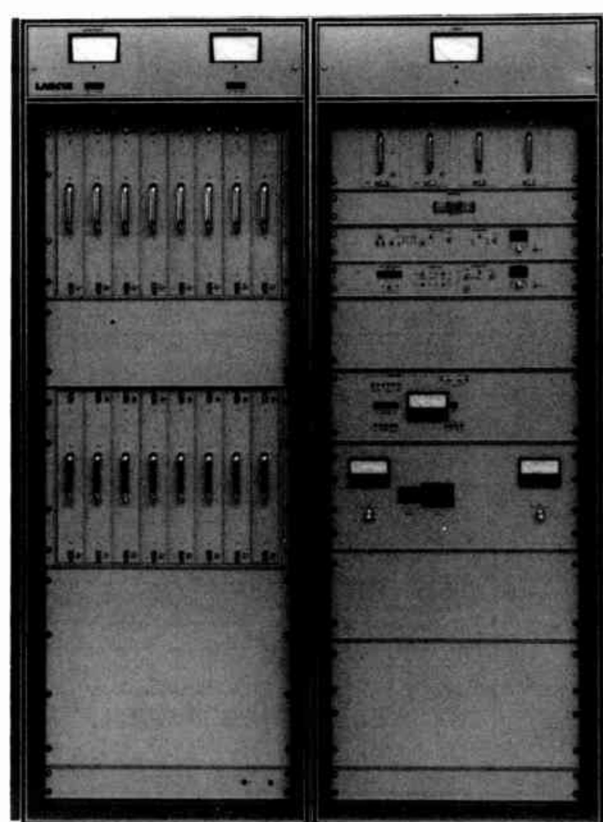

Figure 38. Modular VHF-TV transmitter (Model TTS-12M). (Photo courtesy of Larcan)

By combining a few or many RF modules, it is practical to create transmitters at any power range up to 60 kW. Solid state transmitters maintain their performance over extended periods of time due primarily to the fact that they have no tuning controls nor filament emission degradation with time. Another significant advantage is that no warm-up time is required. Solid-state transmitters can be producing full rated power within seconds of activation. Since solid state transmitters are of a different structure than tube transmitters, it is worthwhile to review some of the new transmitter architecture.

AGC

An automatic gain control (AGC) system is used to maintain constant power output from the transmitter. Ambient temperature changes will cause gain changes in a solid state amplifier or a faulty RF power module will cause a reduction in final output power. Then, RF drive power must be boosted to maintain constant power output. In most cases a detected RF sample of the PA output is fed to an input of a comparator. The exciter output sample or a voltage proportional to the exciter output is applied to the other input of a comparator. The DC output is then integrated and fed to an attenuator which varies the RF drive level at a low power level.

Combining Multiple Amplifier Cabinets

When combining RF power amplifiers, they must be matched in phase and gain for maximum power to the antenna and minimum power to the reject load. Electronic phase shifters and attenuators must have the capability for remembering their settings in case of AC power failure.

RF Amplifiers

Combining several RF power modules to achieve the desired transmitter output power increases the parallel redundancy and the on-air availability described earlier. Choosing the optimum power level for the PA modules of a solid-state transmitter is not an easy task. This point is illustrated in Fig. 39.

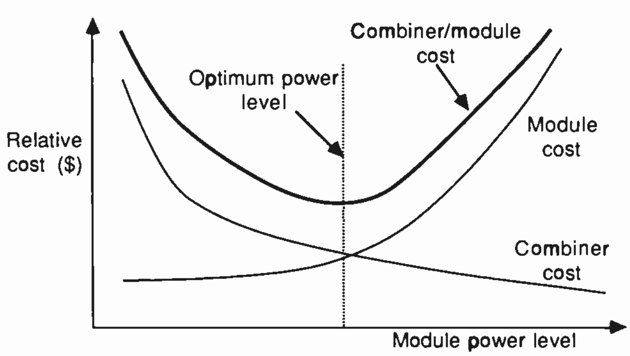

Figure 39. Module cost versus module power level.

A 1 kW output power module has been adopted in nearly all manufacturers' PA modules based on overall cost, practical weight, and size limitations.

Self-protection of each PA module against various fault conditions is good engineering practice. It is desirable that one sub-assembly failure not cause another sub-assembly failure. By using self-protecting modules, the cabinet control logic and overall transmitter control logic can be kept very simple, thus improving overall reliability. Self-diagnostics for the module aid in minimizing the time to repair. Protection from over-voltage, RF overdrive, VSWR, overtemperature, and ensuring proper load sharing among devices is essential to maintaining amplifiers for long life.

Modular amplifiers, which can be removed while "hot" can help in improving overall on-air availability. If an amplifier module fails, the transmitter can continue to function properly indefinitely without disrupting transmitter operation. If a spare PA amplifier is kept at the station, it can be used while the failed unit is repaired or returned to the manufacturer.

Temperature compensated, regulated bias supplies for the amplifiers are essential. Otherwise, performance and power output would vary roughly in direct proportion to temperature or supply voltage changes.

Amplifier level faults are most easily verified by swapping modules in different slots. If the fault follows the module it is an internal module problem but if the fault remains at the same slot after substituting the module, then the problem may be somewhere else in the system.

Solid-State Devices

Both bipolar and field effect transistor (FET) technology exist today as suitable RF amplification devices. Power amps are operated in class AB for the best trade-off of efficiency and linearity. The driver amplifiers usually contain class A operated RF amplifiers. Although both types have their merits, FETs have some advantages over bipolar devices.

FETs have a higher amplification factor than bipolar transistors, helping to reduce the number of devices required as driver stages. Higher supply voltages help to reduce the current capacity of the power supply. Simpler bias circuitry minimizes parts count.

Cooling System

Proper cooling of the solid-state modules is extremely important in obtaining a high MTBF. The MTBF of a FET or transistor essentially doubles for every 10°C drop in the actual FET junction temperature.

Distributed cooling systems employing more than one fan offer good redundancy. Current motor/fan technology has matured to the point where a few larger direct drive fans can be equally as reliable as, or more reliable than many smaller fans. Since many RF power amplifiers may be employed, a large volume of air is needed to adequately cool the heatsinks. Low pressure fans or blowers may be used if heatsink fin density is not high. This aids in reducing audible noise generation from the transmitters. The heat is distributed over a large volume of air and thus the temperature rise is relatively low; on the order of five to seven degrees Celsius.

Power Supplies

Power supply design is another area which is critical to the reliability of a solid-state transmitter. Since FET and bipolar devices are low voltage devices, the power supplies which serve them provide low voltage and high current. Therefore, high reliability connections must be guaranteed in the DC distribution. Since available power output from a FET or bipolar transistor varies roughly as

$$P_o = \frac{(Vcc)^2}{2R_L}$$

it is desirable that the supply remain very tightly controlled over incoming AC line variation.

Also, any anomaly present such as voltage or current transients or voltage sags at the AC input to the power supply should be significantly suppressed before reaching the amplifier transistor device. Transmitters should successfully pass the applicable portions of the ANSI/IEEE C62.41 transient testing standard (also referred to as the IEEE-587 standard).

Since the amplifier's current demand will vary with picture level, the power supply output voltage must remain stable from very little load (i.e., white picture) to very large loads (i.e., producing sync output power.)

Efficiency of the power supply is important since the lost power appears as waste heat energy.

Control Systems

If individual amplifier modules and power supplies are self-protecting, control and monitoring functions can be kept simple and straightforward.

One approach for the control system is to use a single controller to control and monitor all the functions of the transmitter.

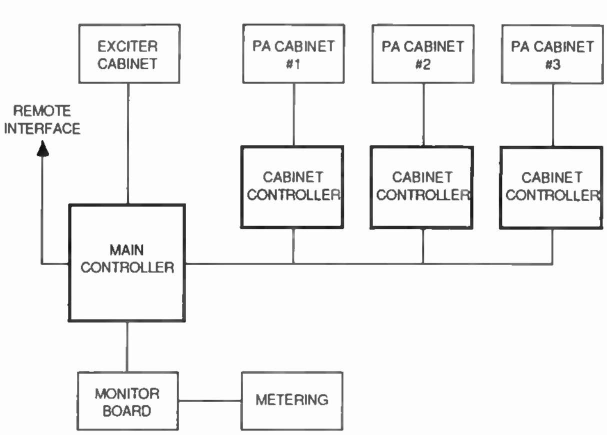

Figure 40. Distributed control and monitoring.

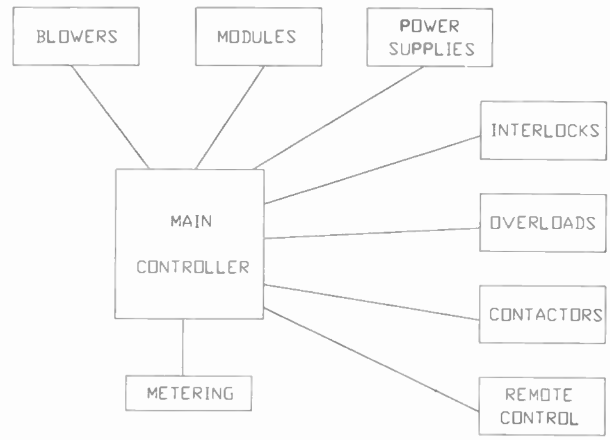

Figure 41. Centralized control system.

Another approach is to distribute the control system throughout the transmitter. The distributed control system can be designed so that the failure of any individual controller does not affect the operation of the others.

Both distributed control system architecture and centralized control systems are shown in Figs. 40 and 41.

After AC power failures, the controller should have back-up memory to restore the transmitter to the same operating condition as before power was interrupted. This would apply to all the control systems within the transmitter.

A system of indicators is essential to quick fault diagnosis. Some typical status conditions which may be displayed are: exciter fault, VSWR fault, VSWR foldback, power supply fault, controller fault, air loss, door open, failsafe interlock, phase loss, module fault, visual drive fault, aural drive fault, and external interlock(s).

VSWR foldback reduces power during high VSWR operation, such as antenna icing, and restores RF power back to normal when difficulties are removed. This is a technique used to keep transmitters on the air. Other options used to enhance the on-air capability of solid state transmitters may include dual exciters, 20% aural power, and redundant drive chains. An example of a VSWR foldback block diagram is shown in Fig. 42.

AC Distribution

Tube-type transmitters typically have one AC service connection to the transmitter. A more reliable method is to provide power to the modular RF amplifier cabinets through a distributed AC power feed system in which each cabinet is protected by a separate AC breaker that is external to the transmitter, as shown in Fig. 43. This concept also allows a cabinet to be safely serviced while the remaining cabinets are operational. Phase monitors guard against low voltage, loss of one phase, or reversal of the phase sequencing.

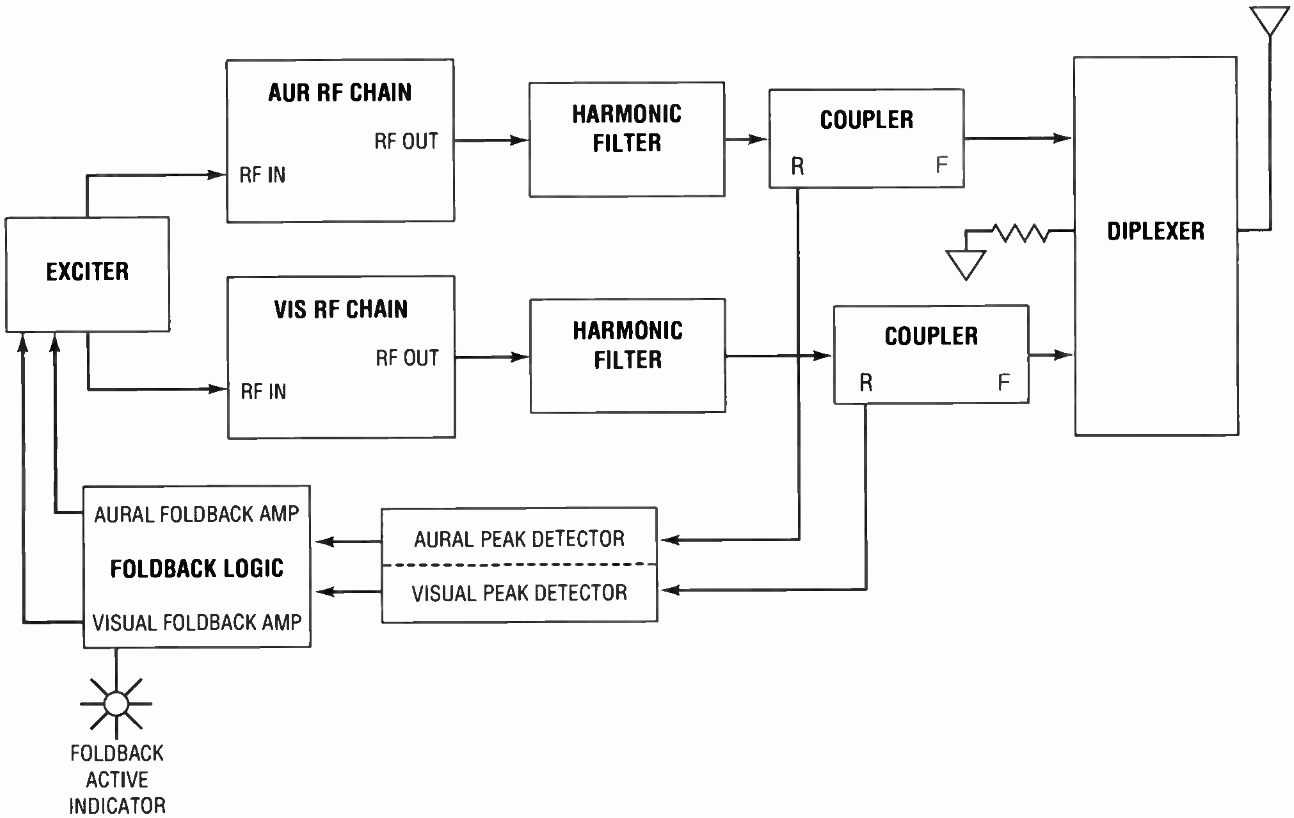

Figure 42. VSWR foldback block diagram.

Combiners and Dividers

There are several choices as to the method used for dividing and combining RF power for the solid-state visual and sound amplifier modules. The most predominant method used has been with in-phase N-way ring combiners. Two common examples are described below.

Microstrip Wilkinson Combiner

Fig. 44 shows an example of this type of combiner. Microstrip is used as the transmission line to carry the RF power. When all amplifiers are operating, equal voltages are presented to each side of the load resistor so that no power is dissipated. When an amplifier failure occurs, the power is distributed between the loads and the output. In this type of combiner, the impedance of the transmission lines and the length of the lines may be varied to achieve the desired impedance transformation.

Balanced reject loads are used to absorb RF power in case of an amplifier failure and to provide isolation for the other amplifiers.

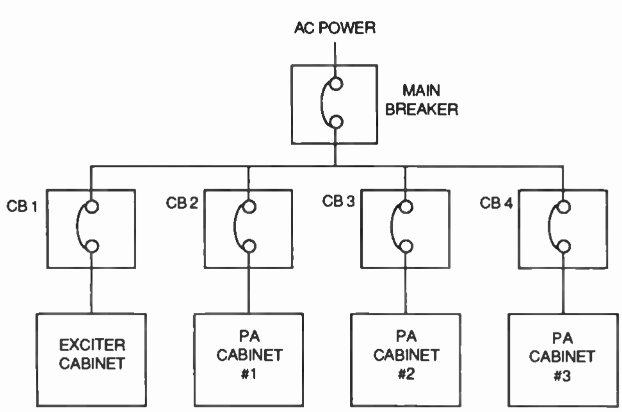

Figure 43. Distributed AC power system.

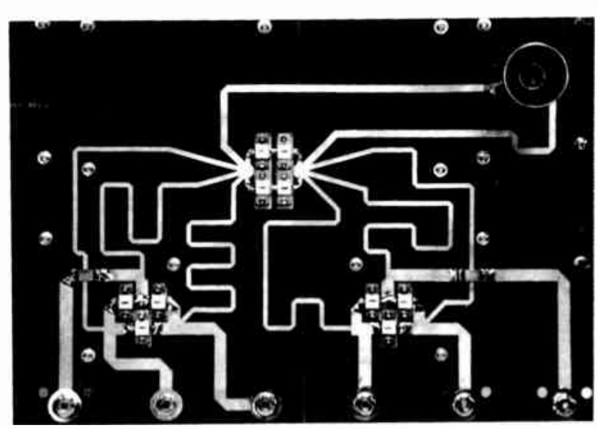

Figure 44. Microstrip Wilkinson combiner.

The combiner is housed in a shielded casing so that outside fields cannot alter the balanced configuration. In case of an amplifier failure, the reject loads conduct heat through the flange to the heatsink where the heat is exchanged to the moving air stream. This type of combiner is used generally for lower numbers of amplifiers (i.e., two to six).

Ring Combiner

Fig. 45 shows an example of this type of combiner. The higher power handling capability of the coax lines used in this combiner will also allow a large range of amplifiers to be combined, (i.e., two to 20). It also provides isolation from one amplifier to another using reject loads which are not in the direct RF path to the output. The operation of the multiport combiner is easily understood by first understanding a two-way combiner.

Refer to Fig. 46 for a simplified version of the combiner. Each of the transmission lines is a quarter wavelength. When equal voltages are applied to both input ports (both amplifiers operating) the combined signal arrives at the output. This is true for three reasons: (1) the distance from each input port to the output is electrically equal whether the signal follows the shorter path or the longer path, (2) the signal from one amplifier arrives at the load port out of phase with that from the other amplifiers so no power is dissipated, and (3) the signals from amplifier 1 arriving at input port 2 via the short and long paths are out of phase and vice versa. *Thus under normal conditions, all of the power appears at the output, none is absorbed in the loads, and there is complete isolation between amplifiers.*

Power is absorbed in the load resistors only when an amplifier is not operating. Assume that only amplifier number 1 is operating. The signal path is electrically equal not only for the long and short paths to the output but also for the right and left paths to either load resistor. The power from the operating amplifier

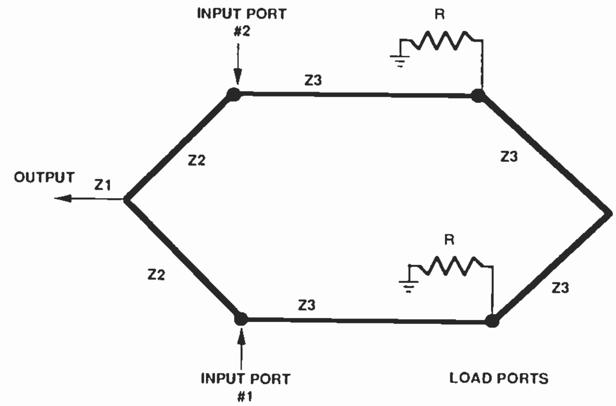

Figure 46. Two way ring combiner.

is split equally between the output and the isolation loads. Due to the isolation inherent in the network, the input ports remain matched even when one or more amplifiers are removed.

Since the transmission line that connects the amplifier port to the output port is a quarter wavelength long, and 75 ohm transmission line is used, the 50 ohm amplifier impedance is transformed to: $(75/50) \times 75 = 112.5$ ohms. For combining N amplifiers, the impedance at the output combiner junction is 112.5/N. This impedance is then matched to 50 ohms.

In this type of combiner, the reject loads may also be mounted to a grounded structure. Removing the heat from this structure should be done as quickly and efficiently as possible. One method to accomplish this is to use a heat pipe for the mounting structure. In case of an amplifier failure or removal, the reject load temperature rises, the fluid in the lower section of the heatpipe heats up until it vaporizes. The vapor rises to the finned area where the heat is exchanged to the moving air stream. The vapor condenses as it releases its heat and returns to the bottom of the pipe to absorb more heat.

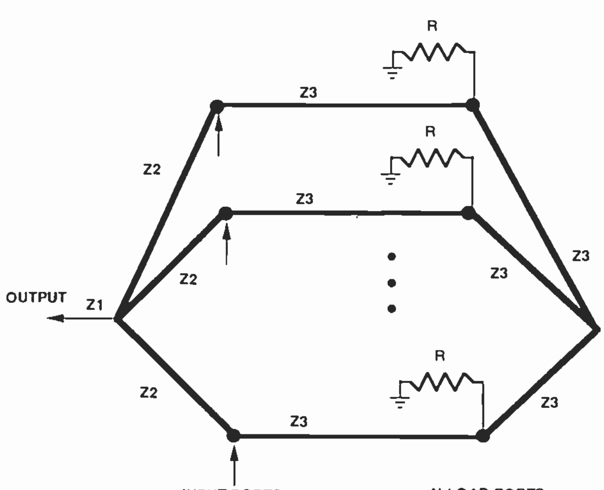

Figure 45. N-way ring combiner.

VHF TUBE TRANSMITTERS

Triodes and tetrodes are still used in the RF power stages of television transmitters. This section will highlight some of the facts on high power gridded transmitter tubes. The parts of the power tube will be reviewed.

General

A vacuum tube uses grids to control the flow of current through the tube. The cathode emits the electrons which travel to the plate. The plate is more positive than the cathode. The grids control this flow of electrons, thereby controlling the plate current. They also can modulate the electron stream causing the plate current to have the same waveform as the grid voltage, depending on class of operation.

A triode is a three element tube consisting of:

1. A heated cathode which emits electrons.
2. A control grid which modulates the electron stream in accordance with the DC and AC voltages impressed between the control grid and cathode.
3. A plate which accepts the electron stream. The plate is positive with respect to the cathode.

Input signals, DC and AC, are applied between control grid and cathode. Output signals, DC and AC, flow to the tube output load impedance by way of the plate and cathode.

A *tetrode* is a four-element tube which has a *screen grid* added between the control grid and plate. The screen grid acts as an electrostatic shield which helps to isolate the plate output signal from the control grid input signal, and is operated at a positive DC potential with respect to the cathode. This potential is much lower than the DC plate voltage and is usually operated at AC (RF) ground potential.

The tetrode has higher gain than the triode. The plate voltage has minimum effect on the plate current as long as the instantaneous plate voltage is greater than the screen grid DC voltage. The plate voltage is normally allowed to swing close to, but not below, the value of DC screen grid voltage. If the tetrode screen grid is not maintained at AC (RF) ground potential, the tube can take on the characteristics of a triode. The tetrode input bias and signal are applied between the control grid and cathode and are similar in performance to the triode. The output AC (RF) signal current path in the tetrode is from the plate, through the load impedance, and returns through the screen grid.

The Cathode

A power grid tube will have high peak and average current levels. Therefore, the cathode must be hot to emit many electrons. It normally requires large heater power at low voltage and high currents. DC current is often used to reduce AC noise levels. It is usually directly heated (the heater in the cathode) to provide quick warm up with lower heater power. Some type of cooling to remove excess cathode heat from the tube filament/cathode contacts and the tube socket may be required.

The Grids

The voltages (DC, AC, and RF) of all grids are measured with respect to the cathode. Grids can have current flow which is positive when the grid accepts electrons from the electron stream or negative when the grid emits electrons.

Grids can emit electrons and negative grid current can occur because they are located close to the hot cathode. The grids can become very hot and have small amounts of thermionic emission (primary emission) or electrons emitted by being bumped off by other electrons (secondary emission).

As tubes age, some of the cathode electron emitting coating may be deposited on the relatively cooler grids thereby increasing their tendency to emit electrons.

The control grid has a negative DC bias and an AC driving signal superimposed upon it. The instantaneous grid current can be negative when the grid voltage is swinging maximum negative, zero when the grid is only slightly negative, or positive when the grid is positive.

The screen grid has a positive DC bias and is at AC ground potential. The instantaneous screen grid current is negative when the plate voltage swings maximum positive, and positive when the plate voltage swings close to or below the screen grid DC voltage, and zero when the plate voltage is between these extremes.

Both grids have instantaneous positive, zero, or negative currents that follow the voltage swing. The average of these currents is the DC grid current. Since both DC voltage and current are present in both grids, the grids can dissipate power. The control grid also has AC (RF) voltages and currents present so that AC power dissipation in grids must also be considered.

The DC plate power that is applied to the tube is either converted to AC (RF) output power or dissipated as heat. This heat is developed in the plate itself and must be removed by air or water cooling.

Below 30 MHz, RF amplifiers use lumped components to implement the matching circuits for the tube input and output. At VHF and UHF frequencies, several problems make the use of lumped components (L&C in the same purchase) impractical.

The Transmission Line Cavity

As frequency increases, resonant circuits are smaller to reduce inductance and capacitance, larger in diameter to reduce skin effect, and closer to the tube to reduce the effects of stray inductance, and there is difficulty in predicting exactly what values of resistance, inductance, and capacitance a component or circuit may have.

These problems can be managed in low-power circuits, but with high power circuits, arcs and shorts due to high DC and RF voltages become a problem. Larger size and spacing of components are a good start towards arc and short prevention, but this is in opposition to the smaller size and spacing needs dictated by the high frequency operation. Also in high power circuits, the unpredictability of the circuit values of R, L, and C make it difficult to control the vitally important parameters of dissipation, efficiency, and reliability of operation.

One solution to the above problem is the resonant transmission line cavity amplifier. In this type of amplifier the tube becomes part of a resonant transmission line. The elements of these tubes themselves are arranged to look like concentric coaxial transmission lines. The design of these power tubes stresses low inter-electrode capacity and low distributed inductance. The stray inter-electrode and distributed capacity and inductance of the tube becomes part of the resonant transmission line. The resonant transmission line is physically larger than the equivalent lumped constant LRC resonant circuit operating in the same frequency. This larger physical size aids in solving the

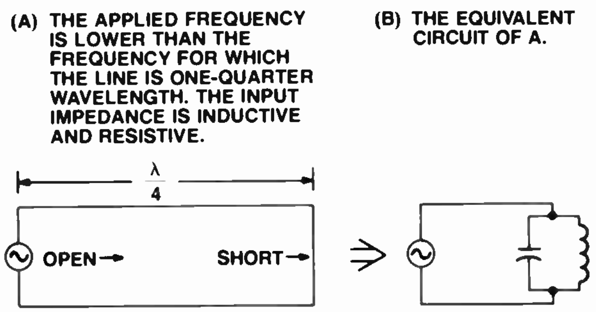

Figure 47. Shorted quarter wavelength line.

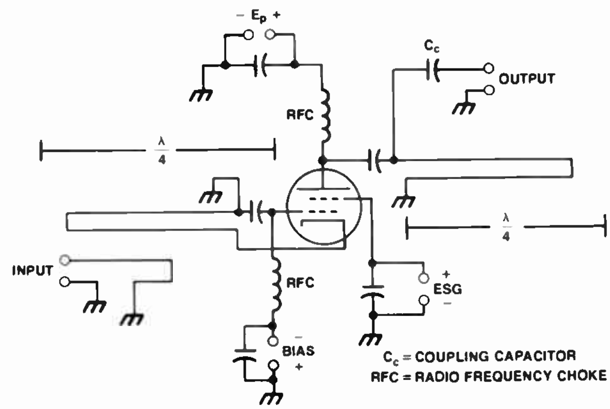

Figure 49. A shorted quarter wavelength transmission line amplifier.

high power operation problems of skin effect losses, prevention of arcs and shorts, and yields reliable and predictable operation. A commonly used transmission line cavity amplifier uses a quarter wavelength transmission line as its resonant element.

The Shorted Quarter Wavelength Line

A shorted quarter wavelength transmission line has a very high, purely resistive input impedance. Electrically, it looks like a parallel resonant circuit as shown in Fig. 47).

The Shorted Transmission Line Less Than a Quarter Wavelength Long

When the physical length of the line is less than one quarter wavelength, the impedance will be lower and the line will look inductive. Refer to Fig. 48. This inductance will be used to resonate with capacitive reactance in the tube and surrounding circuit.

Quarter Wavelength Cavity and Amplifier

In Fig. 49, shorted transmission lines are used to resonate the inputs and outputs of this amplifier. Notice that the length of the lines is less than a quarter wavelength but the tube's shunt input and output capacity and its series lead inductance will electrically lengthen and resonate the transmission lines. The input is shown inductively coupled, but it could just as easily have been capacitively coupled to the cathode. The input could also have a lumped constant resonant circuit or a transmission line resonant circuit since its power level is low. The output coupling is capacitive, but it also could have been inductive. The construction of the tube lends itself to transmission line tuning techniques.

Coaxial Construction of a Tetrode RF Power Amplifier Tube

The Anode (Plate)

The plate resembles a copper cup with the plate contact ring welded to the mouth and the cooling fins silver soldered or welded to the outside of the cup as shown in Figs. 50 and 51.

The contact ring is bonded to the base ceramic spacer through a strain isolation ring. This ceramic spacer is the same ceramic that is shown above the screen contact ring shown in Fig. 52.

The Screen Structure

The screen grid consists of many vertical supports fastened to a metal base cone. The other end of the metal base cone fastens to the screen contact ring. The inductance of the individual vertical supports is reduced by building the screen grid of many of vertical

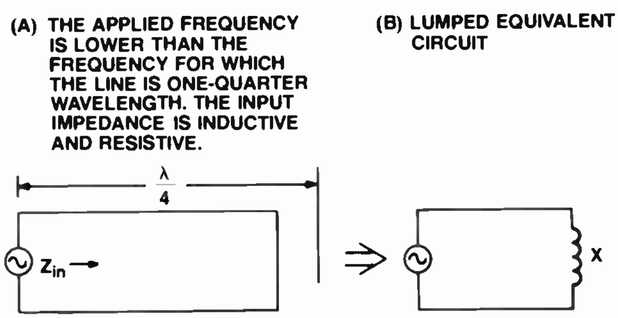

Figure 48. Shorted line less than one-quarter wavelength.

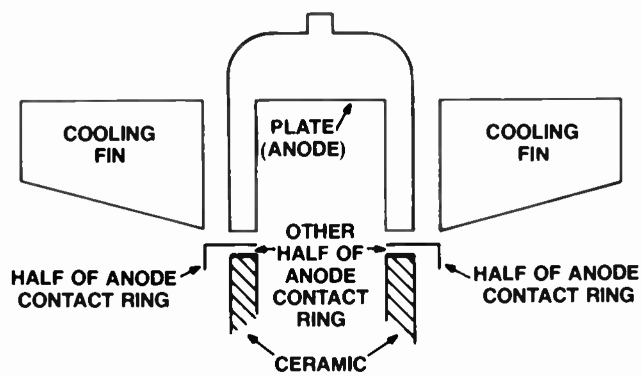

Figure 50. Cutaway view of the anode structure.

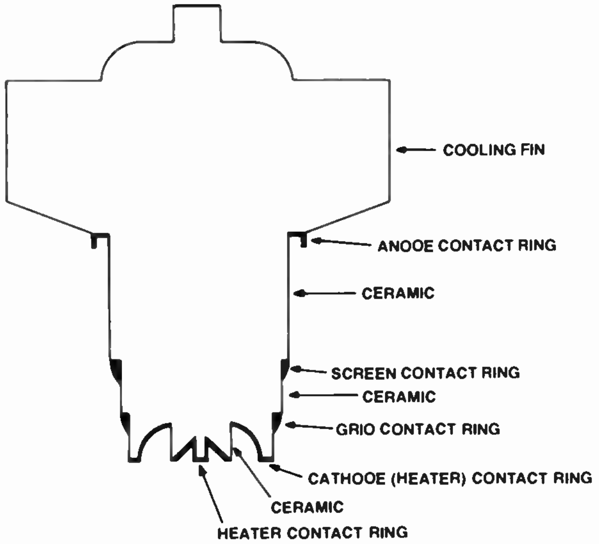

Figure 51. Cutaway view of the exterior of a RF tetrode.

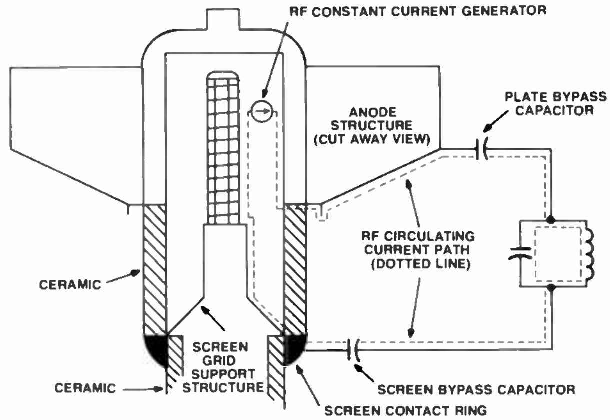

Figure 53. Showing the plate and screen assembly and RF circulating current path (dotted line).

supports in parallel. The vertical supports are held rigid by horizontal rings welded to them and a metal cap on the top of the assembly. The screen contact ring, metal base, and metal base cone also function to reduce lead inductance and RF resistance due to skin effect (refer to Fig. 52).

A cutaway view of the plate circuit and the screen circuit in Fig. 53 shows a concentric construction that resembles a coaxial transmission line.

Consider that the output RF current is generated by an hypothetical current generator between the plate and screen grid. The RF current travels along the inside of the plate structure on its surface (skin effect), through the ceramic at the bottom of the anode contact ring, around the anode contact ring, across the bottom of the fins, and to the band around the outside of the fins. From here it flows through the plate bypass capacitor to the RF tuned circuit and load, and returns to the screen grid. The return current travels through the screen contact ring, up the cone, and up the screen bypass capacitor, then through the screen grid to return to the hypothetical generator. The screen grid has RF current returning to it but due to its low impedance, the screen grid is at RF ground potential. The RF current generator appears to be feeding an open ended transmission line consisting of the anode (plate) assembly, and the screen assembly. The RF voltage developed by the anode is due to the plate impedance presented to the anode by the resonant circuit and its load.

The control grid assembly and the cathode assembly are also cylindrically constructed and concentric. The control grid assembly is constructed similarly to the screen grid but slightly smaller. Fig. 54 shows the screen grid, control grid, and the cathode assemblies as they are placed in the tube.

Fig. 54 also shows the current path of an RF generator feeding a signal into the grid/cathode assembly. It resembles a transmission line terminated by the RF resistance of the tube's electron stream. The outer contact ring for the cathode heater is the inner conductor of this transmission line.

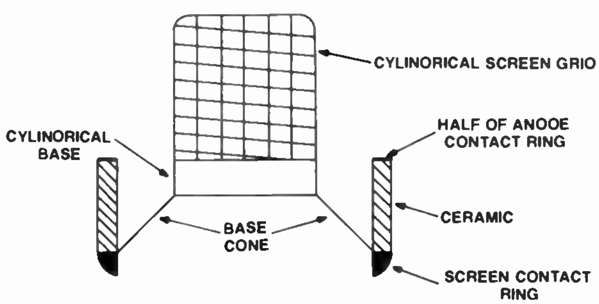

Figure 52. The screen grid assembly.

Double-Tuned Tube Power Amplifiers For TV Transmitter Applications

Television RF power amplifiers use tetrode tubes because of their high gain, good linearity, good efficiency, and high power advantages. A double-tuned output circuit is used to achieve proper bandwidth and efficiency.

As an example, the double-tuned overcoupled amplifier shown in Fig. 55 should not be thought of as an amplifier and a socket into which a tube is placed. The tube is an integral part of the cavity. The internal electrical properties of the tube will determine the amplifier gain and power handling capabilities. It will also dictate the dimensions and functions of the circuitry.

Effects of Tuning an Overcoupled P.A.

All double-tuned overcoupled visual power amplifiers have four controls to accomplish output tuning.

Plate tune (primary tune) resonates the plate circuit and tends to tilt the response and slide it up and down the bandpass (shown as A on Fig. 56, also Fig. 57 and Fig. 58).

Coupling sets the bandwidth of the PA. Increased coupling increases bandwidth and lowers the PA efficiency. When the coupling is adjusted, it can tilt the response and change the center of the bandpass necessitating the readjustment of the plate tune control (shown as B on Fig. 55, also Fig. 56 and Fig. 58).

Secondary tune resonates the secondary cavity and will tilt the response if adjusted. Generally it will not slide the response up and down the bandpass as will the primary tune (shown as C on Fig. 55, also Fig. 56 and Fig. 59).

Loading (secondary load or output load) determines the value of ripple in the response. Heavier loading (maximum C or minimum L) creates a haystacked response and light loading creates excessive ripple. Adjustment of the loading control usually tilts the response and changes bandwidth. This necessitates readjustment of secondary tune and coupling. In some cavities, primary tune may also have to be readjusted. The coupling control will also effect the value of ripple, but its greatest effect will be on the bandwidth (shown as D on Fig. 55, also Fig. 56 and Fig. 60).

Tuning For Power

Sweep the entire transmitter into the antenna or dummy load at 100% power. If tuning of any part or

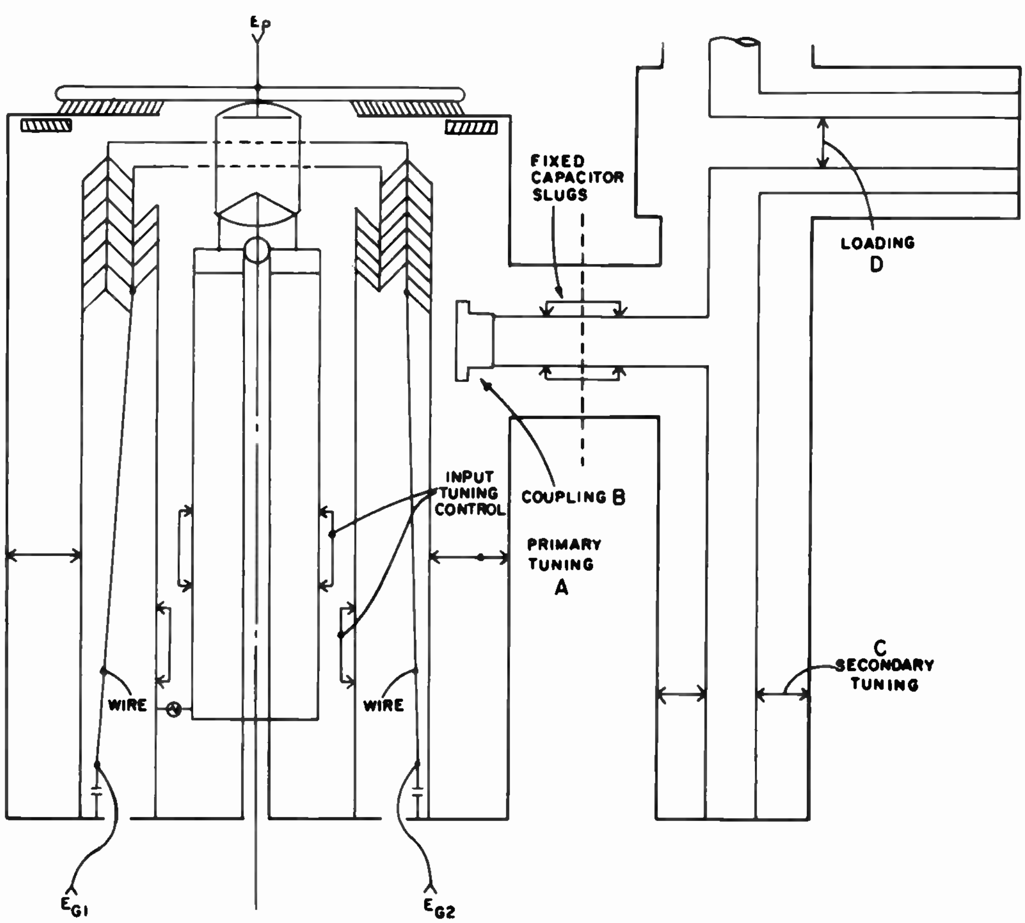

Figure 55. High band coaxial transmission line cavity amplifier for TV use.

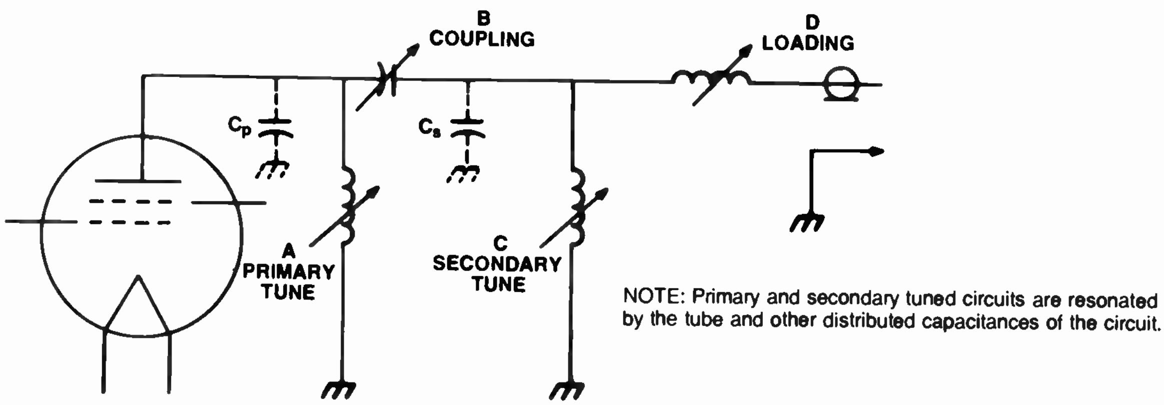

Figure 56. Double-tuned power amplifier.

all of the transmitter is in doubt, check the following. Observe the frequency response, reflected power (VSWR), plate current, screen grid current, and grid current. If the output response is not right, check each stage, starting at the exciter, to be sure each stage is flat and has the correct bandwidth. The final amplifier should be the narrowest of all stages.

After the transmitter sweep is completed and the overall response has the proper bandwidth, transmit a black picture, (video set at blanking, 75% modulation), operate into the station load and check for:

1. Proper sync level at the transmitter output. Adjust the visual exciter linearity corrector as necessary.
2. Excessive plate dissipation.

Plate dissipation = (Plate voltage × Plate current) − (Average RF output power)

3. Excessive screen current. The screen current will increase rapidly at higher power if the PA is lightly loaded. Very light loading can cause sync compression.
4. Excessive grid current, if PA is loaded too heavy, can cause sync compression.
5. Amplifier output efficiency. It can also be a guide to proper operation of the stage. The efficiency at

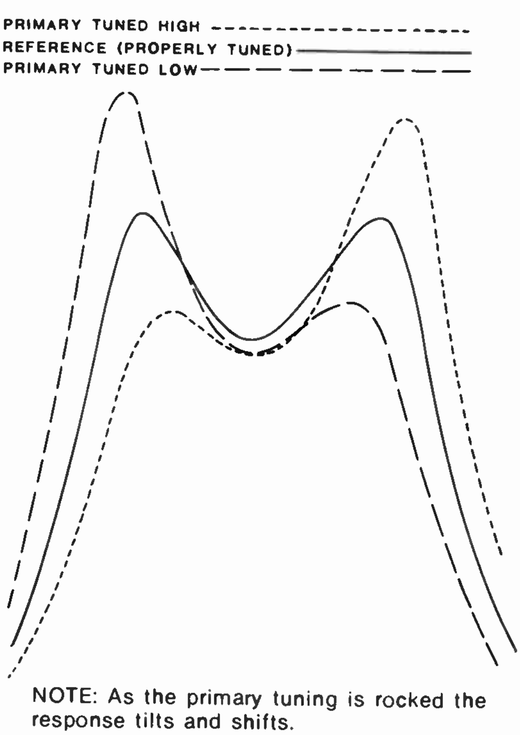

Figure 57. Primary tuning.

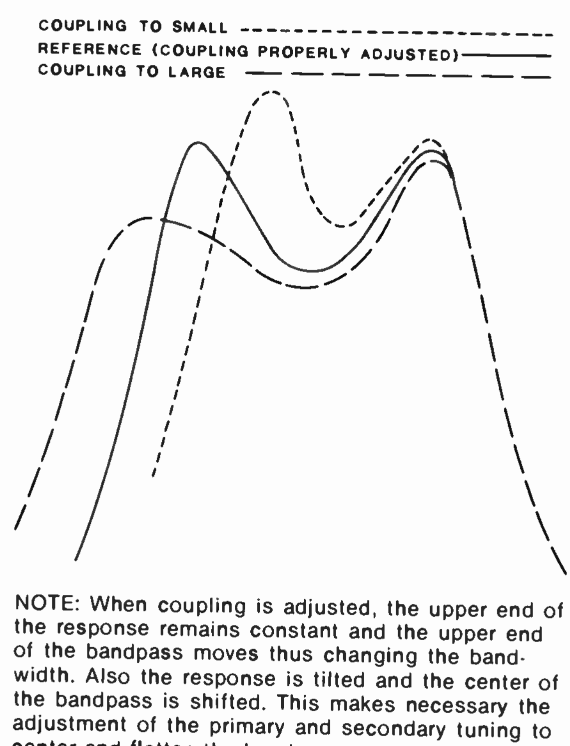

Figure 58. Coupling plate loading.

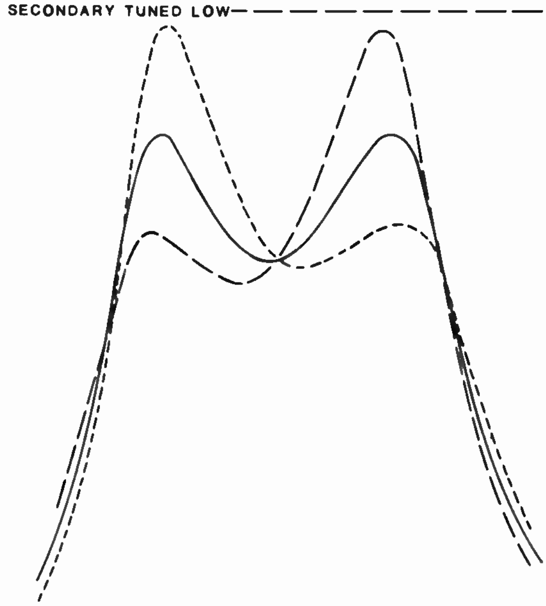

NOTE: As secondary tuning is rocked, the response tilts, but it tilts in the opposite direction to the primary. Thus, the secondary and primary tuning can be changed together to shift the response up or down in frequency.

Figure 59. Secondary tuning.

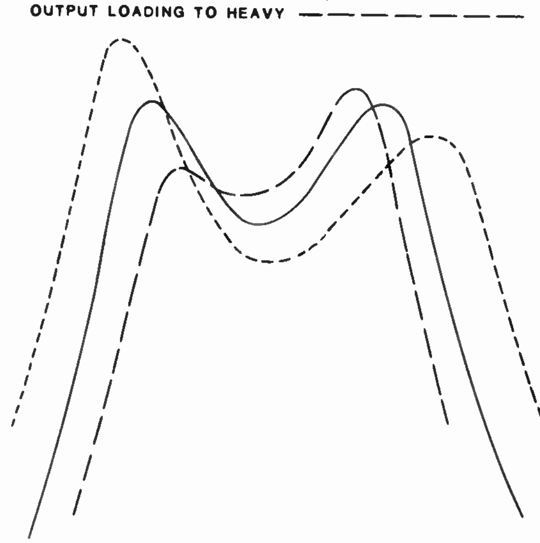

Figure 60. Loading adjustments.

VHF typically will range from 41% to 45%. At UHF the range is somewhat lower.

$$\text{Efficiency} = \frac{\text{Average power output}}{(\text{Plate voltage} \times \text{Plate current})}$$

Heavy Loading	Smaller Ripple	Lower Plate Impedance	Higher I_p and Positive I_g Lower Gain	Lower Positive I_{sg}
Light Loading	Larger Ripple	Higher Plate Impedance	Lower I_p and Positive I_g Higher Gain	Higher Positive I_{sg}

It is assumed that the RF output power is measured by an accurately calibrated RF wattmeter or by a calorimeter. If the wattmeter is not accurate, the amplifier dissipation and efficiency may be in doubt and the tube life may be shortened. If the wattmeter reads low, 100% output power will appear difficult to obtain. The amplifier might be trying to produce more than its full rated power. The symptoms would be high plate dissipation, and sync compression. These are the same symptoms that improper tuning could yield.

If the wattmeter reads high, power will appear easy to obtain and efficiency will appear high.

Plate dissipation might appear low and in reality be high. This will become apparent over a long time by a blackened anode.

A calorimeter is the most accurate way of measuring power but is not always practical. If the wattmeter is to be calibrated, send the wattmeter transmission line section, the sampling slugs, and the meter (with the meter cable) together with information giving your frequency and power to the manufacturer for calibration.

The power measured on a calorimeter or on the wattmeter is average power. To find peak power (assuming a black picture with no setup) use this formula:

$$\text{Peak power} = \frac{\text{Average power}}{0.595}$$

If a large value of plate current is required to make power, it indicates that the plate voltage is not swinging very far.

The low plate voltage swing is also indicated by the low screen current. Remember that positive screen current flows only during the time that the plate voltage swings close to the screen voltage.

The low swing of plate voltage along with the high swing of plate current indicates a low plate impedance (heavy loading).

$$\text{Plate impedance } (Z_p) = \frac{\text{The swing of plate voltage } (\delta e_p)}{\text{The swing of plate current } (\delta i_p)}$$

To make the amplifier more efficient and bring plate dissipation down, the plate impedance must be increased. To increase the plate impedance, the amplifier loading must be decreased by performing the following corrections:

Solid line —Transmitter overall response
Dotted line—The part of PA response outside of the transmitters bandpass.

Figure 61. Nonsymmetrical response caused by the amplifiers outside the transmitters bandpass. Solid line is transmitter overall response. Dotted line is the part of PA response outside of the transmitters bandpass.

1. Sweep the transmitter and decrease the PA loading.
2. This will cause the response to tilt. Correct this tilt by adjusting the secondary tuning.
3. Decreasing the loading will also cause the bandwidth (and ripple) to increase. This can be counteracted by decreasing coupling.
4. Changing coupling will cause the response to tilt. This can be corrected by adjusting the primary and/or secondary tuning.
5. The above procedure may have caused PA response to slide up or down out of the bandpass. It will show up as an asymmetrical bandpass (as shown in Fig. 61). It can be corrected by adjusting both primary and secondary tune simultaneously to center the response.

The transmitter's overall response will have the same bandpass but will now have slightly more ripple. The ripple content in the transmitter's overall response should still be within the 0.25 dB to 1.25 dB limits.

CAUTION: When changing loading, coupling, and primary and secondary tuning, it is possible to get the PA bandwidth too wide. The excessive bandwidth of the PA may be masked by narrow driver response. This excessive bandwidth will cause PA overdissipation. Correct bandwidth is shown in Fig. 62 and improper bandwidth is shown in Fig. 63.

Once again, transmit a black picture into the dummy station load. Switch the vestigial sideband filter and the linearity corrector in and check sync level at the transmitter's output. Plate current and grid current should be lower and screen grid current should be higher. The amplifier efficiency should fall between 41% to 45%.

This is a general tuning procedure given to illustrate tuning methods, control interactions and tube operating characteristics. It will work well with most double-tuned overcoupled power amplifiers. For specific tuning information on a given transmitter, the manufacturer's instructions should be consulted.

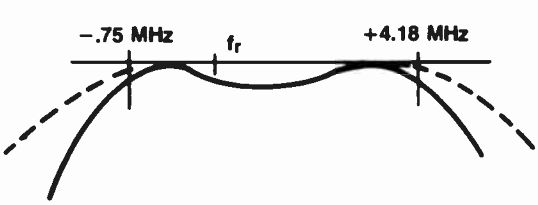
UHF TRANSMITTERS

There has been a significant amount of new technology introduced recently regarding UHF amplifiers used in TV transmitters. Most of this has been concentrated in enhancing the efficiency of the UHF amplifiers.

The introduction of the multiple depressed collector klystron and klystrode[5] to UHF TV transmitters has dramatically reduced transmitter power consumption. Those new technologies will be addressed in this section. However, a basic background is helpful to the understanding of the new devices.

Basic Klystron Theory and Practice

The klystron uses velocity modulation to serve as an amplifying device. The electron beam emitted from the cathode is accelerated to high velocity by the



NOTE: The driver bandwidth is the dotted line, and the PA bandwidth is the solid line. The solid line also represents the overall transmitter bandpass.

Figure 62. Proper bandwidth.

Figure 63. Improper PA bandwidth.

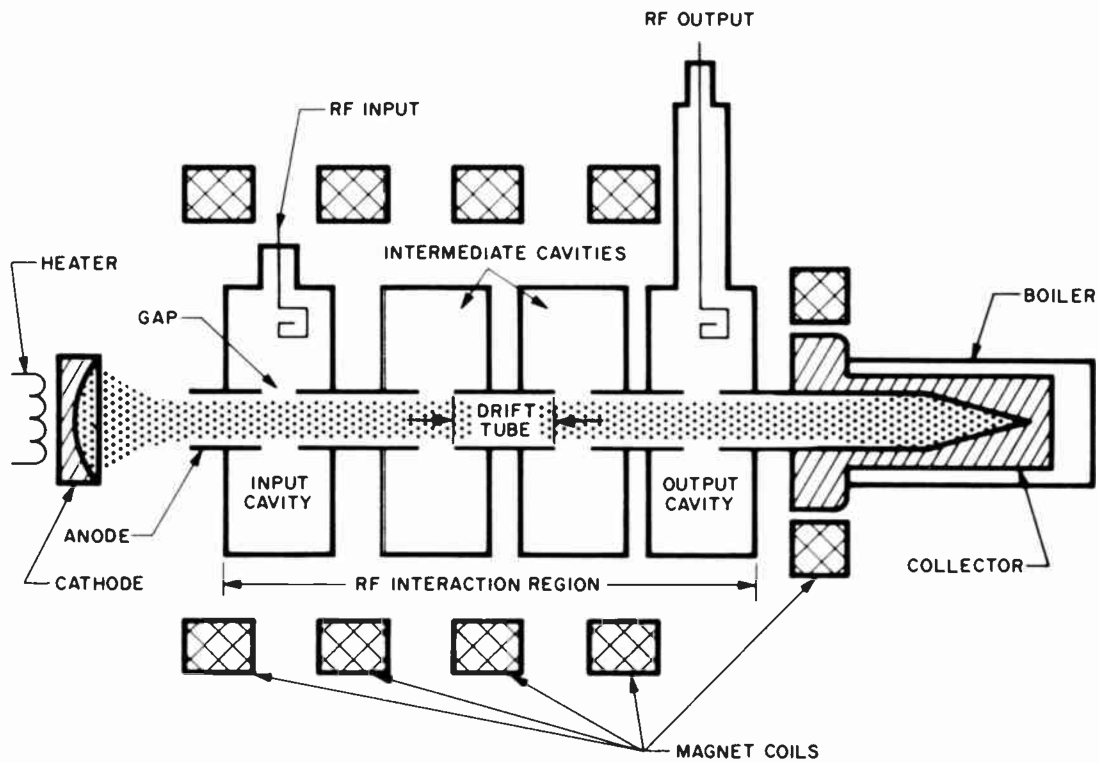

Figure 64. Principal elements of a klystron.

electric field between the cathode and anode and is directed into the RF interaction region, as shown in Fig. 64. An external magnetic field is employed to prevent the beam from spreading as it passes through the tube. At the other end of the tube, the electron beam impinges on the collector electrode, which dissipates the beam energy and returns the electron current to the beam power supply.

The RF interaction region, where the amplification occurs, contains resonant cavities and field-free drift spaces. The first resonant cavity encountered by an electron in the beam (the input cavity) is excited by the UHF signal to be amplified, and a RF voltage is developed across the gap. Since electrons approach the input-cavity gap with equal velocities and emerge with different velocities, the electron beam is said to be *velocity modulated*. As the electrons travel down the drift tube, bunching develops, and thus the density of electrons passing a given point varies cyclically with time.

The RF energy produced by this interaction with the beam is extracted from the beam and fed into a coaxial or waveguide transmission line by means of a coupling loop in the output cavity. The DC beam input power not converted to RF energy is dissipated in the collector.

The cavities can be mounted external to the klystron as shown in Fig. 65 or can be included in the vacuum envelope as shown in Fig. 66.

All cathodes have optimum ranges of operating temperature. The operating temperature of the cathode

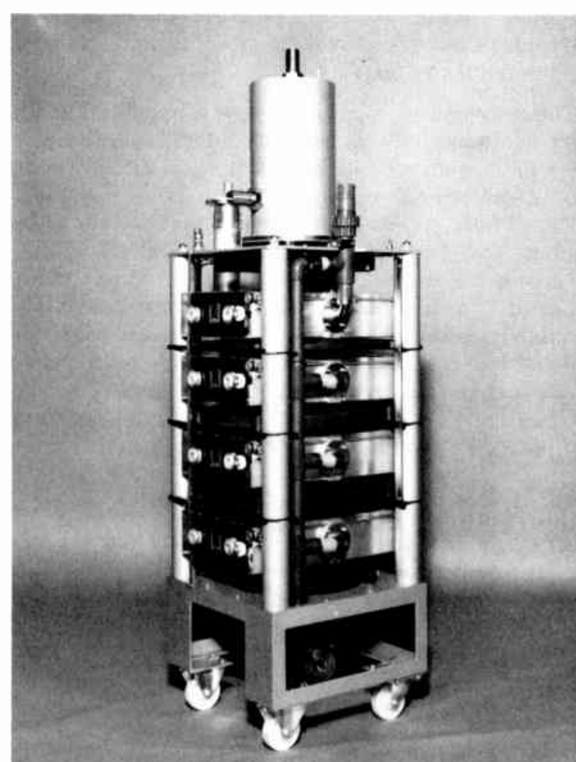

Figure 65. External cavity klystron.

Figure 66. Integral cavity klystron.

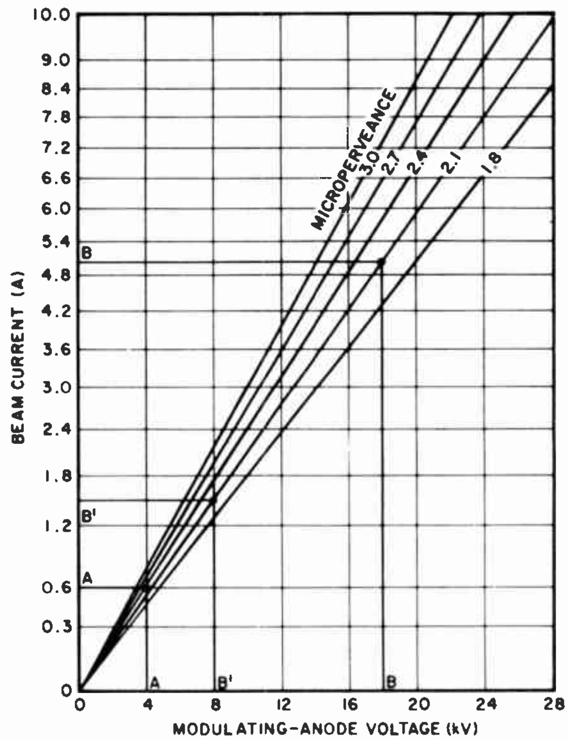

Figure 67. Beam current variation with modulating-anode voltage.

must be high enough to prevent variations in heater power from affecting the electron emission current (beam current) in the klystron. However, the temperature of the emitting surface must not be higher than necessary, since excessive temperature can reduce cathode life.

Perveance and the Modulating Anode

Perveance is a function of the geometry of the cathode-anode structure. In klystrons manufactured today, there are two electrodes which may control the beam current: The modulating anode, and a lower voltage (0 to 1,400 volts) electrode typically used for pulsing the beam current. (Examples are: Beam Control Device (BCD), Annular Control Electrode (ACE), and Annular Beam Control (ABC). If the low voltage electrode is connected to the cathode, the modulating anode voltage controls beam current which can be calculated using the following equation:

$$I_b = K \times E^{3/2}$$

where: K = Perveance constant of the klystron
I_b = Beam current in amperes
E = Beam voltage

Fig. 67 shows the relationship between beam current and voltage described in the above equation. Two examples for using the graph are given. In example A, if a modulating anode of 4,000 volts with respect to the cathode beam voltage produces a beam current of 0.6 amp, the intersection point lies on the 2.4 microperveance line. The perveance is expressed as 2.4×10^{-6} or 2.4 micropervs. Operating condition B illustrates a practical television transmitter situation in which a common beam supply of 18 kilovolts is used to power both the visual and aural klystron. At 18 kV, the visual tube operates at a beam current of approximately 5.0 amperes if the modulating anode is connected (through an isolating resistance) to the body of the tube, and the perveance is 2.1 micropervs. Since the aural output power required is much less, the DC input power is less than that required to operate the visual tube. Points B' indicate that if the modulating anode is supplied with only 8 kV (through a voltage divider) then the intersection with the 2.1 microperv line yields a beam current of only 1.5 amperes, thus accomplishing the necessary reduction of input power for aural service.

Magnetic Field

Electromagnetic coils are placed around the klystron to develop a magnetic field along the axis of the electron beam which controls the size of the electron beam and keep it aligned with the drift tubes. If the magnetic field is interrupted or insufficiently controlled the electron beam will land on surfaces other than the collector and may destroy the tube.

Cavity Tuning

The resonant frequency of each of the cavities of a klystron can be adjusted in two ways to the operating frequency of the transmitter. The inductance can be changed by changing the volume of the cavity in external cavity klystrons, or the capacitance of the drift-tube gaps can be changed in integral cavity klystrons.

Cavity/Transmission Line Coupling

Fig. 68 illustrates magnetic-loop coupling, where the RF energy is fed through a coaxial line with its center conductor inserted into the klystron cavity. The end of the center conductor is formed into a loop. This forms a simple one-turn transformer which couples RF energy into or out of the cavity through a coaxial transmission line. Intermediate cavities may have their loops coupled into RF loads to vary the "Q" of the cavities to change the overall bandpass characteristics of the klystron.

Effect of RF Drive Power on RF Output Power

Fig. 69 shows RF output power as a function of RF drive power applied to the tube. From this curve, we see that when the RF drive power level is low, the RF output power is low. As the level of RF drive power increases, RF output power increases until an optimum point is reached. Beyond this point, further increases in RF drive power result in less RF output power. Because of these effects, two zones and one point have been labeled on the curve. In the zone labeled "Underdriven", RF output power increases when the RF input power is increased. The point labeled "Optimum" represents the maximum RF output power obtainable. Klystrons are said to be saturated at this point, since any further increase in RF drive only decreases the RF output power. The zone formed at the right side of saturation is labeled "Overdriven". To obtain maximum RF output power from a klystron, sufficient RF drive power must be applied to the tube to reach the point of saturation on the curve. Operating at RF drive levels beyond the saturation point will only overdrive the klystron, decrease RF output power, and increase the amount of beam interception at the drift tubes (body current). Klystrons tuned for TV service are operated within the underdriven zone of Fig. 69.

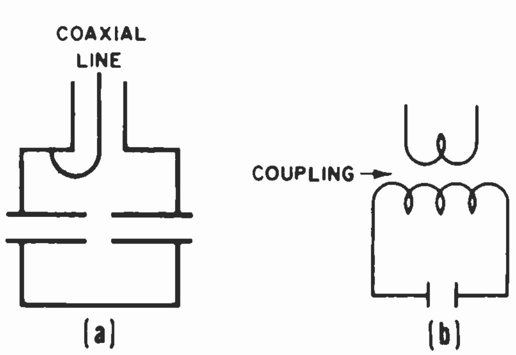

Figure 68. Loop coupling and equivalent circuit.

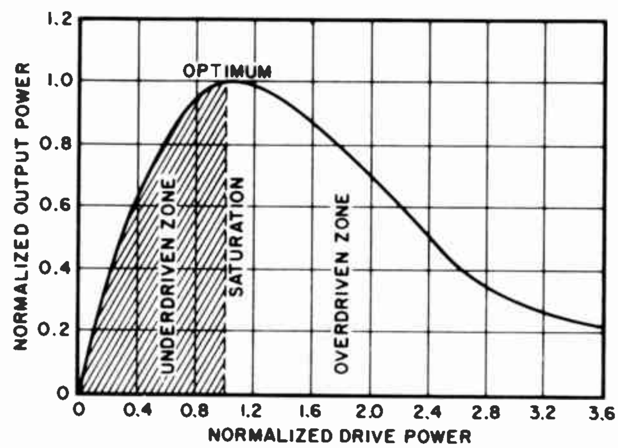

Figure 69. RF output power as a function of RF drive power.

Fig. 70 shows how RF output power changes with various levels of RF drive power applied to a klystron under different tuning conditions. Point A represents the drive saturation point for a synchronously-tuned tube. Point B shows a new point of saturation that is reached by tuning the penultimate (closest to the output cavity) cavity to a somewhat higher frequency. By tuning the penultimate (next to last) cavity still further, Point C is reached. There is a point, Point D, where increasing the penultimate cavity frequency no longer increases RF output power. Instead, it reduces the output power as shown at point E.

Klystron Efficiency

Klystron "efficiency" has often been measured by dividing Peak RF output power by the DC power input. Since klystrons have been compared using "peak RF output power" the term efficiency is not valid because it is possible to have greater than 100% efficiency with some amplifiers.

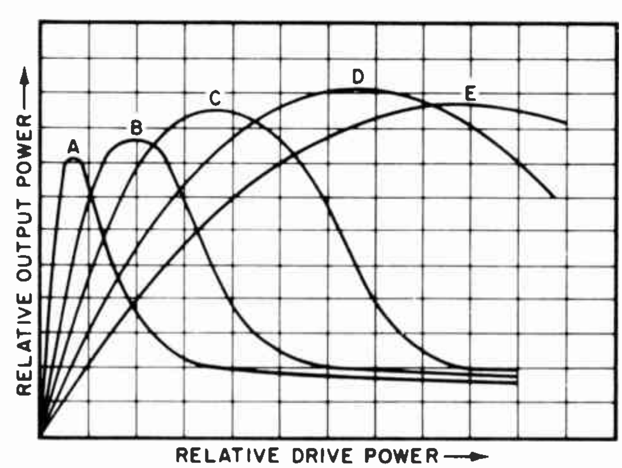

Figure 70. Output power variation with drive power under different tuning conditions.

The term "Figure of Merit" is a more valid terminology and is calculated as follows:

$$\text{Figure of Merit} = \frac{\text{RF power output}}{\text{DC input power}}$$

where DC input power is measured using a 50% APL signal and RF power output is the peak of sync value for visual.

This is a measure of the klystron stage only. Total transmitter or plant efficiency would include the power consumed by the magnets, heat exchanger blower, pumps, driver, and control circuits.

Tuning

There are a number of methods of tuning klystrons. They are:

- High gain tuning for monophonic aural service
- Broadband for MTS aural service
- Visual service with fixed beam current
- Visual service for pulsed beam current
- Tuning for integral cavity klystrons employing the variable visual coupler

It is best to consult the transmitter manufacturer for specific information regarding tuning and mode of operation desired. However, some basic information can be presented here:

AMPLIFIER DEVICE	FIGURE OF MERIT
TETRODE	.9 – 1.0
INTEGRAL CAVITY KLYSTRON	.65 – .75
EXTERNAL CAVITY KLYSTRON	.65 – .75
KLYSTRODE OR IOT	1.1 – 1.3
DEPRESSED COLECTOR KLYSTRON	1.2 – 1.3

General Klystron Tuning Considerations

The output cavity is generally tuned to the carrier frequency. It is essential to operate with the coupling loop adjusted so the output cavity slightly over coupled. Fig. 71 shows the relationship of output power to proper coupling loop adjustment. If the coupling loop is adjusted so that the cavity is under-coupled, arcing and ceramic fracture resulting in klystron failure may occur.

The input coupling is adjusted for the best tradeoff of minimum reflected power and best overall bandpass.

Intermediate cavities may be externally loaded to lower Q and increase bandwidth.

The penultimate or next to last cavity is tuned above the passband. The integral cavity klystron penultimate cavity tuning location is generally 10 MHz to 15 MHz above the passband, while the tuning location for the four cavity external cavity klystron is 6 MHz to 8 MHz above the passband.

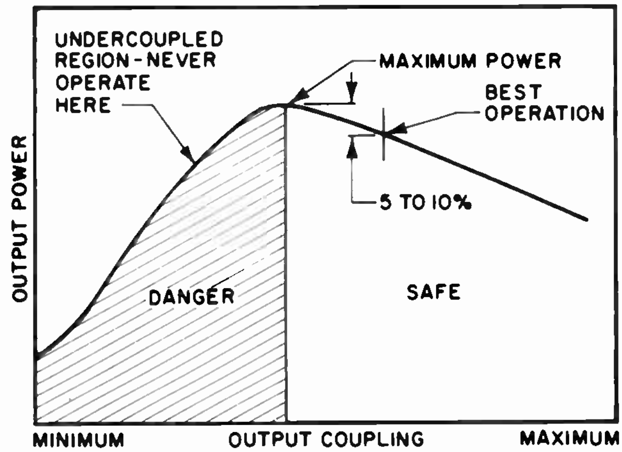

Figure 71. Adjustment of output coupling control.

Variable Coupler for Integral Cavity Tubes

The purpose of the variable load coupler is to improve the klystron Figure of Merit. This is accomplished by raising the impedance presented to the klystron. The variable load coupler as shown in Fig. 72 has a shorted transmission line stub which is tuned beyond a quarter wavelength to present a capacitive susceptance load to the output transmission line. This capacitance susceptance (or inductive reactance) in parallel with the load impedance is transformed back through an approximate ⅜-wavelength to present a substantially resistive load to the output coupling loop of the final klystron cavity.

Transmission line formulas aid in the analysis of how the variable coupler functions.

For example, assume that the transmitter and variable load coupler are terminated with a 50 ohm impedance. If the tuned short is exactly 0.25 wavelength long, the equivalent load impedance at the junction of the tuned short can be represented by:

This impedance, transfored back to the klystron ⅜-wavelength away is given by the equation:

$$Z_{in} = Z_0 \frac{[Z_L + jZ_0 \tan\beta l]}{[Z_0 + jZ_L \tan\beta l]}$$

In this case Z_L = 50 ohms and Z_0 = 50 ohms.

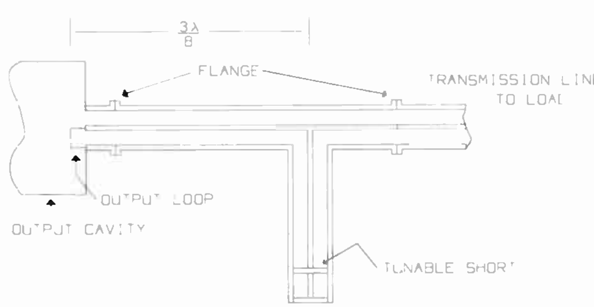

Figure 72. Variable visual coupler.

However, when the tuned short is longer than 0.25 wavelength, an inductive reactance is added in parallel with the 50 ohm load impedance.

Assume for example that the tuned short was lengthened such that the resultant load impedance was now 50 − j10 ohms.

Using the same equation, where $\beta = 2\pi/$(one electrical wavelength) and l = the electrical wavelength between the equivalent load impedance and the klystron.

In this case, l = ⅜-wavelength, $Z_0 = 50$, and $Z_L = 50 + j10$.

Solving this equation yields a new impedance at the klystron of about 61 ohms. Thus the impedance has been raised via the tuning stub. To raise the impedance further, the tuning short must be lengthened again.

The iterative procedure of small adjustments which lengthen the tuning stub allows a suitable compromise between efficient operation and klystron safe operation.

Beam Current Pulsing

For a number of years klystrons were operated at maximum beam current. The mod anode was tied to ground through a resistor. Early model klystrons would draw approximately 7.5 amps at 24 kV for 55 kW peak-of-sync visual operation. The development of more efficient klystrons allowed the reduction of beam currents to near 6.3 amps for 55 kW. With saturation set at 115% of needed power, the klystron was operated in the more linear part of the curve, but excess beam current was being consumed.

Operating the klystron at saturation will improve efficiency but requires more linearity and phase compensation. By using a pulser to switch to a higher beam current during sync and back to a lesser current during video the average beam current is significantly reduced.

Fig. 73 shows the horizontal line timing. Observe that sync is 8% of the duty cycle and video is the remaining 92% of the transmitter signal.

The practical limit of reduction of the video beam current is the point at which tip of burst and back porch signal distortion is not correctable.

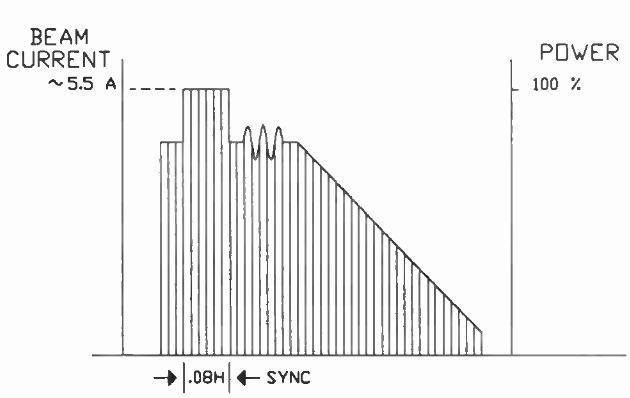

Figure 73. RF envelope vs. beam current.

With beam current pulsing, the effective "Q" of the electron beam and cavity combination is altered. This results as a passband tilt from visual carrier down to the upper edge of the passband. This requires readjustment of the cavities to obtain a flat response. Tilt of as much as 7 dB has been observed. Tuning for high efficiency with beam current pulsing can reduce the gain of a klystron.

Consider the following example of a typical 60 kW external cavity klystron.

In static (nonpulsed) operation, the tube is supplied with enough beam current to saturate at 100% power and a small amount of headroom added for changes in beam voltage. In pulsed operation only enough beam current is supplied to saturate at 100% power during sync. This would normally correspond to about 5.5 amps for a wideband external cavity klystron. The amount of beam current reduction during the video picture is dependent upon operating channel, klystron perveance, available drive power, and precorrection capability.

The optimum value of beam current must be experimentally determined. However, figures of merit of 77% have been achieved. It is important to note that the absolute value of the pulsed efficiency is directly proportional to, and therefore limited by, the efficiency obtained for nonpulsed operation. In order to prevent severe burst and back porch distortion, a small amount of amplifier headroom is needed, approximately 2% to 5%. Typical values of beam current during the video portion of the waveform are 3.4 amps to 3.9 amps.

Pulsed operation for klystrons is accomplished by connecting the beam control electrode to a voltage source of 0 to −1,400 volts with respect to the cathode voltage. During sync, the pulser operates at zero volts. During the video portion of the signal, values of −400 volts to −800 volts are used to achieve reliable high efficiency operation.

In some transmitters, sync is actually reduced or removed from the input video. As the beam current is pulsed, the klystron gain change increases the RF power to produce the proper sync level.

For pulsed operation, DC input power is calculated as follows:

$$\text{DC input power} = \text{Beam voltage} \times [(\text{Beam } I_{sync} \times \text{Sync duty cycle}) + (\text{Beam } I_{video} \times \text{Video duty cycle})]$$

In this example,

$$\text{DC input power} = 24\,[(5.5 \times .08) + (3.7 \times .92)] = 24 \times 3.84 = 92.2\ \text{kW}$$

$$\text{Figure of merit} = 60/92.2 = 0.65$$

Effect of Pulsing on Transmitter Precorrection

With increasing RF drive level, klystron amplifiers exhibit a RF phase change in addition to amplitude compression. This phase change is called incidental phase modulation (ICPM). Very little can be done to reduce ICPM by klystron tuning or selection of magnet current. Also, incidental phase distortion increases rapidly near saturation of the klystron.

The RF phase shift through the klystron will also change as beam current is varied. When the klystron is pulsed during sync the change in beam current causes the phase of the signal to change to a new value. When the klystron switches back to the video current level the previous value of phase returns. To combat this problem, ICPM correctors have been developed. These correctors generally operate at the exciter intermediate frequency (IF) and introduce a correction signal equal and opposite to the distortion produced by the klystron. A phase modulation stage in the exciter may be keyed by sync and adjusted to pre-correct for incidental phase distortions caused in the klystron during pulsing. This is most commonly done at the IF level because of the ease of implementation.

When amplifiers are operating very close to saturation during the color burst, more differential gain and differential phase correction may be needed. However, modern exciters can fully precorrect these conditions.

For maximum efficiency, operate the tube at saturation at sync tip. In a pulsed transmitter, the color burst and black picture content are near saturation as well.

The vector diagram of Fig. 74 illustrates first order klystron nonlinearities and the operation of the ICPM and linearity correctors. The desired TV output signal is represented by an amplified version of the desired instantaneous phasor. However, the transmitter output signal is phase shifted by a phase error and compressed in amplitude. To compensate for this, the signal in the exciter is precorrected by an amplitude expansion, and a correction in quadrature. When the resultant signal is amplified, the output signal will be a replica of the desired TV signal.

Sync pulse oscillations may appear as ringing on the sync pulse when the klystron is operated at saturation. This may exhibit itself as a tearing of the picture or sync. This ringing is believed to be caused by secondary electron feedback enhanced by the reverse gain of the klystron cavities. Rebiasing the tube slightly out of saturation will eliminate the ringing.

Multi-stage Depressed Collector (MSDC) Klystrons

Klystron amplifiers operate by converting energy from a beam of electrons to RF output power. At full output power, about half of the beam power is converted to RF output power. Correspondingly, half the DC input power remains on the beam as it exits the cavity region. In a standard klystron this "spent electron beam" energy is dissipated as heat. The MSDC klystron, however, operates on the spent electron beam, recovering its energy to reduce the dissipated heat.

After the electron beam has completed its job by providing the desired output power, significant energy still remains in the electron beam. The interaction process has produced a wide range of velocities for individual electrons, from nearly stopped to up to twice the initial energy.

In the early 1970s, researchers at NASA investigated collector designs. In 1984, NASA provided the depressed collector technology for development of UHF-TV klystrons. Power recovery in the collector region is accomplished by decelerating the electrons in the spent beam. This can be done by providing an electric field in the collector such that the electrons are slowed before they strike the collector wall. A collector composed of multiple elements is utilized, with each element operated at a negative potential with respect to ground potential.

Consequently, the collector potentials are referred to as being *depressed* below ground. The collector element geometry was carefully selected to provide an electric field shape which would sort the impinging electrons according to their velocity, reducing their energy as much as possible, yet ensuring that all electrons would strike one of the elements and not

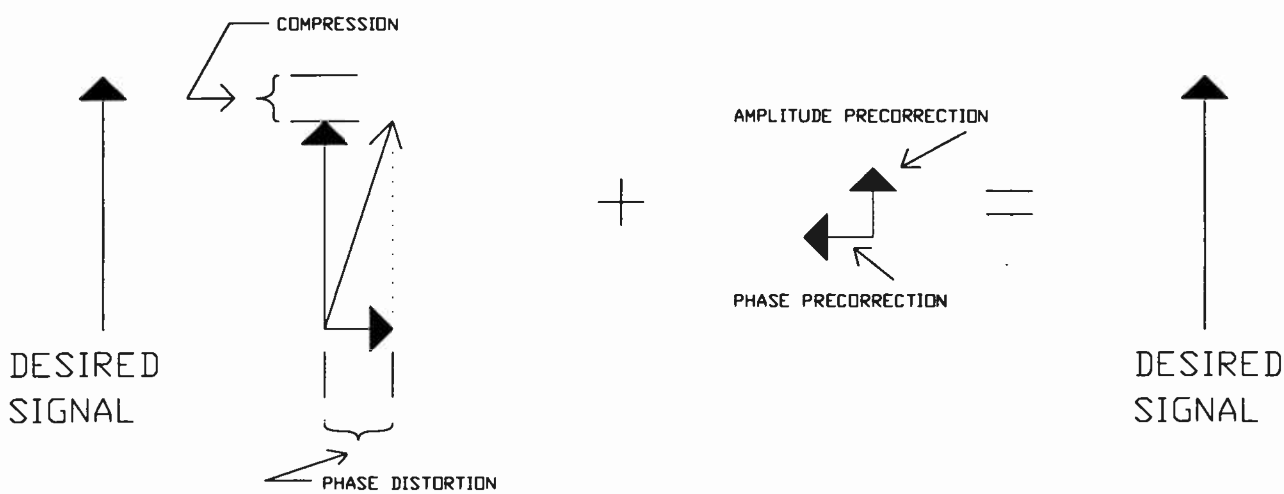

Figure 74. Vector representation of precorrection.

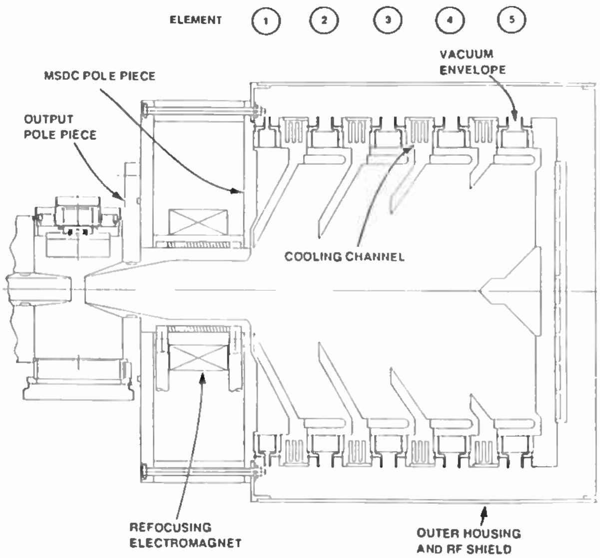

Figure 75. UHF-TV MSDC design.

be reflected back into the electron beam. Modern computer aided techniques facilitated this design effort.

Fig. 75 shows the resulting collector configuration. The collector is composed of five elements and is designed to operate with equal voltages between elements. For the 60 kW klystron, the voltage per collector stage is typically 6,250 volts. This means that element 1 is at ground potential, element 2 is at −6.25 kV, element 3 is at −12.5 kV, element 4 is at −18.75 kV, and element 5 is at full cathode potential of −25 kV.

To make sure that the electron beam is optimized before entering the collector region, a refocus coil is provided just ahead of the collector.

The significant benefit of the depressed collector klystron is the reduction in power consumption for a given power output. The individual collector beam currents will vary depending on the picture level being transmitted. Since the recovering of the spent beam takes place in the collector, it has essentially no impact on the tuning and normal precorrection of the klystron. Therefore, a multi-stage depressed collector klystron tunes the same as a standard klystron and requires the same precorrection as a standard klystron. The depressed collector technique can be applied to either external or integral cavity klystrons. The cooling of the cavities is not affected by the addition of the collector.

To date, these klystrons require the use of a vacuum ion pump. Since the power dissipated in the collector is reduced, only six gallons per minute of high purity water coolant is needed. Although the efficiency performance of the MSDC is dependent upon the transmitter configuration, figures of merit of 1.2 to 1.6 have been obtained in transmitter installations in the field.

Transmitter Design Using Multiple Depressed Collector Klystrons

The primary differences in this transmitter from a standard klystron transmitter are in the beam supply, the cooling system. Fig. 77 shows the power connections made to a MSDC klystron. Since the RF performance of the MSDC klystron is the same as the standard klystron, there are no differences in the RF driver chain.

The cooling system of a MSDC klystron transmitter uses a two-stage heat transfer system as shown in the cooling system block diagram of Fig. 78. The reason a two-stage system is chosen is to allow outside heat exchangers to be used. The cooling system consists of a high purity water loop and a glycol-water mixture

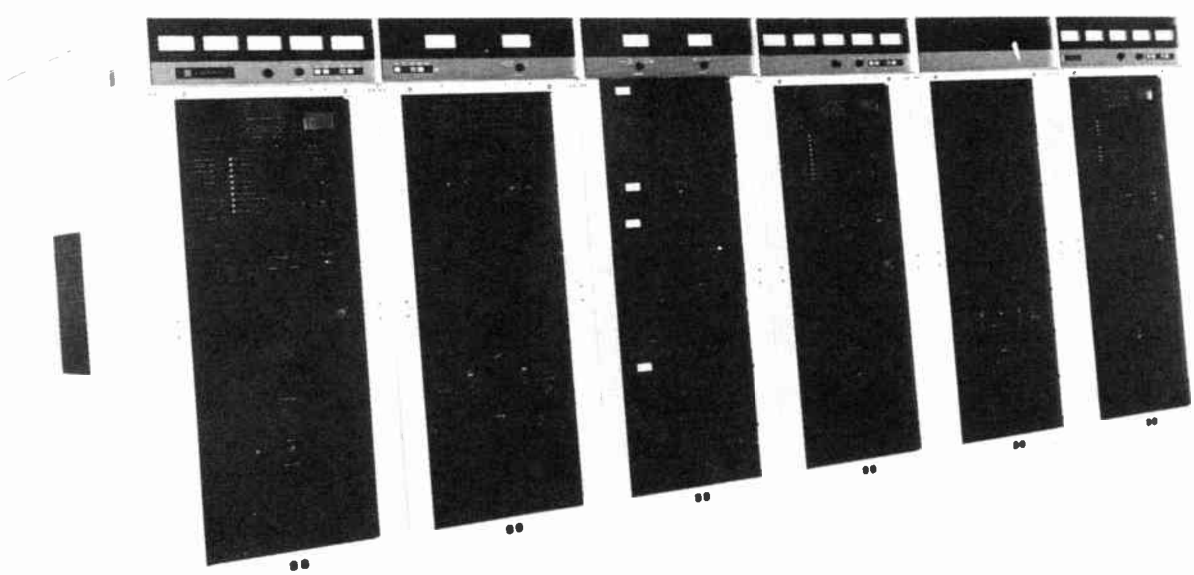

Figure 76. MSDC transmitter.

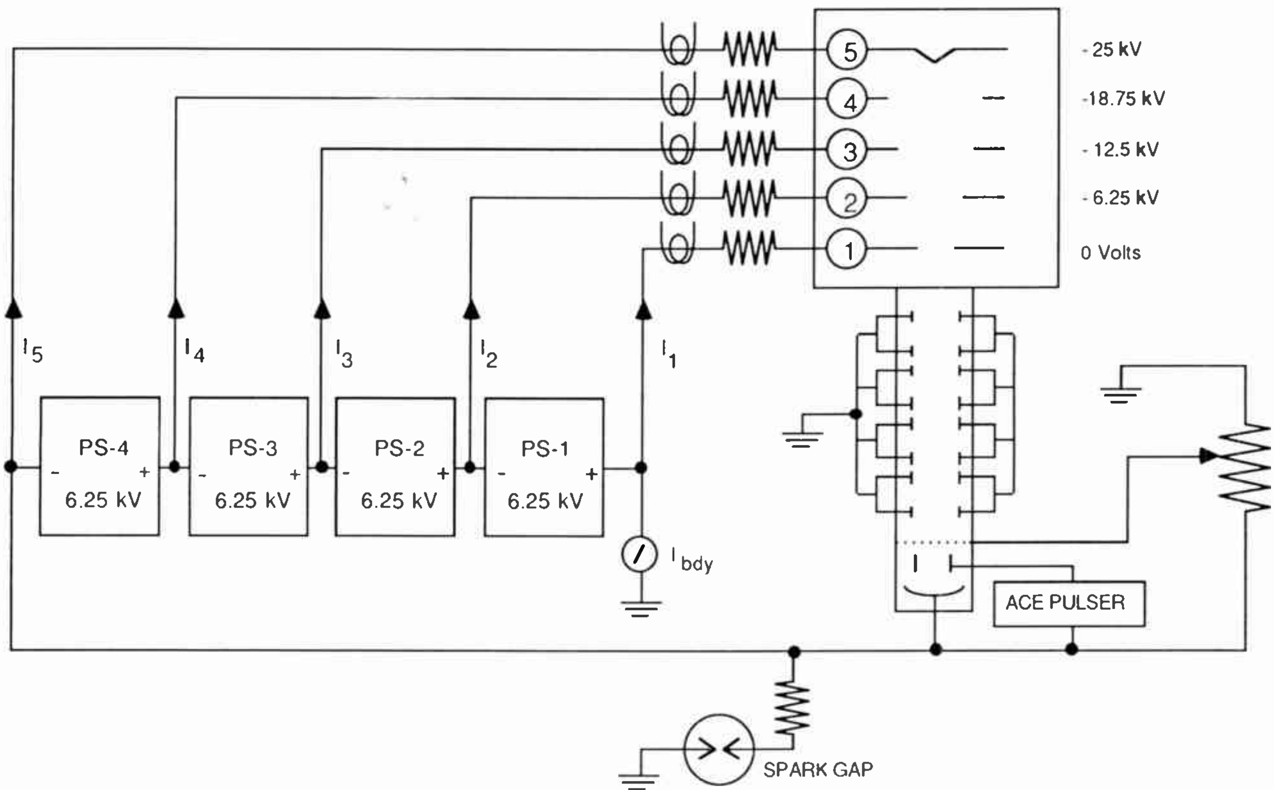

Figure 77. MSDC high voltage connections.

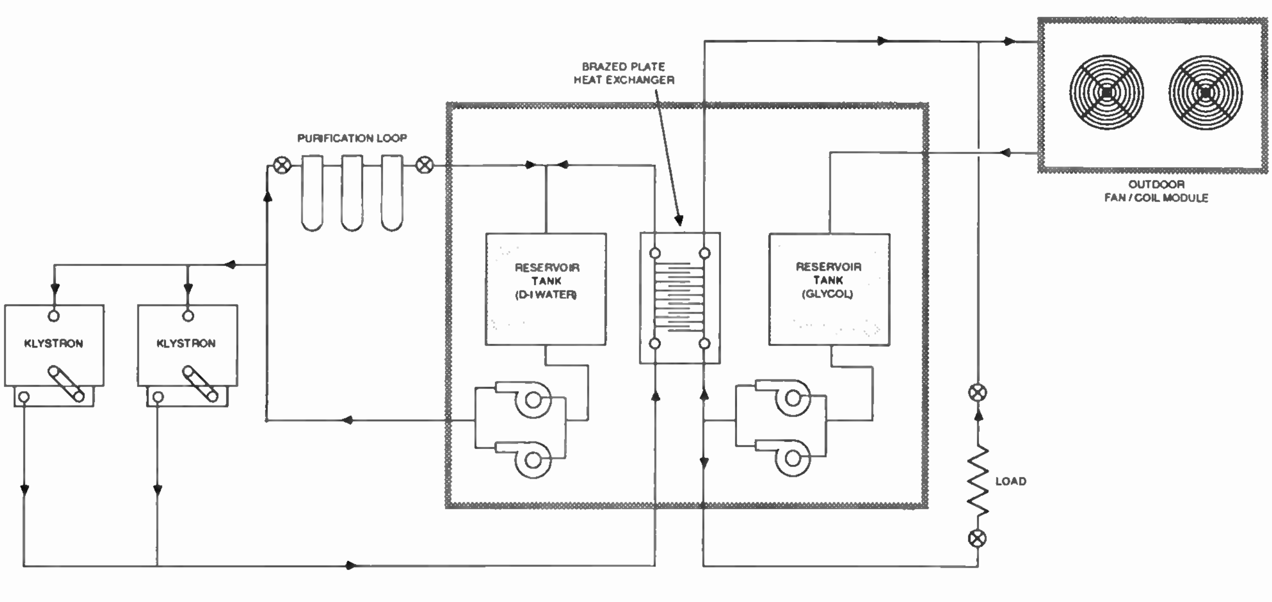

Figure 78. TV-60UM heat exchanger system.

loop. High purity water (resistivity of 200,000 ohm-cm or more) must be used with the cooling system to prevent current flow between collectors. To remove ions, free oxygen and other possible contaminants from the water, a three-stage filter system (purification loop) is used. The filter cartridges sample part of the water flow so the whole system is continuously cleaned. The filter cartridges can be replaced without taking the transmitter off the air.

Separate beam supplies for each klystron are frequently used in TV transmitters.

Since the currents from the beam supplies will change dependent on the power level, there will be video frequency currents present on the power supply leads. Therefore, sufficient bypassing and power supply high voltage wire shielding is required.

Monitoring each section of the beam supply current is required to obtain the currents for power dissipation calculations.

Protection circuitry needs to include magnet overcurrent and undercurrent trip points, beam supply overcurrent and overvoltage sensors (for each collector), water flow sensors, arc detectors within the 3rd and 4th cavities, and sufficient interlocks to prevent personnel from accidentally coming in contact with high voltage.

KLYSTRODE®

The Klystrode® basically combines features of a tetrode and a klystron. Hence, the name Klystrode® was created.

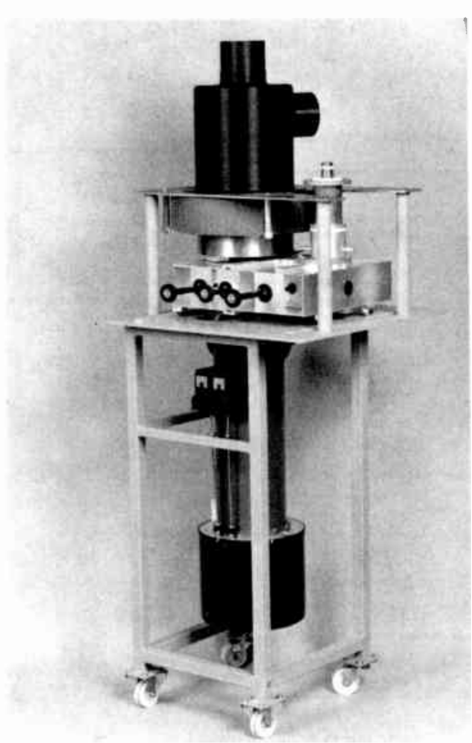

Figure 79A. Klystrode.

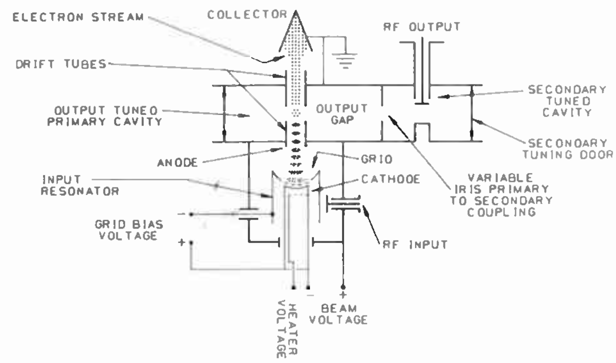

Figure 79B. Klystrode schematic.

A Klystrode® is shown in Fig. 79A. It is composed of an electron gun very similar to a klystron, a control grid, an input cavity, accelerating anode, drift tube, output cavity, and collector. It is physically smaller than a klystron and weighs approximately 90 pounds including its circuit assembly. The tube itself weighs about 45 pounds.

Refer to Fig. 79B. The electron beam is formed at the cathode, density modulated with the input RF signal applied to a grid, and then accelerated through the anode aperture. In its bunched form, the beam drifts through a field-free region and then interacts with the RF field at the drift tube gap in the output cavity. Power is extracted from the beam in the output cavity in the same manner as a standard klystron.

RF input power is applied to the control grid via a resonant cavity. The grid is usually biased negatively. The first part of the tube may be thought of as a triode with a perforated anode through which the electron beam is guided by electric and magnetic fields. The beam is bunched, or chopped, at the radio frequency and is accelerated by the high anode potential. It passes through the anode extension cylinder, which is an electrostatic shield, and then interacts with the RF field in the output gap. The spent beam is dissipated in the collector, separate from the output RF interaction circuit.

The tuned input and output circuits are external. The RF input circuit is a 4 stub tuner which matches the drive source to the high impedance grid. Also included is a circuit which provides a DC block for high voltage. The output circuit cavity is clamped to the body of the tube with techniques similar to those used for external cavity klystrons. The output circuit is double-tuned to achieve the bandwidth required for visual service. The double-tuned output circuit consists of a primary cavity clamped to the body and an iris-coupled secondary cavity. The output transmission line is probe coupled to the electric field in the secondary cavity. Variable controls are used to adjust primary and secondary cavity resonant frequency and the iris coupling.

The grid structure intercepts some electrons causing grid current to flow. On 60 kW models, some material from the cathode migrates to the grid and must be periodically boiled off. A design goal of future Klystrodes® is to eliminate this periodic procedure.

Because the tube only has two cavities it is much shorter than a klystron. The magnetic field requirements of the tube are about 7 volts at 30 amps.

The high voltage circuitry is contained within a shielded compartment on top of the input circuit. This circuitry consists of various filters to contain the UHF fields and prevent instabilities at video frequencies. High voltage, grid bias, and filament power enter this section via high voltage cables.

The fundamental benefit of the Klystrode® is that it may operated as a Class B amplifier. Thus the beam current is proportional to the RF drive signal. Although the efficiency performance of the Klystrode® is dependent upon the transmitter configuration, figures of merit of 1.2 to 1.4 have been obtained for 60 kW visual service from transmitter installations in the field.

In aural service, the Klystrode® is tuned the same as for visual service.

Power gain in either type of service is about 23 dB. Thus drive power is about 300 watts for the visual and 30 watts for the aural (assuming 10% nominal aural power).

The transfer characteristics of the Klystrode® is also a combination of a klystron and a tetrode. A typical transfer curve is shown in Fig. 80. The nonlinearity at white picture power levels resembles that of a tetrode and the nonlinearity approaching peak output power also resembles a tetrode. The amount of nonlinearity is similar to a tetrode and the shape of the precorrection curve is "S" shaped.

Klystrodes® at 15 kW, 40 kW, and 60 kW visual peak sync power levels have been constructed and are in service.

The Klystrode® may also be used as a multiplexed amplifier. This means the diplexer may be eliminated. For example, a tube may be used as a 30 kW visual with a 10% aural signal. Intermodulation products at ±920 kHz from visual carrier generated by the tube can be precorrected by low level IF circuitry.

Cooling of the Klystrode® at the 60 kW power level requires about 25 gallons per minute of water for the collector. The body of the tube is also water cooled.

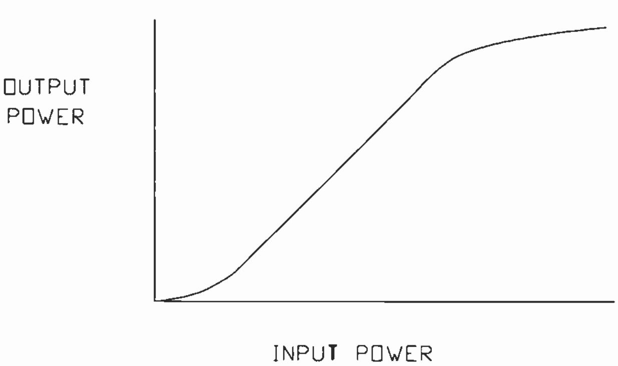

Figure 80. Klystrode transfer curve.

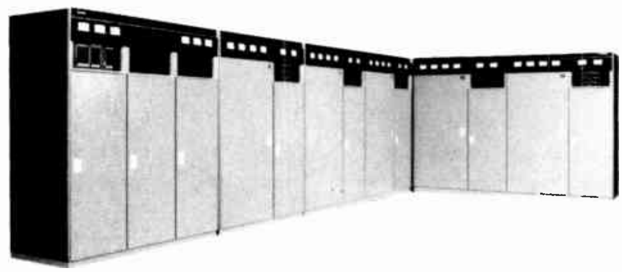

Figure 81. Klystrode transmitter.

A 50/50 water/glycol solution is typically used without any special water purification. The RF input and output cavities are air cooled.

The 15 kW and 40 kW Klystrodes® may be air-cooled. The volume of air and air pressure needed are comparable to a tetrode of similar power.

Two versions of Klystrodes® are needed to cover the entire UHF operating band.

To date, these devices require the use of a vacuum ion pump.

Transmitter Design Using Klystrode®.

Support circuitry for the Klystrode® consists of providing the necessary drive power, precorrection, different types of power supplies necessary, and the protection circuitry. A Klystrode® transmitter is shown in Fig. 81. A Klystrode® transmitter block diagram is shown in Fig. 82.

The Klystrode® uses a beam voltage of 32 kV. Since the beam current changes with modulation, there will be video frequency currents required from the beam supply. The beam supply must be designed to provide excellent regulation from no load to full load and to also provide a low source impedance for all video frequencies. In the event of a high voltage failure, the conventional beam supply should limit the energy dumped into an arc. The Klystrode® supply, being stiffer, requires a triggered "crowbar circuit" to limit the beam supply arc energy. A block diagram of a crowbar circuit is shown in Fig. 83.

The grid bias supply of −10 to −70 volts, with respect to the cathode, typically should "float" with the beam voltage. A simple method of developing the grid voltage is to use zener diodes connected between the power supply and the tube cathode connection and tap the grid to the appropriate zener to obtain the desired bias current. As with klystrons, the Klystrode® magnet power supply must have sufficient energy storage that the beam remains focused until the beam decays. Also, a power supply for the ion vacuum pump is needed with appropriate sensors for the protection circuitry.

Other protection circuitry provided in the Klystrode® transmitter is similar to that needed in the klystron transmitter.

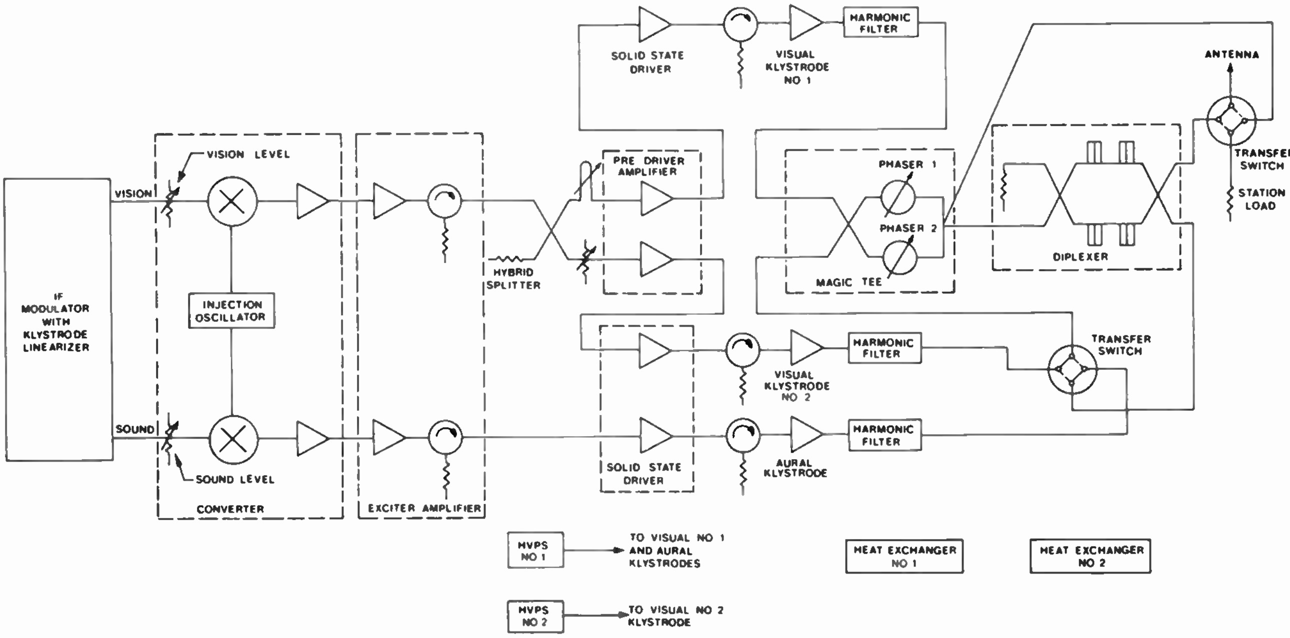

Figure 82. Klystrode transmitter block diagram.

TRANSMITTER COMBINING CIRCUITS AND RF SYSTEMS

A typical RF system for a transmitter will consist of hybrid combiners, (if more than one amplifier cabinet is used), harmonic filters, −3.58 MHz notch filter, and diplexer to combine visual and aural.

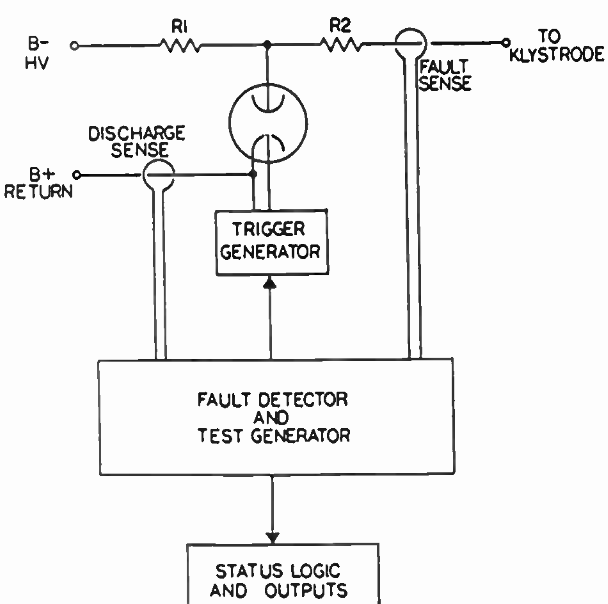

Figure 83. Triggered crowbar circuit.

At VHF frequencies the −3.58 MHz notch filter, harmonic filters, and diplexers are all quite large and are typically supplied as individual units. In some cases, the −3.58 MHz filter is incorporated with the notch diplexer. However, at UHF frequencies, components are smaller and waveguide technology is typically used so the −3.58 MHz notch filter, the notch diplexer aural cavities, and associated hybrids are often integrated into one assembly. Multiple aural notch cavities may be used at UHF frequencies to optimize multichannel TV sound performance and for power sharing when very large powers are used.

This section will review hybrid combiners, notch diplexers, switchless combiners, and Magic Tee RF systems.

Two different types of combining circuits must be considered:

1. Combining of sources with the same frequency (i.e., multiple power amplifiers).
2. Combining of sources with different frequencies (i.e., visual and aural).

For combining of sources of the same frequency, 90° 3 dB hybrid couplers have found almost universal acceptance. Fig. 84 shows the physical model of a 90° 3 dB hybrid coupler.

A 3 dB hybrid coupler consists of two identical parallel transmission lines mounted in a common outer conductor and coupled over a length equal or approximately equal to the quarter wavelength of the operating frequency.

The construction is symmetrical, i.e., both inner conductors have the same physical dimensions with

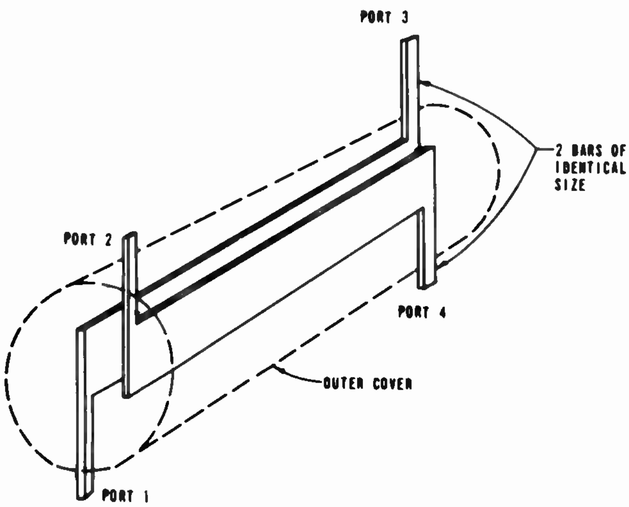

Figure 84. 90° 3 dB hybrid coupler.

respect to the outer conductor. The 3 dB hybrid coupler can be used as a power splitter or as a power combiner. Fig. 85 shows the 3 dB hybrid coupler as a power splitter, and Fig. 86 shows the 3 dB hybrid coupler as a power combiner.

One of the common uses of the 3 dB hybrid is to combine two frequencies that are relatively close (visual and aural) in a back-to-back hybrid configuration called a notch diplexer. The first step in building a notch diplexer can be shown by combining two 3 dB hybrids back to back as shown in Fig. 87A.

The input hybrid will act as a splitter while the hybrid at the output will act as a combiner. The visual signal is inserted into the left hybrid and will appear at the antenna port as shown in Fig. 87B.

If we now add the aural signal as in Fig. 88, we can see that it is passed through the 3 dB hybrids but does not appear at the antenna port as required.

If we now add two very high Q notch cavities tuned to the aural frequency, as depicted in Fig. 89, we can introduce a short circuit to the aural frequency. These shorts circuits cause the aural signal to be reflected back into the 3 dB hybrid where the same 3 dB hybrid now effectively acts as a power combiner and passes

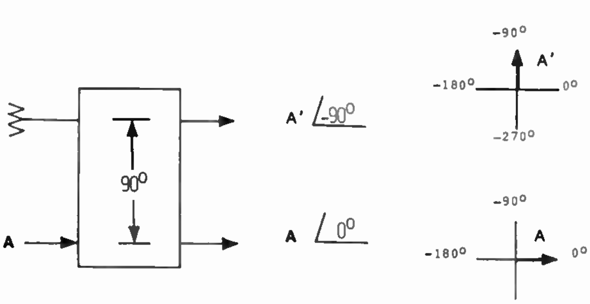

Figure 85. 3 dB hybrid as a power splitter.

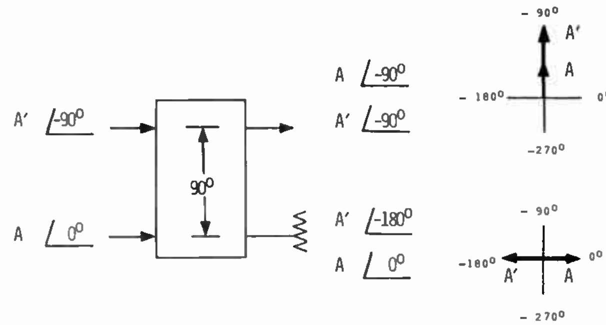

Figure 86. 3 dB hybrid as a power combiner.

the combined aural signals to the antenna port along with the visual signal.

The aural notch cavities are theoretically not seen by the visual signal since they are high Q cavities tuned to the aural frequency. In reality, the aural cavities do cause some amplitude roll-off and group delay of the high end of the visual passband.

Another use of the back-to-back hybrids can be seen in Fig. 90 which shows a single signal source driving a power splitter (Hy1) and dual amplifiers (A1 and A2). Real world amplifiers do not have exactly the same gain and phase shift through the amplifier especially if the amplifier has tuning controls. This hybrid arrangement can be used for visual or aural signals. Gain (AT1 and AT2) and phase adjustments are used to keep the amplifiers' output signals (A1 and A2) at equal output power and 90° phase difference so that they can be properly combined by the power combiner (HY2) with a minimum of reject load power.

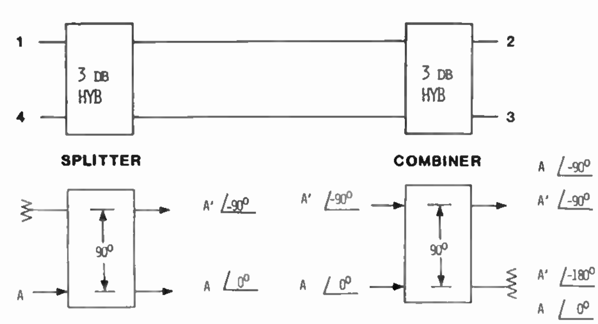

Figure 87A. Back-to-back hybrids.

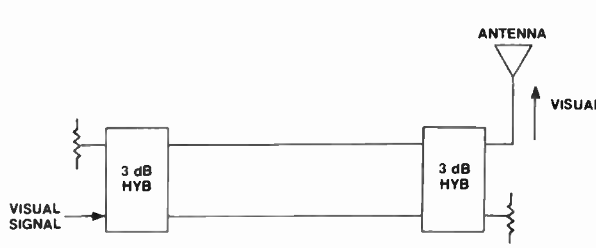

Figure 87B. Visual signal applied to back-to-back hybrids.

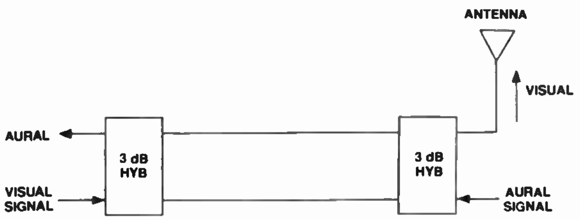

Figure 88. Aural signal applied to back-to-back hybrids.

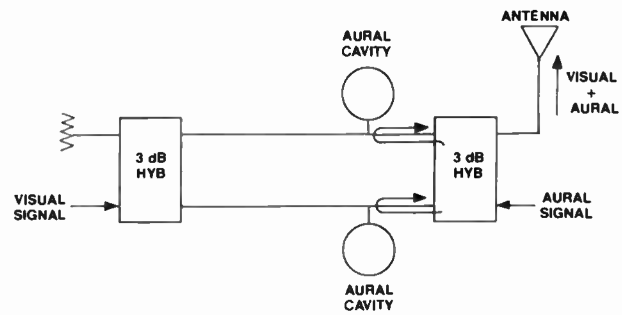

Figure 89. Aural and visual signals applied to back-to-back hybrids with aural notch cavities to reflect aural signals back to antenna port.

A typical use of this system would be the driving of two power amplifier chains in parallel with a single exciter. HY1 would be a low power splitter while HY2 would be a high power combiner. A1 and A2 would be the complete amplification chain consisting of multiple stages of solid state and/or tube amplifiers.

Differences in amplifier chain gain are compensated for by attenuators AT1 and AT2 which vary the amount of input signal applied to the amplifier chains. Differences in phase are compensated for by the length of cable between the attenuators and the amplifier chain. Optimum phase and gain adjustments are determined by minimum power being dissipated by the reject load and maximum power into output load as shown in Fig. 90.

Effective power transferred to antenna or load with respect to differences in phase or gain of amplifier chains can be seen in Figures 91 and 92 respectively. As can be seen from these figures, a 60° error in-phase will cause only a 25% reduction in output power. If one amplifier has only half the output power of its counterpart, a 3% reduction in power (in reference to the combined input powers) will result. For example, let transmitter A = 5 kW, transmitter B = 10 kW, K^2 = Pa/Pb = 0.5 which gives a K of 0.707 which equals approximately 3% in Fig. 92 or approximately 14.55 kW of useful power out of the hybrid. Worst case for amplifier gain differences occurs when one transmitter is not producing any output. In this case half of the remaining transmitter's output (25%) will be dissipated in the reject load and the other half (25%) will be applied to the antenna.

A typical dual transmitter with notch diplexer is shown in Fig. 93.

Switchless Combiners

As discussed in the previous section, dual transmitters may be combined using hybrids to obtain maximum power. However, if one of the transmitters were to be disabled, the combined power output would drop to 25% of the nominal value. In order to continue operating at a reasonable power level many stations have employed coax switches to bypass the hybrid as shown in Fig. 94 to boost the transmitter power back to 50% of nominal operating power. During the switching process, however, it is necessary to take the transmitter off the air.

An alternative which allows the transmitter to stay-on-the-air while changing power from 25% to 50% is to use a "switchless combiner." A switchless combiner uses phase shifting with back-to-back 3 dB hybrids to accomplish the correct direction of power output.

A diagram of a transmitter using a switchless combiner is shown in Fig. 95. As identified in Table 1, nominally both transmitters are producing equal power and

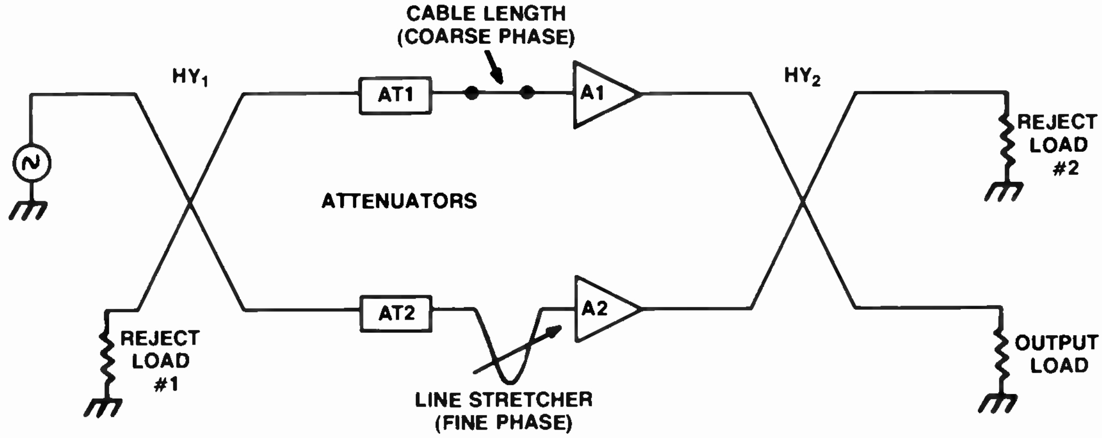

Figure 90. Typical parallel amplifier with single signal source.

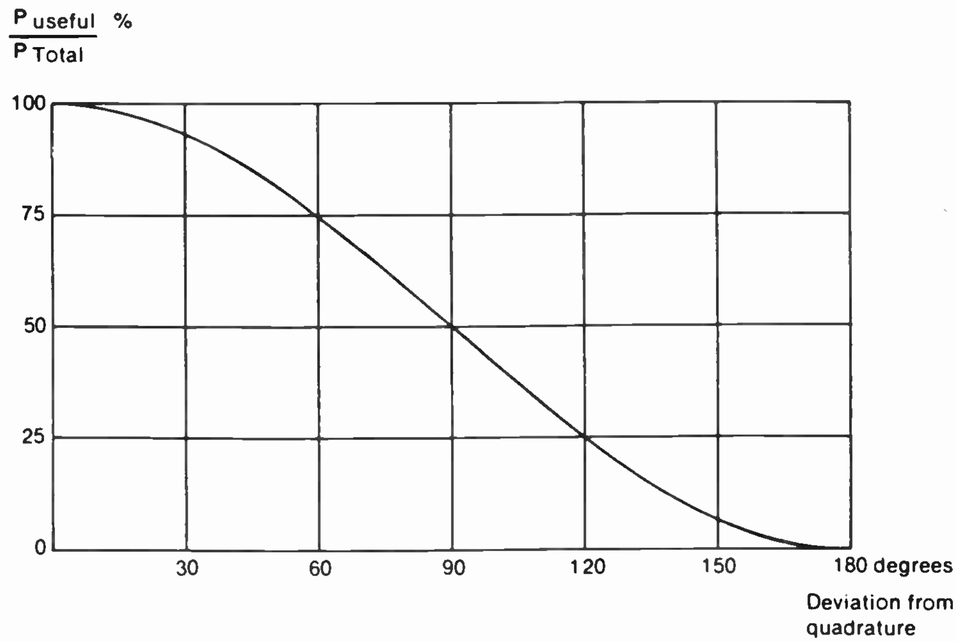

Figure 91. Hybrid coupler phase sensitivity.

are 90° out of phase. When transmitter A is disabled, Phase Shifter 1 (PS1) is energized changing the phase relationship as shown in Table 1. Transmitter A is routed to the switchless combiner load. When transmitter B is disabled (and assuming transmitter A is enabled) Phase Shifter 2 (PS2) is energized changing the phase relationship as indicated in Table 1. Now, transmitter B is routed to the switchless combiner load.

With one transmitter routed to the antenna and one transmitter routed to the combiner load, it is possible to perform adjustments on the transmitter connected to the load without impacting the on-air signal provided a separate exciter is used. (For more detail on this subject see "Subjective Tests on a Switchless Combiner TV Transmitter System" noted in the bibliography.)

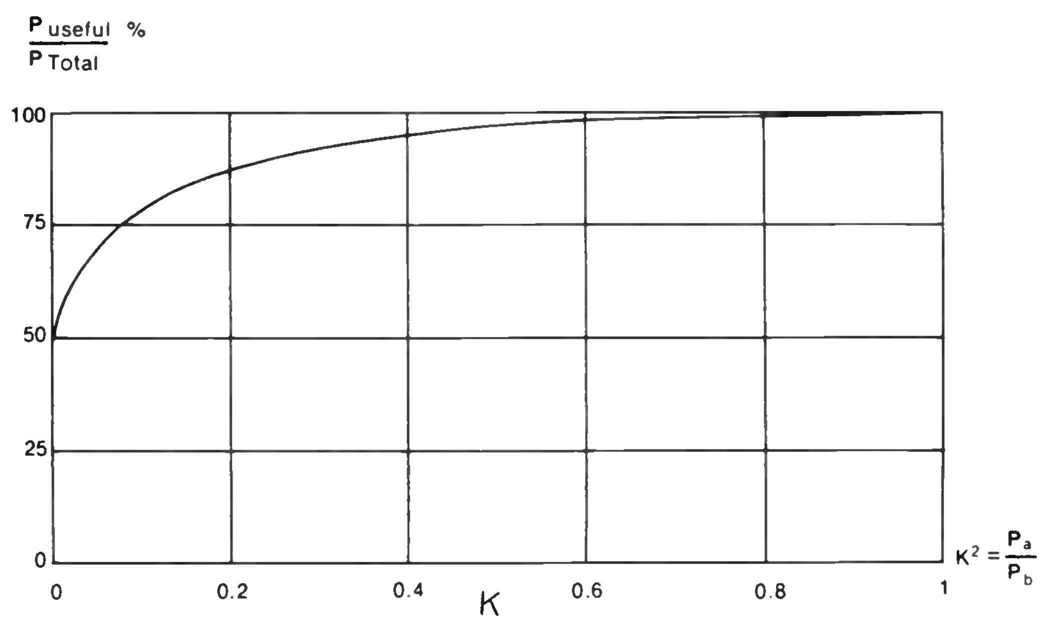

Figure 92. Power imbalance in hybrid couplers.

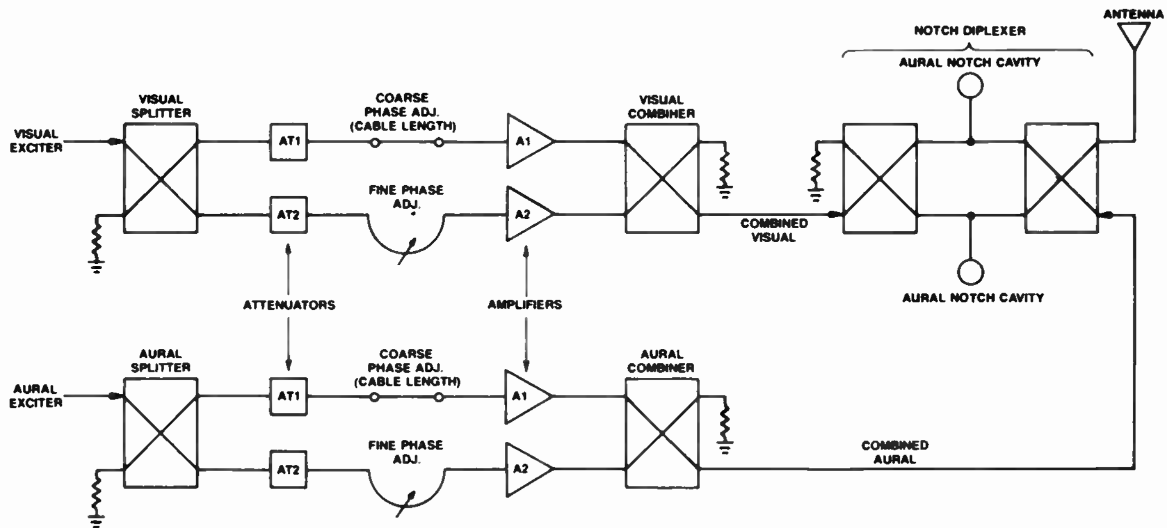

Figure 93. Typical dual transmitter with notch diplexer.

The switchless combiner concept has significantly increased the on-air availability of VHF transmitters.

UHF Magic Tee RF Systems

Since a similar problem exists for UHF transmitters, a similar concept can be applied again. However, since components are smaller many of them can be integrated into one assembly.

UHF transmitters typically are not dual systems but often do employ multiple visual amplifiers as shown in Fig. 96. A 180° hybrid implemented in waveguide accompanied by phase shifters located in the waveguide can accomplish the same function as the switchless combiner does with dual transmitters. See Table 2 for a diagram of what the phase relationships are and which amplifier is routed to which device.

One example of a unitized RF system, shown in Fig. 97, consists of a waveguide magic tee combining/switching system, a waveguide notch diplexer, two waveguide transfer switches, a 50 kW coaxial reject/test load, and a 100 kW waveguide test load interconnected and mounted within an open frame. The "magic tee" system provides visual amplifier power combining and power routing of either visual amplifier to the

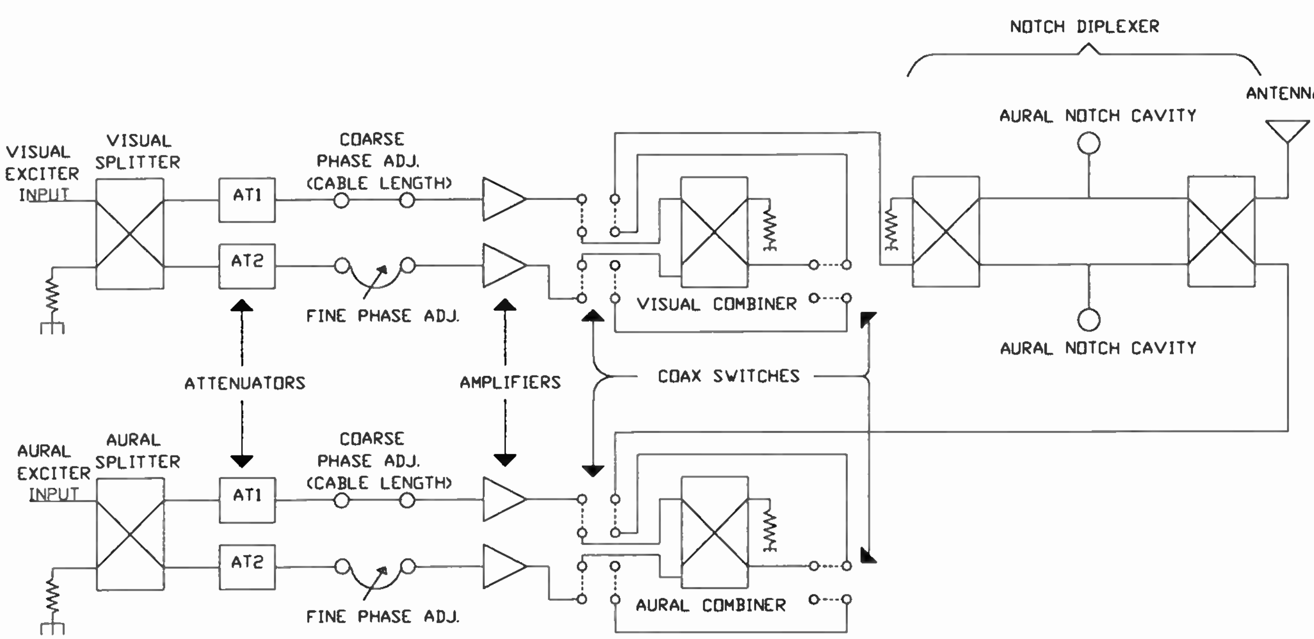

Figure 94. Typical dual transmitter with coaxial switchers.

diplexer or 50 kW coaxial test load. The diplexer combines the visual and aural transmitter outputs. It is equipped with a lower color subcarrier notch filter and aural notch cavity de-tuning mechanisms to allow multiplexed visual/aural signals to be passed through the diplexer from visual input port to the antenna output port during emergency operation. One wave-guide transfer switch routes the diplexer output either

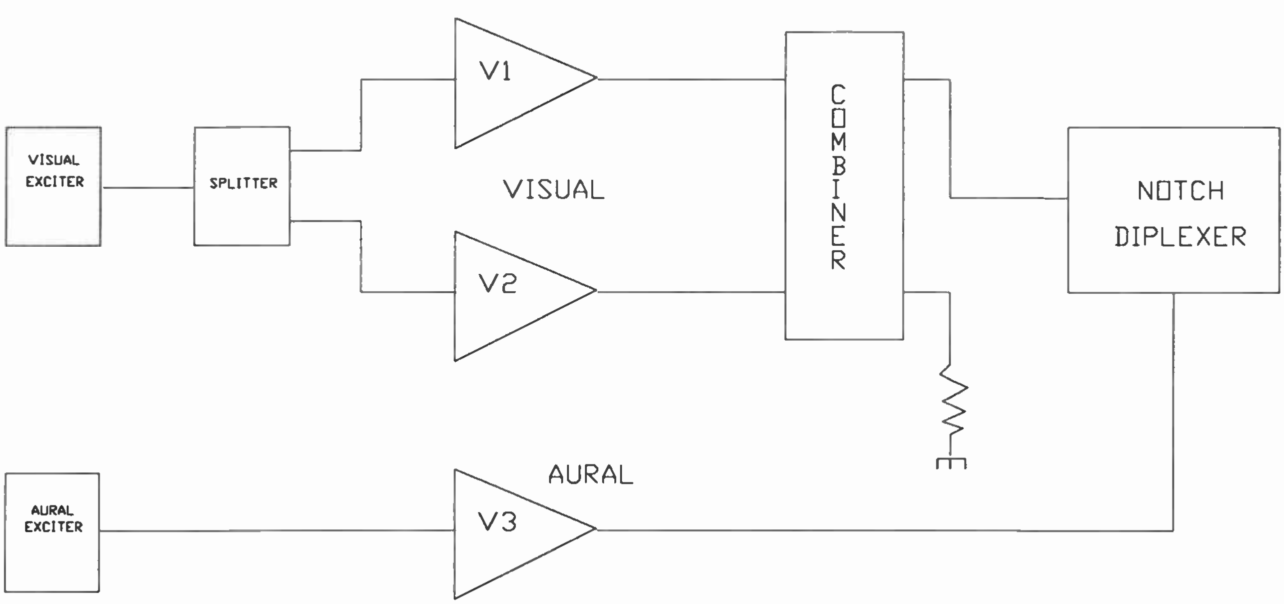

Figure 96. UHF transmitter with multiple visual amplifiers.

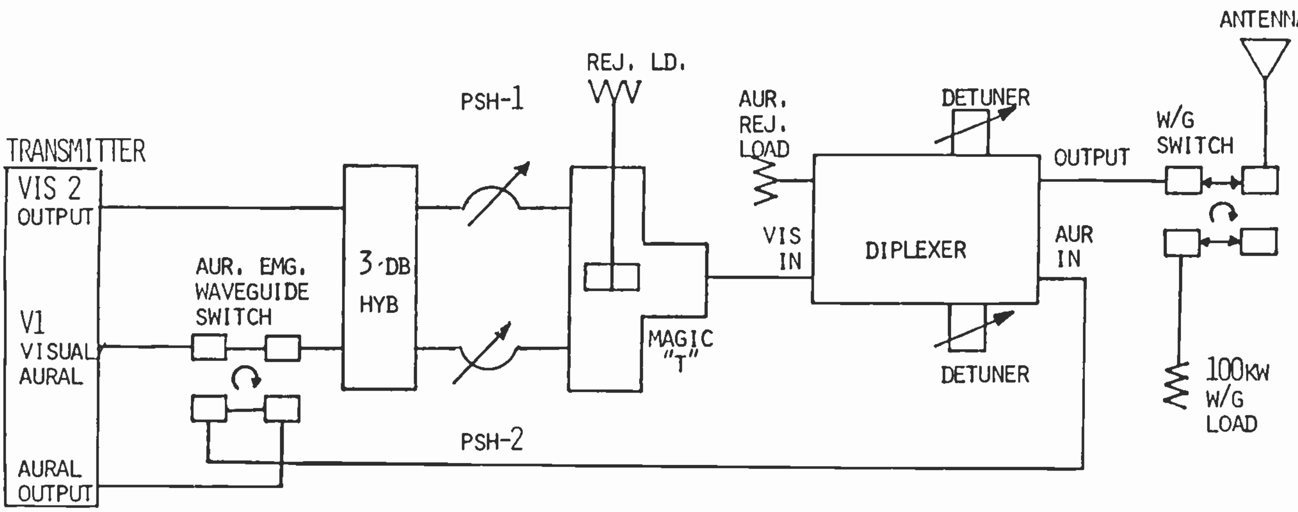

Figure 97. Unitized RF system.

to the antenna or to the 100 kW waveguide test load. The other waveguide transfer switch can route the output of a visual amplifier to the aural input of the diplexer. This feature allows a visual amplifier to become an aural amplifier in the event of failure of the normal aural amplifier. A control logic system is installed in the transmitter to coordinate transmitter and RF system operations. All functions of the RF system can be operated from the front of the transmitter or from a remote location.

PERFORMANCE MEASUREMENTS

The quality of the broadcast television transmitted signal is the resonsibility of the broadcaster. The introduction of IF modulation, solid state SAW vestigial filters and sophisticated precorrection circuits improved critical signal performance parameters two to one. Precision demodulators with synchronous detection and SAW filters are capable of near ideal detection. New test waveforms and digital signal synthesis now provide accurate test signal generation to complement the improved transmission facilities.

Home receivers employ high tech circuits including comb filters for luminance, stable SAW IF filters, high resolution display devices, and sophisticated LSI video processing circuits.

It is difficult to show the correlation between signal quality and audience ratings. The issue of viewer enjoyment is easier to demonstrate. Many scientific studies relating signal degradation to perceived quality have been made over the years.

The Electronic Industries Associates Standard RS-508 takes into account empirical quality factors and reflects a common denominator for new transmitter performance. This standard is a valuable reference document which describes performance parameters, standards and methods of measurements.

A thorough proof-of-performance at the time of installation is an invaluable record of normal operating performance. It also serves as verification of proper signal quality and emission standards. The number of detailed measurements required after the "proof" usually can be limited since several performance characteristics are a measure of the same impairment. Also some test waveforms are more useful for transmitter adjustment than others.

Transmitter measurements can be broken down into two primary categories as follows: frequency response and linearity.

Performance dependent on frequency response and group delay are sometimes referred to as linear distortions. That is, these distortions are not signal level dependent. In the time domain 2T, modulated sine-squared pulses, and multiburst waveforms are used in identifying and correcting distortions. In the frequency domain, swept amplitude and group delay measurements can be used but are normally reserved for out-of-service testing.

Linearity performance includes distortions which are signal level dependent and are a function of the instantaneous luminance level and on the average picture level over several lines. For example, level dependent chroma gain and phase are called differential gain and phase respectively. Luminance gain variation called low-frequency nonlinearity, and frequency response versus brightness which is the change in swept response with static luminance level are other level dependent distortions. Nonlinear responses can also change as a function of average picture level. To test for this, one line of the video waveform is alternated with four lines containing a static luminance level. Fig. 98 contains a modulated staircase with three average picture levels.

Modern transmitters are designed for unattended operation for extended periods of time. A transmitter operating with adequate cooling, regulated power lines and properly adjusted, may need only be checked in detail every three or four months or whenever a major component is replaced or repaired.

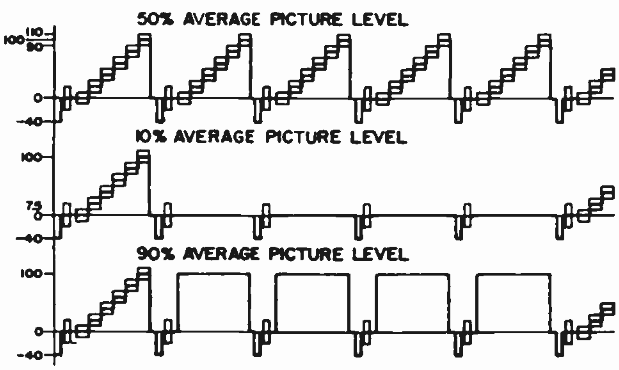

Figure 98. Modulated staircase waveform.

The following pretest checklist and sequence of tests are presented as a general guide for a properly adjusted transmitter.

Pretest Checks:

- Test equipment
- Input video
- Output transmission line, station load, and antenna
- AC mains input
- Record meter readings, adjustment settings, and key performance parameters

Transmitter Test Sequence

1. Exciter linear and nonlinear performance check.
2. Intermediate and driver linear amplifier performance check.
3. Swept frequency response.
4. Modulation depth (Include UHF pulser and sync ICPM adjustments).
5. Power output meter calibration.
6. Nonlinearity response checks. (Differential gain, ICPM, differential phase, etc.)
7. Linear response checks. (Group delay, pulse tests, composite waveform K factors, etc.)
8. Record meter readings, adjustment settings, and key performance parameters.

Many adjustments are interrelated and require returning to previous tests to verify proper performance. The sequence above is intended to minimize the number of adjustments.

At the time of a periodic measurement and adjustment sequence, it is a good practice to record meter readings and adjustment settings before and after the test. These recordings will indicate normal setting range and can aid in getting the transmitter back to near-normal in the event of mistuning errors during adjustments.

For off-air monitoring, a picture monitor is convenient for identifying gross video degradations quickly. Vertical interval test signals containing the composite waveform or other specialized test signals are useful for keeping track of depth of modulation, and several linear and nonlinear responses. These test signals are displayed on a waveform monitor and vectorscope. Records of transmitter meter readings and performance data are very useful in maintaining a transmitter at a high performance level. Maintenance logs should include date, time duration of outages, corrective action taken, and where possible, identify cause.

Monitoring TV Multichannel Sound

Maintaining a high quality aural signal requires high quality monitoring facilities. To be able to perform the proof-of-performance measurements is another important reason to have a monitor that demodulates the RF signal and separates the components in the composite MTS signal for analysis.

An ideal modulation monitor should consist of, but not be limited to, the following functions:

1. Demodulates the composite signal from the aural carrier.
2. Separates the components in the composite MTS signal for measurements.
3. Capable of off-air monitoring.
4. Covers all VHF and UHF channels.
5. Suitable for proof-of-performance use.
6. Contains a precision (BTSC) expander.

Equipment Needed

In order to make satisfactory measurements of video signals, a certain minimum of test equipment is required. Measuring the output of a television transmitter at baseband requires a precision television demodulator. For greatest accuracy, this demodulator should provide a zero carrier reference pulse for determining percentage of modulation, and ideally will have both a synchronous and envelope detection mode.

For most baseband measurements, a video waveform monitor is all that is needed, but to do a complete analysis of a system requires some additional equipment. The waveform monitor should include a provision for making measurements on vertical interval test signals (VITS) and provide filtering to allow separate examination of the luminance and chrominance components of color television signals.

In addition to the waveform monitor, a vectorscope must be used for making certain measurements on color signal components, particularly differential gain and phase measurements. The waveform monitor and vectorscope are all that are required to accomplish these measurements, but if a greater level of accuracy is desired in timing measurements, a conventional oscilloscope with an associated digital counter/timer would be a great asset.

PREVENTATIVE MAINTENANCE

A good preventative maintenance program should include periodic inspection and cleaning of the equipment. A vacuum cleaner is preferred to remove dust instead of compressed air which will simply blow the dirt into the air and let it fall back down on something else. A paint brush can be used to dislodge dust from delicate circuit boards. Avoid using a nylon bristled brush with a plastic handle as the static charge may damage CMOS or other static sensitive components. A natural bristle brush with wooden handle and metal binding is recommended.

High voltage wires and insulators must be cleaned with denatured alcohol, or other cleaner capable of removing the dirt without leaving any residue. Meter cases are cleaned with Glass Wax or other nonstatic cleaner.

Air filters should be replaced or cleaned as necessary to maintain adequate air flow to the equipment. A second set of washable filters can save time when using a single transmitter in critical service by quickly switching the clean filters and washing the dirty ones later. Blowers should be inspected to see if the curved fins are filled with any debris that would reduce air flow. Motor windings may collect a layer of dirt and interfere with the cooling of the motor itself. The fins of high-power tubes must be cleaned of any obstructions which may have passed through the air filters. Bearings should be lubricated and checked for excessive noise.

Color change in silver plated cavity parts can be a sign of over-heating and may require the disassembly of the cavity to check for obstructed air passages or loose connections. Set-screws in gear and chain drive tuning mechanisms should be checked for tightness. Black silver-oxide is a good conductor and need not be removed. Small parts should be dipped in Tarnix® for cleaning. Be sure to flush the parts after cleaning to remove any residue. Scotch-Brite® is a good nonmetallic cleaning pad for silver-plated parts. Remember that you do not want to remove the plating when cleaning these parts.

High current wires may move during turn-on surges and can suffer abrasions which may eventually cause an arc if not properly dressed away from sharp edges. Wiring on terminal boards may loosen through thermal cycling and vibration. All connections must be checked to be sure they remain tight. If wires need to be replaced, the correct gauge, voltage rating, and temperature rating must be considered when selecting the replacement.

Edge connectors on printed circuit boards should be cleaned with Cramolin® or other cleaner. A small amount of this cleaner is applied to the edge connector and then removed with a lint-free cloth. Do not use pencil erasers as this will remove gold or silver plating from the edge traces, and could degrade the connection or create an intermittent later as the sulfur in the eraser causes chemical reaction to the edge connector material.

Back-up systems or emergency modes of operation should be checked periodically. The worst time to discover trouble in the back-up equipment is when you need to put it on the air. Relays need some exercise to keep their contacts polished and in working order.

Transmitter site cleaning should also include a check of the building for such things as leaks in the roof which may cause damage to the transmitter, and presence of insects or small animals which may wander into unwanted areas.

Intake blowers with filters capable of creating positive pressure in the room can minimize the need for cleaning by keeping the dust out. A careful record must be maintained in order to establish a good history for future reference. Such a log will include a description of what was done, when it was done, and the name of the person performing the work. The question "How often must the transmitter be cleaned?", can be answered by "How often does it need cleaning?" Seasonal events such as harvesting in farm locations, severe weather, construction projects, in and around the transmitter building can require special action, but usually a pattern will emerge that allows the maintenance to be scheduled on a regular basis.

A complete set of meter readings taken when the equipment is working properly and updated weekly or monthly can greatly assist the engineer when trying to diagnose problems.

Create a maintenance program with weekly, monthly, quarterly, semi-annual, and annual tasks evenly spread throughout the year.

The following list of items can be used to develop a maintenance routine for any broadcast television transmitter facility:

Maintenance Items

Prefilter manometer readings
Inspect prefilters
Replace prefilters
Post-filter manometer readings
Cabinet input air manometer reading
Inspect transmitter air filters
Replace transmitter air filters
Vacuum cabinets
Clear tube fins or accumulated dust
Measure blower currents
Clean fan blades and motor windings
Connections checked for tightness
Inspection of MOVs

Recommended Data to be Recorded

Record all parameters on meters or user displays
Record DC input power and calculate dissipation (if applicable)
Record transmitter currents in black picture and at idle (no RF drive)

Visual Performance Checks

Ensure proper video level
Ensure proper sync level
Optimize differential gain
Optimize ICPM
Optimize differential phase
Optimize group delay using T pulses

Ensure proper power calibration
Ensure proper audio processor set-up
Optimize swept response

Aural Performance Checks
Ensure proper modulation levels
Ensure proper SCA input levels
Ensure proper power calibration
Ensure proper audio processor set-up
Optimize audio frequency response
Check and optimize distortion
Optimize stereo separation
Check and optimize crosstalk between MTS channels

Control System Checks
Verify proper operation of all interlock circuits
Verify proper operation of all overload circuits
Verify proper operation of all control processes (VSWR foldback, filament timing, coax switches, etc.)

RF amplitude response as a function of frequency is the variation in gain over the frequency range of the channel. The use of a television sideband analyzer or other frequency selective voltmeter provides a suitable means to measure a television transmitter amplitude response versus frequency.

At one time or another, just about every component part of a video signal must be measured or adjusted. It is good engineering practice that each part of a transmission plant including studio, distribution, transmitter, and monitor equipment provides minimal distortion to the video signal. Furthermore it is not recommended that one part of the system correct for another part except within a given system such as the precorrection circuits used in a transmitter to compensate for certain RF components. The signal going into the transmitter should be a standard NTSC video signal meeting its full specifications. The transmitter's correction circuits should not have to compensate for incoming video problems.

The overall amplitude of the signal and each of its component parts have strictly defined levels, and the relationship between the parts is also critical. Refer to RS-508 for a description of specific electrical performance parameters and standard test methods.

AIR SYSTEMS FOR TRANSMITTERS

Most electronic equipment which requires forced air cooling has the required blower or fan already designed into it. However, equipment such as transmitters, dissipate large amounts of power. Air which has already passed through the equipment and has picked up heat must be removed from the immediate vicinity of the equipment (exhaust air) in order to prevent the hot air from being recirculated. In addition to the air removal requirement, provisions must be made for sufficient make-up air (intake air) to replace that which has been circulated through the equipment and removed.

If the equipment user is to provide adequately for hot air exhaust and fresh air intake, the maximum and minimum environmental conditions which the equipment may operate in and the following information from the equipment manufacturer must be known:

Altitude: ______________________

Max. temp: ______________________

Min. temp: ______________________

Total air through the transmitter:

CFM ______________________

Pressure drop within the critical portion of the air circuit (across the transmitter tube for example. This is required for checking purposes after the system is built.)

Air pressure (Inches of water) ______________

Air temperature rise through the transmitter: ______

Air exhaust area: ______________________

Exhaust Air

Equipment layouts usually provide for heated air to exit from the top surface of the cabinet. The size and location of this exhaust area is usually shown on a manufacturer supplied outline drawing.

Most broadcast equipment internal air systems are designed to be operated into free space (back pressure of 0.0 inches of water) so any exhaust ducts must have minimum loss. A good practice usually is to design for no more than +0.1 inches of water pressure in the duct close to the exhaust area of the transmitter.

Any exhaust installation other than a large cross section duct (equal to the cross section of the transmitter exhaust port) with no bends, and with a long radius turn outside the transmitter building for weather protection, will need an exhaust blower or fan.

Keep in mind that the recommended system is sized only for cooling the transmitter and any additional cooling load in the building must be considered separately when selecting the air system components. The transmitter exhaust should not be the only exhaust in the room as heat from the peripheral equipment would be forced to go out through the transmitter.

The "sensible-heat" load is the sum of heat loads such as solar radiation, heat gains from equipment and lights and personnel in the area that is to be cooled.

The following hypothetical exhaust duct design illustrates the key cooling concepts:

Air flow (volume) through transmitter = 325 CFM (ft^3/min)

Air exhaust area = 3.4 square ft

$$\text{Air exhaust velocity} = \frac{325\ \text{CFM}}{3.4\ \text{ft}^2} = 94.5\ \text{ft/min}$$

The 94.5 feet per minute air velocity is relatively low which will allow a transition to a smaller diameter pipe if desired. Assume a transition down to a 10-inch diameter pipe, thus the following:

$$A = \frac{D^2}{4 \times 144} = \frac{100}{4 \times 144} = .545\ \text{square ft}$$

$$V = \text{CFM}/A$$

where: D = Duct diameter
A = Exhaust duct cross-sectional area
V = Exhaust duct air velocity

$$V = \frac{325\ \text{CFM}}{\text{dia. pipe } .545\ \text{ft}} = 596\ \text{ft/min air velocity in a } 10''$$

In a 10-inch diameter pipe the air friction chart in Fig. 99 gives 0.06 drop per 100 ft of pipe with a flow of 325 CFM. Assuming for this hypothetical design there is 20 ft of straight pipe to a roof, with two 90° elbows to turn the pipe down for weather protection, the total loss of the exhaust system may be estimated as follows:

Fig. 99 shows loss is 0.06″/100 ft. Since 20 ft is 0.2 of 100 ft,

0.2″ × 0.06″ = 0.012″ of water pressure drop in 20 ft of pipe

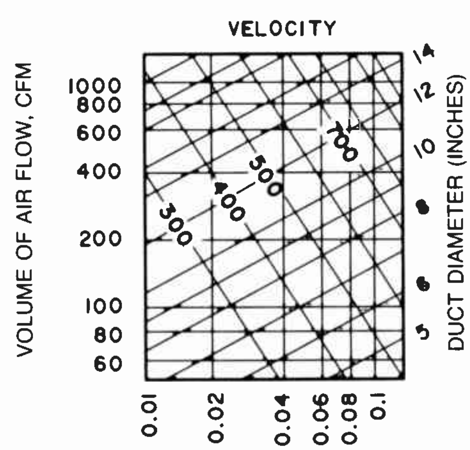

Figure 99. Friction loss in pipes.

Considering the static pressure drop of two 90° elbows, to give a 180° bend in the pipe, it is found from Fig. 100 that a 10 inch elbow at 900 ft/min gives less than 0.01 pressure drop, and there is just under 600 feet per minute in the system. Adding the two drops (one for each 90° elbow) and the 20 ft section of 10 inch pipe together, the result is:

0.012″ + 0.01″ + 0.01″ = 0.032″ of water total pressure drop

Therefore, no exhaust fan is necessary as the 0.032 inch of pressure is less than the 0.1 inch pressure level that requires a fan.

If the installer has a problem in exhausting the transmitter in this simple fashion (for example a roof exit is not available), and it is required to add two additional 90° elbows and a straight run of 10 inch pipe 100 ft long, the pressure drop in the hypothetical design exhaust system will be:

Friction loss in 20 ft of 10″ dia. pipe	=0.012
4 elbows × .01″ (water) each	=0.04″
Friction loss/100 ft of 10″ dia. pipe	=0.06″
	=0.112″ of water

The 0.112 inch of pressure now exceeds the level at which a fan is needed.

Because the transmitter manufacturer recommends no more than a 0.1 inch water pressure loss in an exhaust system, good engineering practice indicates that an exhaust fan is now required in this configuration. The performance curve on the fan shown in Fig. 101, indicates that it will deliver 325 to 330 CFM into 0.1 inches of water back pressure. This is sufficient to handle all of the air coming from the transmitter and overcome all of the estimated duct losses in this configuration.

The outline drawing illustrated in Fig. 102 shows a typical exhaust duct and blower system. The recommended minimum ceiling height to properly handle exhaust air as shown is 12 ft The outline drawing also indicates a typical air intake and prefilter system.

Intake Air

An intake vent and blower should be sized to provide a desireable slight positive room pressure. Installing a manometer to sense pressure drop across the filters can help determine replacement interval of prefilters.

If existing space on site will not permit the construction of the transmitter manufacturer's recommended air system, care must be taken to modify the design to fit the available space and still properly cool the transmitter.

Referring again to Fig. 101, examination of the curve shows that at 325 CFM delivery, this fan will develop a static pressure of 0.1 inch water which is sufficient to overcome the less than 0.01 inch pressure drop of a 10-inch diameter 90° elbow installed on the outside wall of the building for a weather hood, as well as a filter and screen to clean the incoming air.

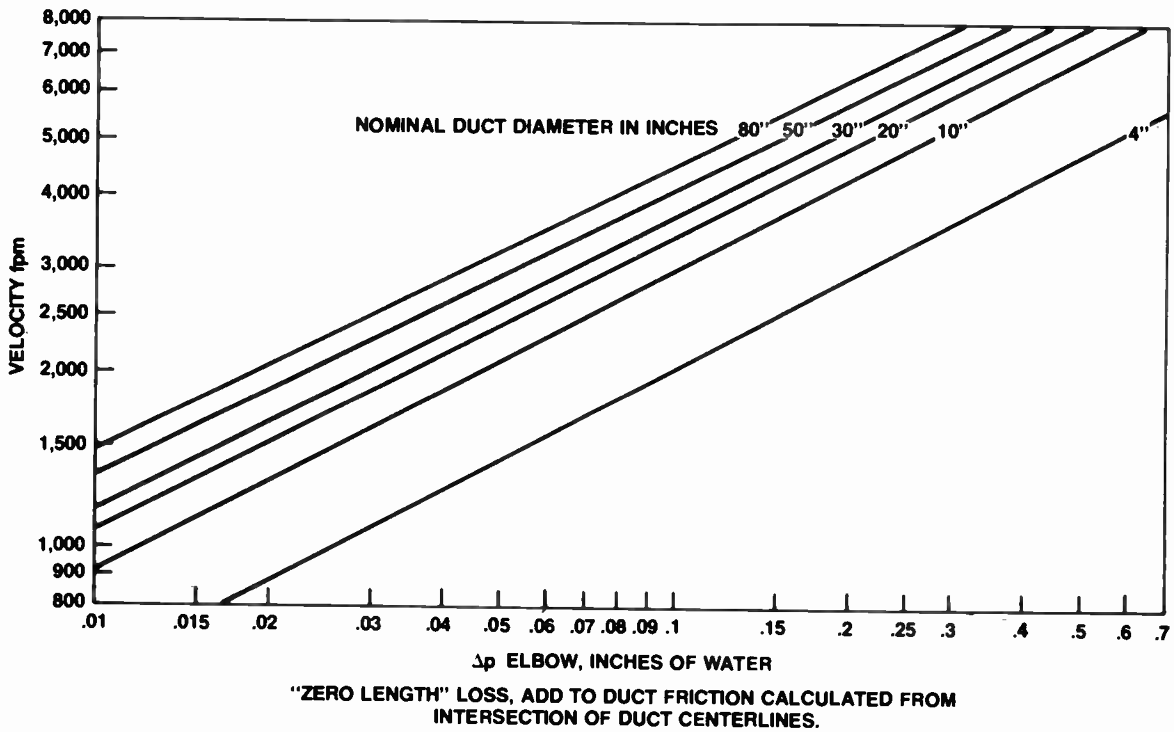

Figure 100. Friction loss in 90° elbow.

20 ft of pipe = .012"
2 elbows at .01" each = .02"
.032" total loss, maximum.

Additional flushing air is recommended for the removal of heat from any surrounding equipment that shares space with the transmitter. It is a recommended guideline to keep input air no greater than 5° C above ambient.

The above calculations are a very simple example of an air system. Most television transmitters, both UHF and VHF, have multiple enclosures with large volumes of air required. In these cases the equipment user is required to combine the heat exhaust air from several enclosures into a complex duct system. When these circumstances occur, the safest practice is for the user to contract for the services of a heating, ventilating, and air-conditioning (HVAC) consultant or company. The cost involved in having the best possible air exhaust and supply system will pay for itself in extended transmitter life and lower service costs.

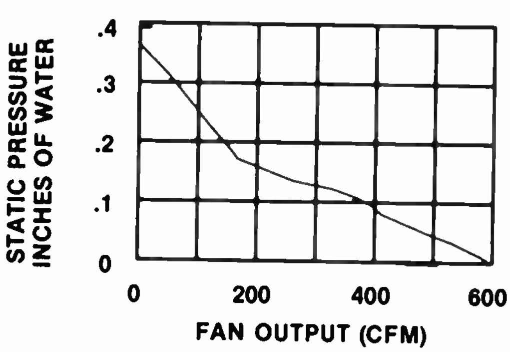

Figure 101. Vaneaxial Caravel fan performance curve.

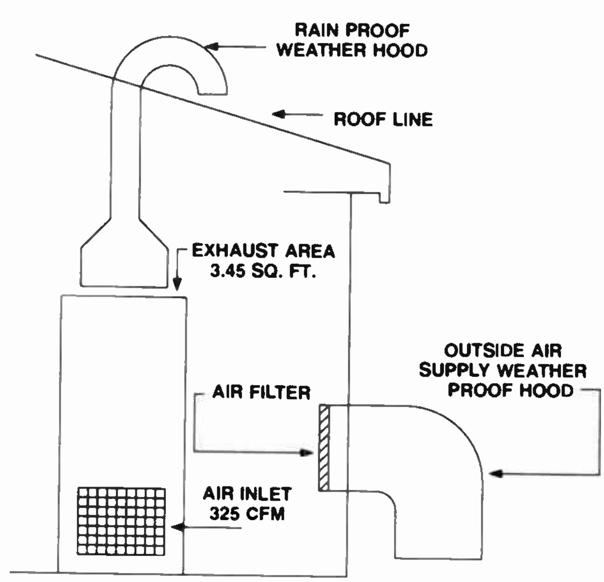

Figure 102. Suggested intake and exhaust duct installations.

Air Conditioning

It is a common practice to set the transmitter into a sealed wall to produce a plenum chamber and supply it with outside air, while providing separate air conditioning for the front side to cool personnel and source equipment.

In areas with severely polluted air, it may be necessary to run the transmitter on air-conditioned air to avoid bringing in corrosive salts or gaseous contaminants.

The amount of air conditioning will depend on several factors. It is strongly recommended that the air conditioning be shared by a number of units rather than one large central system so that operation can continue in the event of the failure of one unit. Air conditioning units are usually listed by "tons" of cooling capacity with "one ton" equal to 12,000 BTU per hour.

Again, consult experienced professionals in the area of HVAC design to achieve the desired result and to prevent problems from developing in the future.

3.6 Multichannel Television Sound

Edmund A. Williams
Public Broadcasting Service, Alexandria, Virginia

INTRODUCTION

Multichannel Television Sound (MTS) is a generic term for the process of adding subcarriers to the aural carrier of a television station. The development of a stereo MTS system was accomplished through the Broadcast Television Systems Committee (BTSC) of the Electronics Industry Association (EIA) and is known as the BTSC system for television stereo sound. Some of the subcarriers in the BTSC system are designed to be received by the general public and may be used for a variety of purposes including: stereophonic sound, secondary audio channel for a second language or other program related aural service, commercial communications, and data. Other subcarriers may be used by the broadcaster for professional uses such as news crew cues, transmitter telemetry or other digital or analog, and aural or data services. Non-MTS subcarriers need not be related to the program on the video or aural portion of the television signal itself. The BTSC stereo system is completely compatible with monophonic receivers.

Modern broadcast television transmitters are designed to accommodate multichannel sound. Older transmitters are likely to require revised tuning procedures and more attention to overall performance will be necessary to prevent degradation to the stereo signal. Most importantly, new testing and measurement techniques are required to insure that the BTSC multichannel sound signals are transmitted to the receiver in good condition,

The introduction of BTSC multichannel sound, as an all-industry recommendation, permitted receiver manufacturers to develop new models that offer good stereo performance. In 1990, over 25% of all television receivers sold in the U.S. had BTSC stereo. Nearly 20% of all U.S. TV homes have stereo. Most new television programs are produced in stereo. More than 75% of all television stations in the U.S. have BTSC transmission capability. Virtually all video services available to the public (VCR, CATV, satellite, video disk) contain stereo sound tracks.

The addition of stereo to television broadcasting accelerated the use of stereo sound tracks for television program production. Channeling the stereo sound throughout the broadcast facility in turn created challenges to audio design and production, installation, distribution, operation, and maintenance. (See other chapters in this handbook for details.)

During the introduction of the new stereo service, many stations employed stereo synthesizers to provide viewers with an immediate sensation on newly acquired stereo television receivers. Because a large portion of original program material is now produced in stereo, the synthesizer is no longer needed in the audio chain. In fact, using the synthesizer anywhere in the audio chain other than in the studio can severely degrade mono and stereo sound (and enhancements such as surround sound) which in turn may cause distraction and discomfort to the viewer who may make incorrect adjustments to the receiver.

BACKGROUND

The development of the multichannel sound system was accomplished by broadcast industry organizations through the Broadcast Television Systems Committee (BTSC) of the Electronics Industry Association (EIA). The EIA established a laboratory and conducted transmission tests on several potential multichannel sound systems. The system selected by a vote of the BTSC members uses the transmission parameters developed by Zenith Electronics Corporation and the noise reduction system developed by dBx Incorporated. This combination, called the BTSC Multichannel Television Sound system, was recommended to the FCC for adoption as an industry-wide standard. The EIA recommendation was approved by the Federal Communications Commission (FCC) on March 29, 1984 in their Second Report and Order (Docket 21323). While not adopting the BTSC system as such, the FCC provided protection to the establishment of the BTSC system which in turn resulted in a well developed de facto standard. In summary:

1. The FCC protects BTSC equipped receivers from interference from other MTS subcarrier schemes (see FCC Rule Section 73.682(c)).
2. The FCC Office of Engineering and Technology published Technical Bulletin OET-60A, a document that contains the BTSC specifications that are described in FCC Rule Section 73.681.
3. The FCC permitted stations to implement not only the BTSC MTS system but any other MTS system of subcarriers a station desired so long as no interference resulted to receivers designed to BTSC specifications or to regular monophonic sound television receivers.

While the BTSC system is not a standard as such, the Commission provided the next best thing—protection. Therefore, transmitter and receiver manufacturers are able to produce equipment conforming to the BTSC system with full knowledge that a compatible, protected MTS system is recognized by both FCC and industry. The EIA also developed a set of recommended operating practices aimed mainly at transmitter and receiver manufacturers entitled "BTSC System: Television Multichannel Sound Recommended Practices."

Television stations may employ aural subcarriers for virtually any purpose as long as they do not interfere with the BTSC system or normal monophonic receivers' operation.

It should be noted that the multichannel sound system adopted for use in the United States is unique. The multichannel sound transmission schemes used in other countries have different configurations. In Japan, an FM subcarrier carries either a stereo sound channel or a second language channel but not both. West Germany adopted a two-carrier sound transmission system providing either stereo or second language. In Great Britain, a digitally modulated carrier for stereo sound is inserted above the normal monaural FM carrier. In comparison, the U.S. system with its combination of AM and FM subcarriers can, if desired, simultaneously transmit stereo and a separate program or second language, plus a subcarrier for professional or nonpublic uses. Further, the U.S. system permits stations to employ other subcarrier arrangements, when not using the BTSC system, to serve specific station requirements.

A noise reduction or companding system for the stereo and separate audio program channels was incorporated into the BTSC system from the beginning of MTS service. A high performance compressor is built-in to all BTSC encoders. A matching expander is built-in to all BTSC decoders. They are, therefore, part of the overall system design and not merely an add on feature.

THE BTSC SYSTEM

The design of the BTSC MTS system took into account several major performance objectives and considerations. Among the more important factors were:

1. Compatibility with existing monophonic sound television receivers.
2. Ease of modification of transmitters.
3. Full sound fidelity.
4. The ability of the MTS signals to pass through cable television systems, master antenna systems, and TV translators.
5. The ruggedness to withstand typical transmission impairments (noise, multipath, interference) in the path between the transmitter and receiver.

These factors influenced the design criteria with the result that the single aural carrier system with subcarriers was adopted with an audio companding (noise reduction) system. Also, a separate audio program channel for special programming purposes is included along with space for a nonpublic subcarrier for station use.

It is recommended that all stations contemplating stereo operation obtain a copy of Bulletin OET-60A entitled "Multichannel Television Sound Transmission and Audio Processing Requirements for the BTSC System" published by the FCC.

The BTSC multichannel sound system is designed to be compatible with existing monophonic television receivers and provide high quality stereo sound transmission. The system requirements and performance capability is given below.

BTSC System Requirements

1. The system is compatible with existing monophonic television receivers. Establishing the correct operating levels in the stereo encoder is essential for proper stereo and monophonic operation. Monophonic performance is also a function of the balance of the original audio program material and the distribution and processing within the broadcast plant.
2. The system provides both a stereo and separate audio program (SAP) channel simultaneously. The SAP channel is available on most BTSC equipped television receivers. The quality of the SAP channel, while somewhat limited compared to the stereo and mono channels, is a function of the original program material and the processing used in the broadcast facility.
3. There are provisions for other professional use (PRO) or station use subcarriers. The PRO channel may be used for a variety of purposes for station operations or commercial services. It is not capable of being received on consumer television receivers.
4. A noise reduction (companding) system is employed for both stereo and separate audio program channels. Nearly 30 dB reduction in noise is

achieved through the use of advanced circuit design, compression algorithm, precision components, proper setup, and routine maintenance. The decoders used in all consumer BTSC equipped television receivers are matched to the encoders used in the transmitter. The Electronic Industries Association published a detailed description (EIA Television Systems Bulletin #5) of the entire system entitled "Television Multichannel Sound BTSC System Recommended Practices." and is used by manufacturers of television transmitters, receivers, cable headend equipment, add on adapters, and other equipment which contains BTSC encoders and decoders.

5. The aural carrier deviation capability in the aural transmitter exciter and amplifiers must be increased to accommodate the new subcarriers. The deviation for monophonic transmission remains at 25 kHz. With stereo, SAP, and PRO the deviation may be increased to 73 kHz. Insufficient bandwidth in aural transmission components will result in distortion and crosstalk between channels in the receiver.

Excellent stereo audio quality and separation between stereo and SAP channels can easily be obtained from BTSC stereo exciters. However, the transmission system will degrade some performance parameters, depending upon how well the RF components are adjusted and maintained.

Fig. 1 shows the MTS performance objectives that can be achieved with properly operating BTSC and aural RF transmission equipment, routine maintenance, and good test equipment.

Channel	*Freq Response*	*Noise*	*Distortion*
Main (monophonic)	20–15kHz +/− 1dB	>58dB	<1.0%
Stereo (difference)	100–15kHz +/− 1dB	Dyn*	<1.0%
Separate Audio Program (SAP)	50–10kHz +/− 2dB	Dyn*	<2.0%
Professional Use (PRO)	100–3kHz +/− 3dB	>40dB	<5.0%
Stereo Separation	>40 dB (without NR encoding)		
Crosstalk into SAP or PRO	>50 dB		
Crosstalk into Main (any)	>60 dB (>40 dB for stereo into main)		

*Dyn indicates that the noise varies dynamically with program content and the characteristics of the noise reduction system. Subjectively, the noise will normally be 60 dB below peak operating levels.

Figure 1. MTS performance objectives.

Degradation to any of the above performance parameters will occur under the following conditions:

1. Crosstalk: nonlinear amplifiers, excessive incidental carrier phase modulation (ICPM).
2. Frequency response, noise, and distortion: audio circuitry in stereo encoder or exciter.
3. Noise reduction system artifacts such as pumping or changes in level: improper adjustments in encoder. (Do not adjust without knowledge of the system and proper instrumentation.)
4. Buzz in the received audio: excessive ICPM in the transmitter, video overmodulation, or video energy in the aural carrier passband.

The BTSC System Transmission Format

The transmission format of the BTSC baseband configuration is shown in Fig. 2. The stereophonic

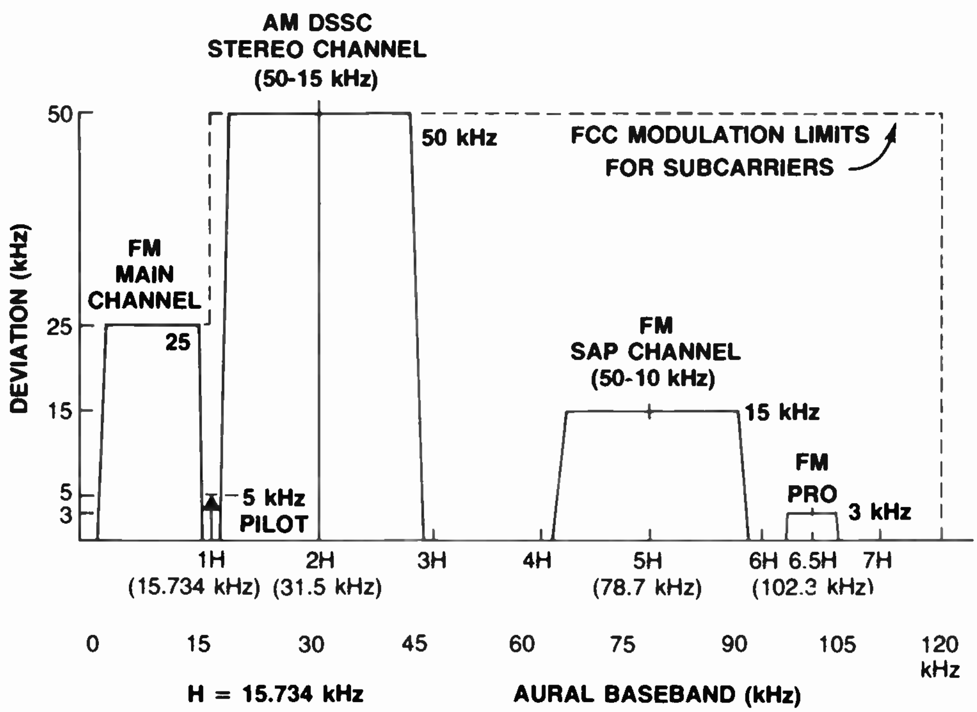

Figure 2. BTSC MTS baseband.

component is transmitted in the form of a difference, or left minus right (L – R), signal that is based on the current U.S. FM stereo broadcast model which is familiar to most broadcast engineers. Subcarriers for cues, data, telemetry, or other station related purposes may also be employed. Space for these professional use, nonpublic subcarriers is provided in the aural baseband. Fig. 3A shows how the BTSC signal is configured at the transmitter. Fig. 3B shows how BTSC is handled in a typical receiver.

Monophonic Channel

The monophonic, or sum channel (L + R), is maintained at its present place in the aural baseband and continues to have 25 kHz peak deviation and the standard 75 microsecond pre-emphasis. The addition of BTSC or MTS subcarriers will increase the overall deviation of the main carrier. Increasing the peak deviation of the aural carrier to 73 kHz (for BTSC) does not result in any degradation to the normal monophonic sound in existing receivers. The monophonic channel is maintained at 25 kHz deviation unlike FM radio broadcasting where the mono channel is reduced when transmitting stereo. This would result in lowering the signal-to-noise ratio of the aural channel and the loudness of the sum channel compared with stations not operating with the BTSC system. Increasing the overall deviation provides the room for the stereo, SAP, and PRO subcarriers to be added to the aural baseband successfully. The fidelity of the main channel monophonic audio is maintained as before. But, because of the closeness of the sidebands of the stereo subcarrier to the main channel, and to prevent crosstalk between channels, BTSC stereo encoder equipment incorporates sophisticated low-pass filters in the audio circuits to limit the frequency response of each audio channel to no more than 15 kHz. Nevertheless, the BTSC system is capable of providing audio quality essentially limited only by the quality of the main or monophonic channel.

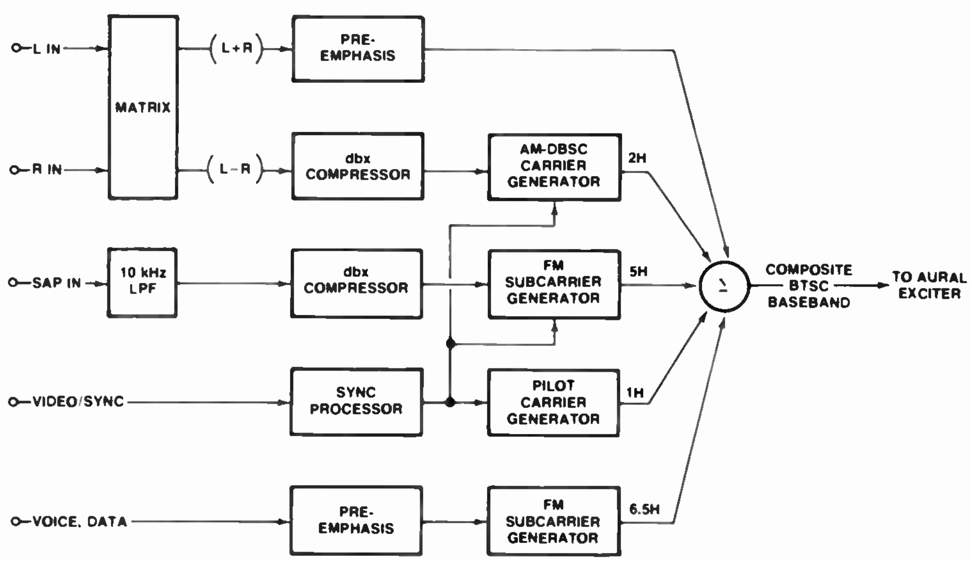

Figure 3A. Typical MTS transmitter encoder.

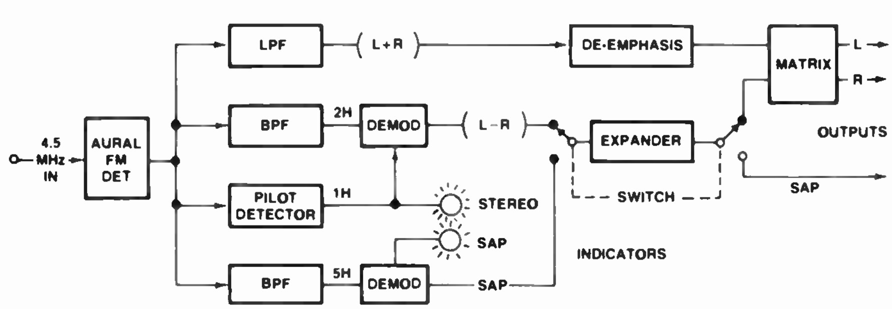

Figure 3B. Typical MTS receiver decoder.

Stereo Subcarrier

The stereophonic subchannel is an amplitude modulated, double sideband suppressed subcarrier. The subcarrier is suppressed to avoid wasting modulation capability. The energy in the sidebands, however, is permitted to deviate the main aural carrier by as much as 50 kHz. The subcarrier operates at twice the NTSC video horizontal scanning rate of 15734.3 Hz or 31468.6 Hz. Station video sync is fed to the encoder to maintain synchronism with the video. The subcarrier is modulated with the stereophonic difference signal, or left minus right (L − R). The maximum peak deviation of the main carrier (injection) by the stereo subcarrier is 50 kHz.

The injection level is related to the companding system algorithm and normally is quite high during stereo program material due to the compression. However, because of the nature of stereophonic sound (little correlation between the sum and difference channels) a form of interleaving takes place that in effect prevents the deviation of the main carrier from becoming the sum of the two components which would appear to produce a total of 75 kHz. Instead, the maximum rarely exceeds 50 kHz. This is because a left-only or right-only signal originating from the studio would produce only a 50% modulated signal in the mono channel even though it produces a high modulation level in the difference channel.

The difference channel of the BTSC system employs the dBx noise reduction circuit (the compression portion of the compander) which precisely controls the maximum modulation level of the difference signal. The preemphasis varies according to the level and frequency of the sound entering the compressor. While the combined deviation of main (L + R) and stereo (L − R) carriers rarely produces more than 50 kHz deviation of the main channel, most stereo encoder manufacturers incorporate some form of peak limiting device in these channels to prevent over deviation.

Note that the difference channel operates in a nonlinear manner by design. That is, the compander processes the audio signal differently at low levels than at high levels. When conducting tests on the difference and SAP channels, a 75 microsecond preemphasis network is substituted for the compressor. Consult the alignment instructions provided by the manufacturer for specific tests and setup requirements.

The selection of the center frequency of the stereophonic subcarrier was based on its relationship with the horizontal frequency (H) component of the video in both the transmitter and the receiver. Crosstalk caused by video signal circuits, power supply, and RF paths in the transmitter generally occur at multiples of H and, therefore, may be cancelled, or at least substantially reduced, in the receiver without significantly affecting overall stereo audio quality.

The first harmonic of H (15734 Hz), present to some extent in many transmitter and receiver audio circuits, is above the hearing range of most viewers and not normally audible. Receiver audio circuits may employ notch or low-pass filters to eliminate all but vestiges of H at the audio output. The second harmonic falls at 2H (31468.6 Hz) which is the frequency of the BTSC stereo subcarrier. By locking the stereo subcarrier frequency to the video sync, the harmonic and subcarrier remain in phase and no beat occurs.

Modulation of the 2H harmonic by 60 Hz (59.94 Hz) field rate sync components of the video signal can also occur in either the transmitter or receiver. The sharp rise time of the 60 Hz component causes the 60 Hz sound to have the characteristic buzz that is heard on some receivers. A related buzz-beat effect is reduced by the use of high-pass filters in the stereo subchannel at the receiver to remove unwanted audio components below about 100 Hz, which can beat with the 60 Hz buzz. While this has virtually no affect on the stereo audio quality, it substantially reduces the low frequency buzz and hum caused by the field rate modulation.

Placing the stereo subcarrier, with its 15 kHz sidebands, so close to the upper end of the main audio channel invites potential crosstalk problems. However, it is essential that the subcarrier frequency be an integer multiple of H as described above. Placing the stereo subcarrier at a higher or odd multiple of H is not desirable due to the much higher noise levels encountered in the upper portion of the aural baseband and the potential for problems with phase-locked loop audio detector circuits in the receiver. A higher subcarrier frequency would also have made the addition of the SAP channel more difficult to implement as well.

The build-up of noise in the aural baseband is shown in Fig. 4. This illustrates why it was important to place the stereo subcarrier as low as possible in the baseband as well as the need for the audio companding system. In FM modulation systems, noise increases at a rate of 6 dB for each doubling of the bandwidth. As a result, the noise the stereo subcarrier would add to the received dematrixed sound is about 23 dB. This is reduced by about 6 dB because the stereo subcarrier

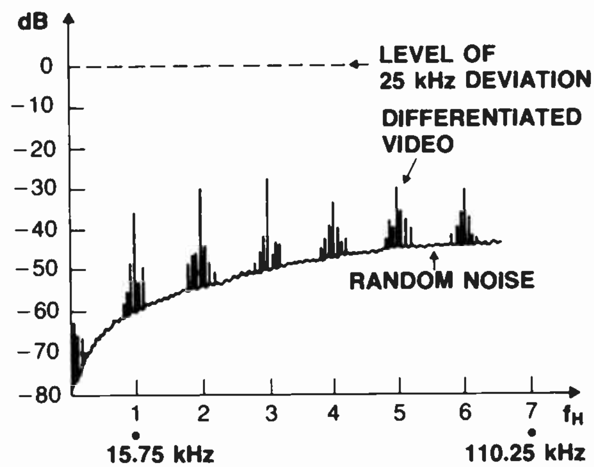

Figure 4. Spectrum of noise on the received aural baseband. (Courtesy of J.J. Gibson, RCA)

deviates the main carrier by 50 kHz compared to the main channel deviation of 25 kHz. The resulting degradation in signal-to-noise is only about 18 dB. Further, modulation components caused by the horizontal and vertical sync signals also add to the noise build-up. Both of these interference sources are easily overcome by the powerful 30 dB BTSC noise reduction system.

The use of an AM modulated, double-sideband, suppressed carrier subcarrier for the stereo channel also provides several other significant advantages over an FM subcarrier. AM subcarrier technology is well known and developed within the FM broadcast industry. Circuit performance refinements have been raised to near perfect levels. Moreover, AM offers (1) lower theoretical distortion levels than would be possible for FM, given the limited spectrum available (30 kHz) for transmission of the stereo subcarrier, and (2) provides an opportunity for further enhancements of the aural channel (by quadrature modulation or other compatible modulation schemes). The frequency response of the stereo subchannel is 15 kHz which properly compliments the main channel.

Pilot Carrier

The amplitude modulated stereo subcarrier is transmitted with the carrier suppressed. In order to provide a reference for the AM detector, an unmodulated pilot signal is transmitted at the TV horizontal line rate of 15.734 kHz which is one-half the subcarrier frequency. The pilot is used in the receiver to reinstate the carrier on the exact frequency and phase as the original. This is similar to the technique employed in broadcast FM stereo transmission systems.

For BTSC stereo, the pilot is locked to the video horizontal sync rate of 15.734 kHz. The pilot modulates the main aural carrier to a deviation of 5 kHz ±0.5 kHz. The stereo encoder requires a feed from the companion video signal in order to obtain its frequency reference. While it is possible that stereo sound receivers could use the horizontal sync information obtained from the receiver video circuits for the reference, there are receivers which do not process the video when decoding the stereo audio and therefore would not have a reference to synchronize the stereo detector.

The pilot also serves to signal that stereo is being broadcast by the station and is used to activate the stereo circuits and indicators in the receiver. Therefore, the pilot must be protected from extraneous signals near the pilot frequency in the aural baseband.

Pilot Carrier Protection

FCC Rule 73.682(c)(3) states that modulation components around the pilot frequency (±20 Hz) must be attenuated to 0.125 kHz deviation (46 dB below maximum modulation of 25 kHz). This is the case whether the station is operating with multichannel sound or monophonic sound.

A disadvantage with having the pilot at the horizontal rate is that there may be some residual horizontal sync modulation components and crosstalk in older transmitters or in program audio content that can cause false indications of stereo and malfunction in stereo decoders in BTSC receivers. Crosstalk of horizontal sync can occur in the exciter or amplifiers of older transmitters. Problems of this sort must be solved by broadcasters and manufacturers by adequately shielding or isolating the sync components of the video from the audio circuits in transmitting and receiving equipment. Modifications may be necessary to existing transmission equipment. The level of horizontal sync modulation and crosstalk components in the visual transmitter 4.5 MHz above the visual carrier can be controlled by installing low-pass video filters, adjusting transmitter visual RF circuits, or improving the 4.5 MHz rejection in the transmitter combiners or diplexers.

Low level sync modulation components with sufficient amplitude to cause false triggering of BTSC receivers can also occur by acoustic pick-up by microphones that are in close proximity of the mechanical vibrations caused by the horizontal scanning circuits in video monitors in studios, news sets, and in announce booths. Installation of identical high-quality low-pass or notch filters in the stereo audio path after the last switching point in the broadcast plant, will effectively eliminate the horizontal sync stray pick up in the studio from interfering with processors, STL facilities, and the BTSC encoder at the transmitter. The characteristics of such a low-pass filter are shown in Fig. 5. Filters should be installed ahead of devices with preemphasis so as not to compound the problem. For example, a standard 75 microsecond preemphasis network has the equivalent of about 15 dB gain at 15 kHz.

Operators of monophonic transmitters should also check their facilities for residual horizontal sync signals in either the aural transmitter or in the combining network at the output of the transmitters. The monophonic audio inputs to transmitters should incorporate a 15 kHz low pass filter.

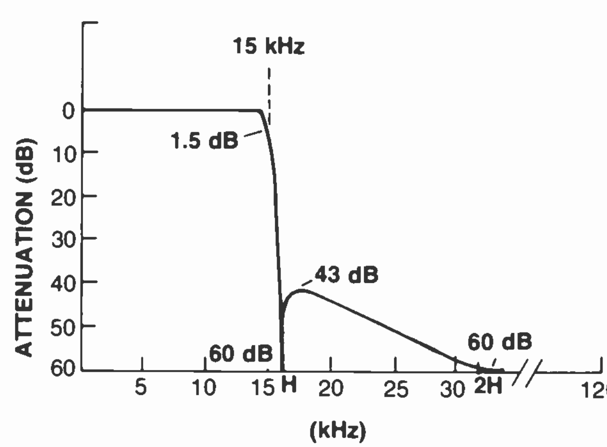

Figure 5. Audio input low-pass filter.

The Separate Audio Program Channel

Multichannel Television Sound transmission may include a separate audio program (SAP) channel in addition to stereo. This SAP channel may be program related or not, as the station chooses. The SAP channel is designed for reception by the public. If it is desired to use the SAP channel for nonpublic uses, the injection level of the subcarrier must be kept below the receiver threshold (about 5 kHz). If the audio information is not intended for the public, viewers with the SAP option switch may wonder about the material if it is not related to the picture in some manner.

The SAP channel subcarrier is located at exactly 5H (78.671 kHz) in the aural baseband. (See Fig. 2.) Although somewhat noisier at this location in the baseband than if it were placed at 4H, there is less chance for crosstalk with the main channel. The same BTSC noise reduction system on this channel provides an adequate signal-to-noise ratio. The audio frequency response is limited to a maximum of 12 kHz. The use of the companding system eliminates the need for separate preemphasis in the SAP channel.

The SAP subcarrier is frequency modulated by program material to a maximum deviation of 10 kHz. The subcarrier injection into the main carrier is limited to a peak deviation of 15 kHz. That is, the subcarrier modulates (deviates) the main carrier by 15 kHz. The subcarrier frequency is locked to 5H when not modulated.

The maximum injection level of 15 kHz of the main carrier by the SAP subcarrier is important. Receivers with SAP decoding equipment will detect the presence of the subcarrier and provide either automatic or manual switching and an indicator light. The receiver SAP decoder is designed to activate when the injection level reaches 8 kHz to 10 kHz. Below this level the receiver will ignore the presence of a subcarrier. To use this portion of the baseband for some purpose other than for program related audio, a subcarrier with an injection of 3 kHz to 5 kHz would probably be ignored by most SAP receivers. A nonpublic use of the SAP subcarrier cannot occur at the same time as regular SAP channel operation but could be used during stereo or monophonic operation.

The SAP channel uses the same noise reduction scheme as the stereo subcarrier. This permits a single expander decoder to be used in the receiver for either stereo or SAP. Most receivers will provide either stereo or SAP but not both at the same time. To make both available simultaneously a receiver would need two expanders. Alternatively, the SAP output could be provided without expansion, but the output would be highly compressed. The sound would be acceptable for most vocal material but would be objectionable for most music.

The Companding System

Companding (combines the functions of compression and expansion) is a term used frequently in the telecommunication industry to describe what broadcasters call noise reduction, a process well known to studio audio technicians. Its use is restricted to systems where there is control over both ends of the circuit. Examples include magnetic analog audio recorders, microwave and satellite circuits, and telephone lines used for program transmission. Simply stated, noise reduction is compressing the dynamic range at the sending end and expanding the signal an equal amount at the receiving end of the circuit. In the process of expansion the noise is reduced. Until the development of the BTSC MTS system, noise reduction techniques could not successfully be used for over-the-air transmission because a complimentary expander is required in the receiver. MTS required the use of expanders in the receiver from the beginning of the service. As a result, MTS is the first broadcast service to use companding as an integral part of the transmission system.

Some FM broadcast stations employ a limited range compression arrangement for an over-the-air noise reduction system. But because few receivers are equipped with the corresponding expander, the compression must be held to about only 10 dB in order to avoid producing objectional side effects and becoming objectional to a listener without a decoder.

Noise reduction was built-in to the BTSC MTS system from the beginning of the service and therefore a high performance system may be employed. Fig. 6 graphically depicts how a typical noise reduction system alters the dynamic range of the program material during transmission according to the content. Dynamic range is reduced from 70 dB to about 40 dB. A matching expander in the receiver restores the dynamic range.

The companding system employed by the BTSC MTS system was specifically designed to operate in the comparatively hostile environments presented by television transmitters, signal propagation, retransmission systems (CATV, MATV, translators) and the receiver itself. Thermal and impulse noise, multipath distortion, and buzz generated by transmitter and receiver all combine to present formidable obstacles for the companding system to overcome.

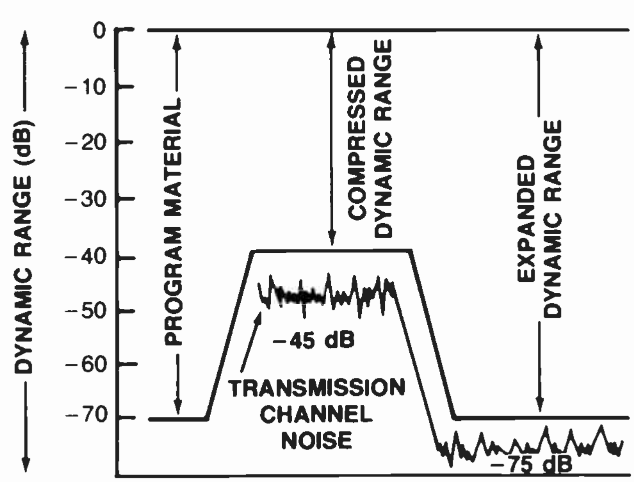

Figure 6. Typical noise reduction action.

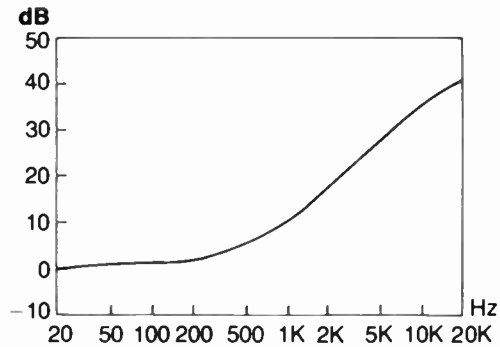

Figure 7A. Fixed preemphasis frequency response.

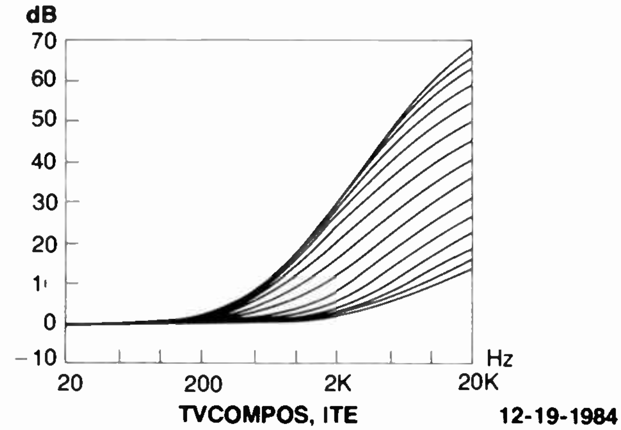

Figure 7C. Frequency-response range of spectral compressor and fixed preemphasis.

The companding system used in the BTSC system employs a combination of (1) fixed preemphasis, (2) spectral compression, and (3) amplitude compression. The fixed preemphasis combines the familiar 75 microsecond rising frequency response with a 390 microsecond network. The resulting curve is shown in Fig. 7A. By itself this extremely steep preemphasis curve would cause problems with high audio frequencies. To avoid this, a dynamic "spectral" compressor (variable preemphasis) circuit is employed to increase the gain of low level, high frequency material and reduce the gain of high level, high frequency audio. Only frequencies above about 200 Hz are affected. High frequency material is increased during transmission by as much as 30 dB at low levels but virtually not at all at high levels. Fig. 7B illustrates the dynamic characteristics of the spectral compressor. A complicated algorithm controls the fixed and variable preemphasis to produce the sharply rising frequency response shown in Fig. 7C.

The third feature of the companding system is the amplitude compressor which reduces the dynamic range, measured in dB, of the input signal by a factor of 2:1 for low frequencies, and 3:1 for high frequencies. In other words, a 40 dB dynamic range audio signal is reduced to 15 dB to 20 dB or less for transmission as shown in Fig. 8. In addition to dynamic range compression, the maximum input level applied to the stereo subcarrier is reduced to just below the maximum modulation of the subcarrier. This feature provides some headroom to accommodate instantaneous peaks without resorting to clipping. High level transients are clipped to avoid severe distortion during reconstruction of the compressed signal in the receiver expander.

The equivalent 75 microsecond mode in the companding system uses a precision 75 microsecond network in place of the dbx compressor when separation, crosstalk, and noise tests are conducted. In this mode the exciter contains only linear elements which allows routine adjustments on the exciter and transmitter and measurements of the main, stereo, and the SAP channels to be performed very much as conventional FM broadcast stereo exciters.

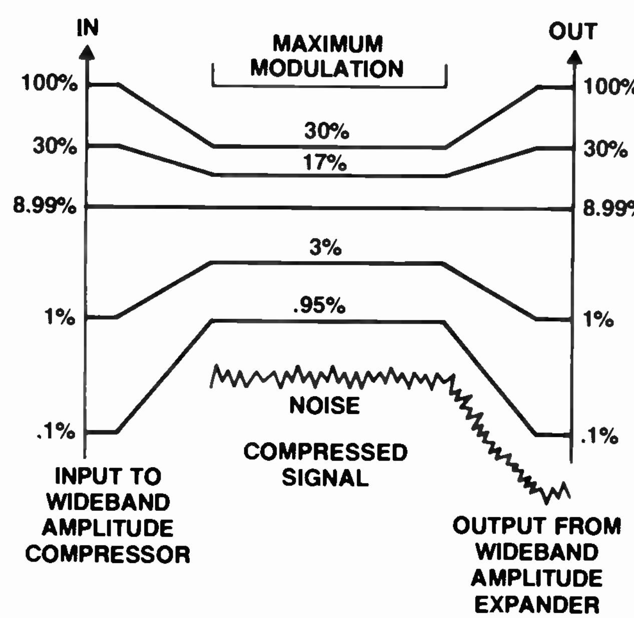

Figure 8. Companding of (L-R) and SAP. (Courtesy of dBx, Inc.)

The use of companders and noise reduction systems is gaining wide acceptance throughout the broadcast industry. It is not unusual for a given program to undergo noise reduction processing five to six times by the time it reaches the viewer. The mistracking of a single companding system in the chain may result in substantial errors in the resulting sound which may be more objectionable than the problems the compander was designed to solve. In order to prevent audible artifacts from occurring, only the highest quality processing and noise reduction systems should be employed, and these must be correctly operated and properly maintained.

Professional Use Channel

The PRO channel is not designed to be received by the public and may be used by the broadcaster for many purposes such as voice cues, signalling, and data transmission. The channel is located at 6.5H (102.28 kHz) ±500 Hz in the BTSC baseband as shown in Fig. 2. The maximum peak deviation of the subcarrier is 3 kHz. The peak deviation (injection) of the main carrier by the PRO subcarrier is 3 kHz. When used for voice or audio transmission, a modulation limiter, 3.4 kHz bandlimiting filter, and a 150 μsec preemphasis network are normally employed. For data transmission, the limiter, preemphasis, and filter are bypassed.

Other Subcarriers

In addition to providing for stereo and SAP subcarriers, the FCC allows television stations to use any other scheme of subcarriers on the aural carrier as long as they do not interfere with the normal operation of monophonic or BTSC television receivers. When not transmitting stereo or SAP, broadcasters may elect to use the aural baseband for subcarriers for nonprogram related purposes. Virtually any kind of subcarrier for program material or data may be transmitted using AM, FM, or other analog or digital modulation methods. Subcarriers may be placed in the aural baseband between 16 kHz and 120 kHz but must avoid the BTSC pilot and SAP frequencies. The maximum deviation of the main carrier by these subcarriers is limited to a total of 50 kHz. Any number of subcarriers may be used. The total modulation of the aural carrier including main channel sound and non-BTSC subcarriers may not exceed 75 kHz.

Stations should avoid placing nonpublic subcarriers within ±10 kHz of the SAP frequency unless the injection level of the subcarrier is kept below 5 kHz deviation. The use of a single subcarrier using the full 50 kHz deviation should be avoided because of the potential of crosstalk into the main channel in some receivers unless extensive compatibility testing is conducted.

Modulation Summary

The FCC permits the BTSC specified multichannel sound signal to modulate the main aural carrier a total peak deviation of 73 kHz. This is produced by the combined main and stereo subcarrier deviation of 50 kHz, the pilot subcarrier deviation of 5 kHz, the SAP subcarrier deviation of 15 kHz, and the PRO subcarrier of 3 kHz for a total of 73 kHz. (See OET-60A section D(b)(6)). Fig. 9 lists the MTS modulation components that should be monitored on a regular basis.

SIGNAL	MONITORED PARAMETER
MAIN CHANNEL (L+R)	25 kHz PEAK DEVIATION
STEREO CHANNEL (L+R)	50 kHz PEAK DEVIATION
MAIN AND STEREO	50 kHz PEAK DEVIATION
PILOT CARRIER INJECTION	5 kHz PEAK DEVIATION
SAP MODULATION	10 kHz PEAK DEVIATION
SAP INJECTION	15 kHz PEAK DEVIATION
OTHER SUBCARRIER	3 kHz PEAK DEVIATION
TOTAL COMPOSITE	73 kHz PEAK DEVIATION

Figure 9. Typical modulation monitor functions.

Other subcarrier arrangements may modulate the main carrier to a peak deviation of 50 kHz. With the main monaural channel at 25 kHz and non-BTSC subcarriers at 50 kHz, the total may not exceed 75 kHz deviation (FCC Rule 73.68(c)(9)).

TRANSMISSION OF BTSC

Transmission Requirements

Many of the technical rules in Part 73 of the FCC Rules and Regulations that described "quality" characteristics of the transmitted signal were deleted by the FCC in 1984. Those rules, requiring stations to meet certain distortion, frequency response, and signal-to-noise performance levels, were eliminated in favor of marketplace pressures on stations to maintain high quality levels. Therefore, there are no FCC Rules which require minimum audio performance levels in the AM, FM, or TV broadcast service. However, rules which act to control interference have been maintained.

The FCC Rules which permit stations to transmit MTS also do not specify performance objectives other than those which are directly related to interference to other services or to the monophonic sound channel. However, because the MTS is a relatively new service, several quality specifications are included in Technical Bulletin OET-60A, published by the FCC Office of Engineering and Technology. Television stations should have a copy of OET-60A. The Electronic Industries Association (EIA) in 1985 produced a set of recommended practices (EIA Television Systems Bulletin #5) for BTSC MTS system written especially for receiver and transmitter manufacturers. The EIA also published the Compandor Complexity Analyses that supplements Bulletin #5.

Transmitter and BTSC encoder manufacturers also publish booklets and manuals describing potential problems encountered in preparing transmission systems of BTSC audio along with methods for measurement and problem correction. Some of these are listed in the references at the end of this chapter.

Because the transmission of stereo sound for television is technically similar to that of FM broadcasting, a review of the chapter on FM broadcasting and stereophonic transmission elsewhere in this handbook provides additional background information. Portions of the BTSC MTS system description are also contained in the Television Transmitter chapter.

The MTS performance objectives achievable under normal operating conditions are shown in Fig. 1. Most of the performance objectives indicate the potential for high audio quality. However, the stereo separation figure may be of some concern to those familiar with the much higher performance of the FM stereo system. More than 30 dB separation is easily achieved in practice above which little subjective improvement is obtained. The nonlinear circuits in the companding system and the critical adjustments which must be made in the BTSC encoding system may produce somewhat less than the 40 dB or more separation easily achieved in broadcast FM stereo operation. The tracking gain between the mono and stereo channels is one of several important operating characteristics that determine the relative separation between channels as shown in Fig. 10A. While it may be possible to balance the gain to a tenth of a dB between the sum and difference channels in FM radio stereo transmission, typical balance is about 0.5 to 0.8 dB in the BTSC system. This is because the noise reduction system compresses the stereo channel by as much as 20 dB, which magnifies the difference when received, decoded, and expanded in the TV receiver. Circuit stability improvements may permit as much as 40 dB in stereo separation in the future.

Phase shift between audio channels will also reduce stereo separation. Only a few degrees difference reduces separation to 30 dB as shown in Fig. 10B. When combined with channel gain differences, separation will be further reduced.

Incorrect stereo channel carrier phase error and the pilot phase error also contributes to reduced stereo separation as shown in Fig. 10C.

A major feature of the BTSC MTS system is that there is no stereo noise penalty as there is in FM stereo. Without the companding system the stereo subchannel is subject to the increased noise in the channel baseband by as much as 23 dB. In FM radio the main or mono channel must be reduced by eight to ten percent to permit the addition of the pilot subcarrier. With TV MTS, the main aural carrier deviation is increased when adding the pilot and stereo subcarriers. There is no reduction in deviation of the mono signal during BTSC stereo transmission as there is when adding stereo in broadcast FM operation.

The crosstalk performance values are the single most important technical parameters with which the broadcaster must be concerned for the BTSC system. Most crosstalk is caused by systems external to the

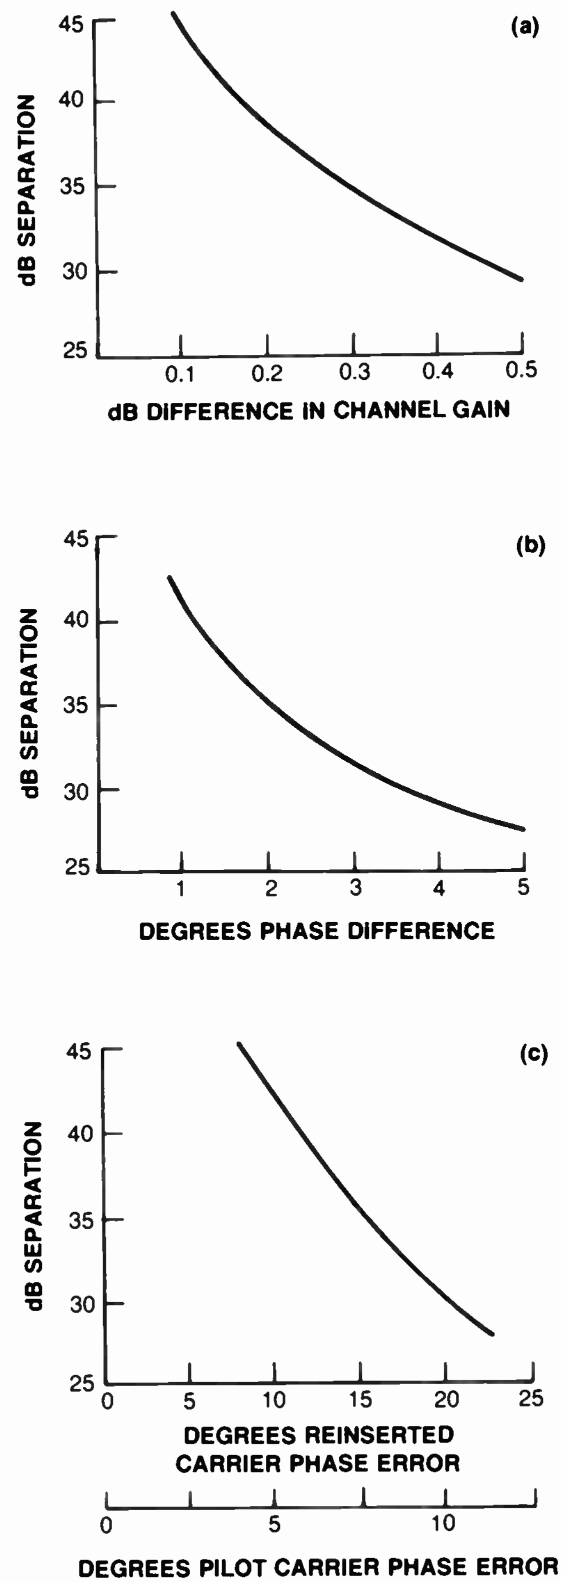

Figure 10. Stereo separation versus (a) amplitude difference between main and stereo channels, (b) phase difference between main and stereo channels, and (c) error in phase of pilot or reinserted carrier.

stereo transmission equipment itself. Nonlinearities in the TV aural exciter and power amplifier stages, combining networks, antenna switching components, and the antenna itself, constitute the main areas in the signal path where crosstalk can be generated. In general, crosstalk into the stereo signals from the SAP will be less than crosstalk from the main channel into the SAP signal. As long as crosstalk levels do not exceed the levels shown in Fig. 11, most crosstalk will be concealed by the companding system.

Other sources of crosstalk are (1) multipath distortion due to poor transmission line and antenna voltage standing wave ratio (VSWR), (2) multipath (ghosts) during the propagation of the transmitted wave, and (3) improper matching in the receiving antenna system. In general, the companding system can conceal noise and crosstalk in the stereo and SAP channels by as much as 30 dB.

Visual Over-Modulation

The most important way to reduce buzz on television receivers is for the broadcaster to insure that the video modulation level is never permitted to exceed 87.5%, the maximum permitted by the FCC. Varying video levels during program production and transients from character and graphics generators can easily cause the visual modulation level to approach or equal cut-off. At this point the aural detector in intercarrier type television receivers loses reference (the aural carrier), and the result is a strong buzz in the received audio. Careful adjustment to video processing equipment will eliminate this problem as a source of buzz. In some cases it may be necessary to add high quality low-pass filters to the video outputs of character and graphics generators to limit the high frequency content.

Incidental Carrier Phase Modulation

The control of incidental carrier phase modulation (ICPM) in the visual transmitter is the second most important performance characteristic of the transmitter that can affect the quality of multichannel sound.

ICPM in visual transmitters must be adjusted and maintained to less than 3° during the luminance portion of the video and to less than 5° during sync in order to keep buzz to acceptable levels as shown in Fig. 12.

Excessive ICPM in the transmitter will cause an audible and annoying buzz in intercarrier sound television receivers. The buzz will be modulated by the action of the expander which will increase the level of annoyance.

CROSSTALK	OBJECTIVES
MAIN INTO STEREO	>40 dB
STEREO INTO MAIN	>40 dB
MAIN INTO SAP	>50 dB
SAP INTO MAIN	>60 dB
OTHER SUB INTO MAIN	>60 dB
OTHER SUB INTO STEREO	>60 dB

Intercarrier type receivers, typical of most receivers, are used for multichannel sound reception because of their high immunity to common-mode phase modulation that can occur in nonlinear active devices or distribution and conversion systems that are found in the path of the television signal before it reaches the receiver. Common-mode phase modulation often occurs in TV translators, master antenna downconverters, and cable system headends and set-top converter equipment.

In intercarrier type receivers, the aural and visual carriers beat together in the video detector to produce the 4.5 MHz aural intermediate frequency (IF) signal. Because common-mode phase modulation affects both carriers (hence the term common-mode), the phase modulation is factored out of the 4.5 MHz carrier. Therefore, phase modulation that occurs on the visual carrier in the transmitter, which is independent of the aural carrier, will produce undesired phase modulation of the 4.5 MHz aural carrier in the receiver and the result will be the familiar buzz.

Phase modulation in the local oscillator of an up or down converter can be caused by the power supply or mechanical vibration. It can also occur if the phase of the composite signal is changed by a nonlinear amplifier. Phase modulation is common-mode when both aural and visual carriers are affected equally. This would be the case when the aural signal is carried as a subcarrier on the visual carrier rather than treated as separate signals as is the case in broadcast transmitters.

Intercarrier receivers carry the aural signal to the detector as a subcarrier. Translators and most CATV systems carry the aural through headend processors as a subcarrier. Therefore, if phase modulation is introduced in these systems, it is common-mode and will be rejected by the receiver. Intercarrier sound receivers cannot reject phase modulation that is introduced independently into the visual or aural carriers at the transmitter.

Phase modulation in the visual transmitter can be caused by hum in the carrier frequency or up-converter oscillators, and by nonlinearities in the visual modulator, IF, and power amplifier stages. Phase correction circuits in the modulator can compensate for most ICPM problems. UHF transmitters which use klystron anode pulsers to achieve higher operating efficiencies may have phase modulation introduced by the pulser modulating the visual amplifier power supply at the video field rate (59.94 Hz) and the line rate (15.734 kHz). The high frequency component is not heard by most viewers but the low frequency component is heard by all as a raspy buzz. An anode pulser on the visual amplifier can cause crosstalk through the common power supply into the aural amplifier. The resulting 15.734 kHz modulation, if high enough, can cause false indications of the stereo indicator on MTS television receivers.

Measuring and Correcting ICPM

ICPM is manifested as differential phase in the demodulated video. Measurement instrumentation requires a TV demodulator with both envelope and quadrature video detectors and a waveform monitor with the ICPM graticules. After measuring ICPM or listening for buzz on a stereo television receiver to determine if ICPM is present, phase adjustments in the modulator or upconverter and retuning the RF stages will result in substantial improvements. ICPM adjustments, if provided on the transmitter exciter, will also affect video differential phase. Once ICPM is corrected, the video correction circuits can be adjusted to compensate for differential phase.

ICPM will be more noticeable on television receivers equipped for multichannel sound. ICPM will affect subcarriers to a greater extent than the main channel. In addition, improved audio performance in the new multichannel receivers makes existing buzz more noticeable. Therefore, stations planning to implement BTSC multichannel sound should check their transmitters for ICPM with an ear toward improving the quality of the mono sound on mono receivers as well as stereo on new MTS receivers.

Synchronous Amplitude Modulation

Synchronous amplitude modulation (SAM), occurs when the frequency swing of the aural carrier is greater than the flattest portion of the tuned circuits through which the carrier passes. A reduction of the carrier occurs where the passband begins to roll-off as shown in Fig. 13. The result of effect is to impart amplitude changes on the RF carrier during FM modulation. The SAM is in sync with the FM, hence the name synchronous AM. SAM is made worse if the RF carrier is not centered within the passband of the tuned circuits in the aural transmitters, combiners, and diplexers.

SAM manifests itself as intermodulation distortion which in turn causes an increase in crosstalk between channels and decreased stereo separation. The SAP and PRO channels are more susceptible to SAM than the main channel especially during high levels of main channel modulation.

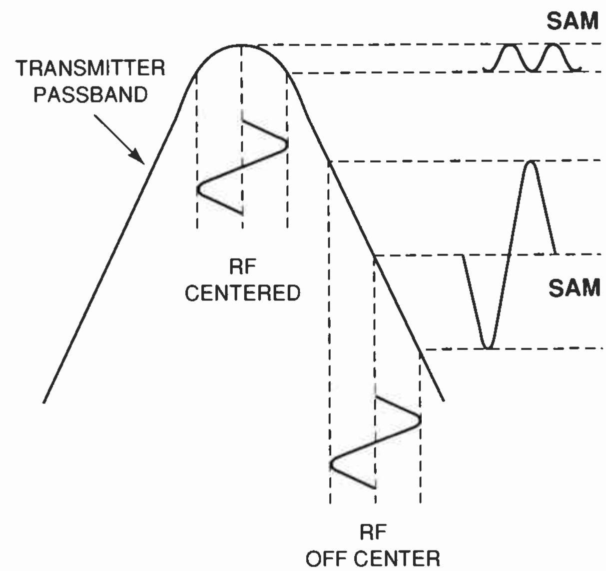

Figure 13. Synchronous Amplitude Modulation (SAM).

Compatibility With Monophonic Receivers

During the development of the BTSC multichannel sound system, considerable effort was spent evaluating the effect of a fully loaded BTSC system on existing monophonic television receivers. Extensive compatibility testing of a wide range of receiver makes and models, under adverse transmission conditions, revealed virtually no significant degradation to either the sound or picture of the desired or adjacent channel caused by the BTSC system, as noted by trained observers.

BTSC sound transmission will not introduce additional buzz or distortion in existing monophonic receivers. On the other hand, nonlinear circuits and the resulting AM-to-PM conversion will nearly always produce buzz which will be more objectional in stereo than in mono. Most of the buzz heard in mono or stereo receivers is usually created in the transmitter or the cable TV system in the form of ICPM or video over-modulation.

Modern monophonic television receivers should not experience significant degradation when receiving a TV MTS signal. In fact, monophonic receivers may actually exhibit a noticeable improvement in performance when tuned to BTSC stereo transmissions due to the improved performance of the stereo exciter, broadband aural RF systems, and lower ICPM in visual transmitter components. Program producers now pay increased attention to stereophonic sound production and processing. (See the chapter on television program production.)

These desirable side benefits easily offset the slight reduction in monophonic modulation level which occurs when transmitting a mostly left or right channel sound. Because the main channel is the sum of left plus right, a right- or left-only signal will produce up to 6 dB less modulation than the sum signal. Producers, however, seldom employ left- or right-only signals except for sound effects and music. As a result, any reduction in modulation will be something between 0 and 6 dB. It could be argued that these several dB reduce the apparent loudness of some program material on a stereo station when compared to a monophonic station. The problem will disappear as more television stations install stereo transmission facilities.

Compatibility With CATV Systems

Most broadcast television signals are carried by Community Antenna Television Systems (CATV) or cable TV. In 1990, more than 50 million subscribers, or over half the homes with TV, have at least one receiver connected to a CATV system. It is important, therefore, that broadcasters be concerned with the quality of the audio as well as the video signal as carried on cable television systems.

The BTSC MTS system was specifically designed to pass through properly adjusted MATV and CATV system headend and distribution equipment and subscriber terminals. The concern that the lower sideband of the upper adjacent visual carrier might affect the wider BTSC MTS modulated aural carrier of the lower channel has not been confirmed. In general, those CATV systems which process off-air signals in an RF mode (that is, where the aural carrier is not demodulated) will have little difficulty in successfully processing and passing an acceptable BTSC MTS signal through the system. The same is true of the RF conversion type set-top converters used by CATV systems.

On the other hand, cable systems with demodulating type headend or subscriber terminal equipment may not be able to pass MTS signals without substantial degradation to the stereo signal due to the use of low pass filters in the composite audio portions of demodulator facilities where stereo and SAP subcarriers are filtered out or severely distorted. Newer cable headend equipment, however, process BTSC stereo with very little degradation by carrying the BTSC composite signal through at IF (such as 4.5 MHz).

The baseband type set-top converter poses the greatest threat to BTSC stereo if the audio is demodulated within the device. This is often done to permit the audio level, as well as the channel, to be controlled by a remote control device. BTSC stereo will not reliably pass through such devices.
